Vitamin B₁₂ and folic acid levels are normal unless combined anemias are present. The reticulocyte count is low because young cells die in the marrow. Unlike iron deficiency anemia, sideroblastic anemia lowers hemoglobin levels and raises serum iron and transferrin levels. In turn, faulty hemoglobin production raises urobilinogen and bilirubin levels. Platelets and leukocytes remain normal, but occasionally, thrombocytopenia or leukopenia occurs.

Treatment

The underlying cause determines the course of treatment. Hereditary sideroblastic anemia usually responds to several weeks of treatment with high doses of pyridoxine.

The acquired secondary form subsides after the causative drug or toxin is removed or the underlying condition is adequately treated. Folic acid supplements may be beneficial when concomitant megaloblastic nuclear changes in RBC precursors are present. Deferoxamine may be used to treat chronic iron overload in selected patients.

Carefully crossmatched transfusions (providing needed hemoglobin) or high doses of androgens are effective palliative measures for some patients with the primary acquired form of sideroblastic anemia. This form is essentially refractory to treatment and usually leads to death from acute leukemia or from respiratory or cardiac complications.

Some patients with sideroblastic anemias may benefit from phlebotomy to prevent hemochromatosis. Phlebotomy increases the rate of erythropoiesis and uses up excess iron stores; thus, it reduces serum and total-body iron levels.

Nursing diagnoses

u Altered oral mucous membrane u Decreased cardiac output u Fatigue u Impaired skin integrity u Knowledge deficit u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will express feelings of increased energy.
- u The patient's skin integrity will remain intact.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will demonstrate the correct oral care routine.
- u The patient's lesions or wounds will show improvement or heal.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Provide frequent rest periods if the patient becomes easily fatigued. Plan activities and diagnostic tests so the patient can rest in between. Monitor his pulse rate often; tachycardia indicates that his activities are too strenuous.
- u Because sideroblastic anemias usually cause weakness, institute safety measures to prevent falls.
- u Administer medications, as ordered. If the patient has pain from complications of the disorder, such as pancreatitis, give analgesics as ordered, and monitor their effectiveness. Also provide comfort measures, and have the patient perform relaxation techniques to help him cope with associated pain.
- u Administer ordered blood transfusions, and monitor the patient's tolerance of the treatment. Notify the doctor if signs of a transfusion reaction occur.
- u If the patient has jaundice or pruritus, provide good skin care to prevent skin breakdown.
- u Watch for complications of therapy. Note any signs or symptoms of decreased perfusion to vital organs (dyspnea, chest pain, dizziness) or of neuropathy (peripheral tingling).
- u Inquire about possible exposure to lead in the home (especially for children) or on the job.

- Identify patients who abuse alcohol; refer them for appropriate therapy.

Patient teaching

- Reinforce the doctor's explanation of the disorder and answer any questions. Be sure that the patient fully understands prescribed treatments and possible complications of organ involvement and preleukemia.
- Teach the patient the importance of continuing prescribed therapy, even after he begins to feel better.
- Advise parents to have all house paint checked for lead and not to allow children to eat paint chips.
- If androgens are used as part of the treatment, teach the patient to recognize and report adrenergic adverse effects.
- If phlebotomy is scheduled, explain the procedure to the patient to help reduce his anxiety. If this procedure must be repeated frequently, provide a high-protein diet to help replace the protein lost during phlebotomy.
- Teach the patient to recognize and report signs and symptoms of heart failure.
- Emphasize the need for proper hygiene and other measures to guard against infections because the patient's weakened condition may increase his susceptibility. Tell the patient to report signs and symptoms of infection promptly, especially urinary tract and pulmonary infections.

THALASSEMIA

Thalassemia, a group of hereditary hemolytic anemias, is characterized by defective synthesis in one or more of the polypeptide chains necessary for hemoglobin production. Because thalassemia affects hemoglobin production, it also impairs red blood cell (RBC) synthesis.

CULTURAL TIP This disorder is most common in people of Mediterranean ancestry (especially Italians and Greeks), but it also occurs in Blacks and people from southern China, Southeast Asia, and India.

Two pairs of polypeptide chains—alpha and beta chains—make up hemoglobin. In thalassemia, diminished synthesis can affect either pair. Structurally, the chains are normal, but the genetic defect decreases their number. In alpha-thalassemia, alpha chain synthesis slows; in beta-thalassemia, beta chain synthesis slows. Some patients with beta-thalassemia have no normal hemoglobin—only hemoglobin S and the minor hemoglobins.

In the most severe form of alpha-thalassemia—hydrops fetalis—severe anemia and heart failure render the fetus hydropic. The fetus is stillborn or dies shortly after birth. Prenatal testing can be used to detect the condition.

Beta-thalassemia (the most common form of this disorder) occurs in three clinical forms: thalassemia major, intermedia, and minor. The severity of the resulting anemia depends on whether the patient is homozygous or heterozygous for the thalassemic trait. The prognosis for beta-thalassemia varies. Patients with thalassemia major seldom survive to adulthood; children with thalassemia intermedia develop normally into adulthood, although puberty is usually delayed; patients with thalassemia minor can expect a normal life span.

Causes

Thalassemia major and thalassemia intermedia result from homozygous inheritance of the partially dominant autosomal gene responsible for this trait. Thalassemia minor is caused by heterozygous inheritance of the same gene. In all three types of thalassemia, total or partial deficiency of beta polypeptide chain production impairs hemoglobin synthesis and results in continual production of fetal hemoglobin, even after the neonatal period has passed.

Skull changes in thalassemia major

This illustration of an X-ray shows a characteristic skull abnormality in thalassemia major: diploetic fibers extending from internal lamina, resembling hair standing on end.

Complications

As children with thalassemia major grow older, they become susceptible to pathologic fractures. This occurs because the bone marrow cavities expand as the long bones thin. These patients are also subject to cardiac arrhythmias, heart failure, and other complications that result from iron deposits in the heart and other tissues caused by repeated blood transfusions.

Assessment findings

In thalassemia major (also known as Cooley's anemia, Mediterranean disease, and erythroblastic anemia), the infant is well at birth but develops severe anemia, bone abnormalities, failure to thrive, and life-threatening complications. Typically, the first signs are pallor and yellow skin and scleras in infants ages 3 to 6 months. Later signs and symptoms include severe anemia, splenomegaly or hepatomegaly with abdominal enlargement, frequent infections, bleeding tendencies (especially toward epistaxis), and anorexia.

Most children with thalassemia major have small bodies and large heads and may be mentally retarded. Infants may have mongoloid features because bone marrow hyperactivity thickens the bone at the base of the nose.

Thalassemia intermedia comprises moderate thalassemic disorders in homozygotes. Patients with this condition show some degree of anemia, jaundice, and splenomegaly and may exhibit signs of hemosiderosis caused by increased intestinal absorption of iron.

Thalassemia minor may cause mild anemia but usually produces no signs or symptoms and is often overlooked.

Diagnostic tests

In thalassemia major, laboratory test results show a decreased RBC count and hemoglobin level, microcytosis, and increased reticulocyte, bilirubin, and urinary and fecal urobilinogen levels. A low serum folate level indicates increased folate use by hypertrophied bone marrow. A peripheral blood smear reveals target cells,

microcytes, pale nucleated RBCs, and marked anisocytosis. Quantitative hemoglobin studies show a significant increase in hemoglobin F and a slight increase in hemoglobin A₂. Diagnosis must rule out iron deficiency anemia, which also produces hypochromia (slightly lower hemoglobin level) and microcytic (notably small) RBCs. X-rays of the skull and long bones show thinning and widening of the marrow space because of overactive bone marrow. Long bones may show areas of osteoporosis. The phalanges may also be deformed (rectangular or biconvex). The bones of the skull and vertebrae may appear granular. (See [Skull changes in thalassemia major.](#))

In thalassemia intermedia, laboratory test results show hypochromia and microcytic RBCs, but the anemia is less severe than that in thalassemia major. In thalassemia minor, test results also show hypochromia and microcytic RBCs. Quantitative hemoglobin studies show a significant increase in hemoglobin A₂ levels and a moderate increase in hemoglobin F levels.

Treatment

Treatment of thalassemia major is essentially supportive. For example, infections require prompt treatment with appropriate antibiotics. Folic acid supplements help maintain folic acid levels despite increased requirements. Transfusions of packed RBCs raise hemoglobin levels but must be used judiciously to minimize iron overload. Splenectomy and bone marrow transplantation have been tried, but their effectiveness has not been confirmed.

Thalassemia intermedia and thalassemia minor generally don't require treatment. Iron supplements are contraindicated in all forms of thalassemia.

Treatment of children is more difficult. Regular blood transfusions may minimize physical and mental retardation, but transfusions increase the risk of deadly hemosiderosis and iron overload. Continuous subcutaneous infusion of iron-chelating agents may help produce a negative overall iron balance. If rapid splenic sequestration of transfused RBCs necessitates more transfusions, a splenectomy may be performed.

Nursing diagnoses

u Altered growth and development u Altered parenting u Altered tissue perfusion (cardiopulmonary) u Body image disturbance u Knowledge deficit u Risk for infection

Key outcomes

- u The patient won't develop cardiac arrhythmias.
- u The patient will remain hemodynamically stable.
- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express positive feelings about himself.

Nursing interventions

- u Watch for adverse reactions (shaking chills, fever, rash, itching, and hives) during and after RBC transfusions for thalassemia major.
- u Administer antibiotics as ordered. Observe the patient for adverse reactions to them.
- u Provide an adequate diet, and encourage increased consumption of fluids.
- u Provide emotional support to help the patient and his family cope with the chronic nature of the illness and the need for lifelong transfusions.

Patient teaching

- u Stress the importance of good nutrition, meticulous wound care, periodic dental checkups, and other measures to prevent infection.
- u Discuss with the parents of a young patient various options for healthy physical and creative outlets. Such a child must avoid strenuous athletic activity because of the resulting increased oxygen demand and the inherent tendency toward pathologic fractures. Reassure the parents that the child may be allowed to participate in less stressful activities.
- u Teach the parents to watch for signs of hepatitis and iron overload, which are always possible with frequent transfusions.
- u Refer the parents of a child with thalassemia for genetic counseling if they have concerns or questions about the vulnerability of future offspring to this disorder. Also, refer adult patients with thalassemia minor and thalassemia intermedia for genetic counseling; they need to recognize the risk of transmitting thalassemia major to their children if they marry another person who has thalassemia. If they choose to marry and have children, all their children should be evaluated for thalassemia by age 1.
- u Be sure to tell patients with thalassemia minor that their condition is benign.

Polycythemias

Polycythemias are characterized by an abnormal increase in the number of erythrocytes in the blood. Polycythemia may be secondary to pulmonary or cardiac disease or to prolonged exposure to high altitudes. In the absence of a demonstrable cause, polycythemia is considered idiopathic.

POLYCYTHEMIA VERA

Polycythemia vera (also known as primary polycythemia, erythema, polycythemia rubra vera, splenomegalic polycythemia, and Vaquez-Osler disease) is a chronic, myeloproliferative disorder. It's characterized by increased red blood cell (RBC) mass, leukocytosis, thrombocytosis, and increased hemoglobin concentration, with normal or decreased plasma volume. It usually occurs between ages 40 and 60, most commonly among men of Jewish ancestry. It seldom affects children or blacks and doesn't appear to be familial.

The onset of polycythemia is gradual, and the disease runs a chronic but slowly progressive course. The prognosis depends on age at diagnosis, treatment used, and complications. Mortality is high if polycythemia is untreated or is associated with leukemia or myeloid metaplasia.

Causes

In polycythemia vera, uncontrolled and rapid cellular reproduction and maturation cause proliferation or hyperplasia of all bone marrow cells (panmyelosis). The cause of such uncontrolled cellular activity is unknown, but it is probably the result of a multipotential stem cell defect.

Complications

Hyperviscosity may lead to thrombosis of small vessels with ruddy cyanosis of the nose and clubbing (stunting) of the digits. Further thromboembolic involvement can lead to splenomegaly, renal calculus formation, and abdominal organ thrombosis.

Paradoxically, hemorrhage is a complication of polycythemia vera. It may be due to defective platelet function or to hyperviscosity and the local effects from excess RBCs exerting pressure on distended venous and capillary walls.

Cerebrovascular accident (CVA) may also complicate the disease. As well, the incidence of peptic ulcer disease is four to five times greater in patients with polycythemia vera than in the general population.

Assessment findings

In its early stages, polycythemia vera may produce no signs or symptoms. As altered circulation (secondary to increased RBC mass) produces hypervolemia and

hyperviscosity, the patient may report a vague feeling of fullness in the head, rushing in the ears, tinnitus, headache, dizziness, vertigo, epistaxis, night sweats, epigastric and joint pain, and visual alterations, such as scotomas, double vision, and blurred vision. He may also report a decrease in urine output, possibly due to increased uric acid production.

Late in the disease, the patient may report pruritus (which worsens after bathing and may be disabling), a sense of abdominal fullness, and pain, such as pleuritic chest pain or left upper quadrant pain. (See [Common clinical features of polycythemia vera.](#))

Diagnostic tests

Laboratory studies confirm polycythemia vera by showing increased RBC mass and normal arterial oxygen saturation in association with splenomegaly or two of the following:

- u platelet count above 400,000/μl (thrombocytosis)
- u white blood cell (WBC) count above 10,000/μl in adults (leukocytosis)
- u elevated leukocyte alkaline phosphatase level
- u elevated serum vitamin B₁₂ levels or unbound B₁₂ binding capacity.

Another common finding is increased uric acid production, leading to hyperuricemia and hyperuricuria. Other laboratory results include increased blood histamine, decreased serum iron concentration, and decreased or absent urinary erythropoietin. Bone marrow biopsy reveals panmyelosis.

Treatment

Phlebotomy, the primary treatment, can be performed repeatedly and can reduce RBC mass promptly. It's best used for patients with mild disease and for young patients. The frequency of phlebotomy and the amount of blood removed each time depend on the patient's condition. Typically, 350 to 500 ml of blood can be removed every other day until the patient's hematocrit is reduced to the low-normal range. After repeated phlebotomies, the patient develops iron deficiency, which stabilizes RBC production and reduces the need for phlebotomy. Phlebotomy doesn't reduce the WBC or platelet count and won't control the hyperuricemia associated with marrow cell proliferation.

Myelosuppressive therapy may be used for patients with severe symptoms, such as extreme thrombocytosis, a rapidly enlarging spleen, and hypermetabolism. It's also used for elderly patients who have difficulty tolerating the phlebotomy procedure. Radioactive phosphorus (32 P) or chemotherapeutic agents, such as melphalan, busulfan, and chlorambucil, can satisfactorily control the disease in most cases. However, these agents may cause leukemia and should be reserved for older patients and those with serious problems not controlled by phlebotomy. Patients of any age who have had previous thrombotic problems should be considered for myelosuppressive therapy.

Pheresis technology allows removal of RBCs, WBCs, and platelets individually or collectively (and provides these cellular components for blood banks). Pheresis also permits the return of plasma to the patient, thereby diluting the blood and reducing hypovolemic symptoms.

As appropriate, additional treatments include administration of cyproheptadine (12 to 16 mg/day) and allopurinol (300 mg/day) to reduce serum uric acid levels. Treatment usually improves symptomatic splenomegaly; rarely, splenectomy may be performed.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Altered tissue perfusion (peripheral) u Anxiety u Fatigue u Knowledge deficit u Pain u Risk for impaired skin integrity u Risk for infection u Risk for injury

Common clinical features of polycythemia vera	
SIGNS AND SYMPTOMS	CAUSES

Eye and ear

- Visual disturbances (blurring, diplopia, scotoma, engorged veins of fundus and retina) and congestion of conjunctiva, retina, and retinal veins
- Hypervolemia and hyperviscosity
 - Engorgement of capillary beds

Nose and mouth

- Epistaxis or gingival bleeding
 - Oral mucous membrane congestion
- Hypervolemia and hyperviscosity
 - Engorgement of capillary beds

Central nervous system

- Headache or fullness In the head, lethargy, weakness, fatigue, syncope, dizziness, vertigo, tinnitus, paresthesia of digits, and impaired mentation
- Hypervolemia and hyperviscosity

Cardiovascular system

- Hypertension
 - Intermittent claudication, thrombosis and emboli, angina, thrombophlebitis
 - Hemorrhage
- Hypervolemia and hyperviscosity
 - Hypervolemia, thrombocytosis, and vascular disease
 - Engorgement of capillary beds

Skin

- Pruritus (especially after hot bath)
 - Urticaria
 - Ruddy cyanosis
 - Night sweats
 - Ecchymosis
- Basophilia (secondary histamine release)
 - Altered histamine metabolism
 - Hypervolemia and hyperviscosity due to congested vessels, increased oxyhemoglobin, and decreased hemoglobin levels
 - Hypermetabolism
 - Hemorrhage

GI system

- Epigastric distress
 - Early abdominal fullness
 - Peptic ulcer pain
 - Hepatosplenomegaly
 - Weight loss
- Hypervolemia and hyperviscosity
 - Hepatosplenomegaly
 - Gastric thrombosis and hemorrhage
 - Congestion, extramedullary hematopoiesis, and myeloid metaplasia
 - Hypermetabolism

Respiratory system

- Dyspnea
- Hypervolemia and hyperviscosity

Musculoskeletal system

- Arthralgia
- Increased urate production secondary to nucleoprotein turnover

Key outcomes

- The patient will express feelings of comfort and decreased pain.
- The patient won't develop arrhythmias.
- The patient's peripheral pulses will be present and strong.
- The patient's skin color and temperature will be unchanged.
- The patient will remain free from signs and symptoms of infection.

Nursing interventions

- Encourage the patient to express any concerns about the disease, its treatment, and the effect that it may have on his life. Answer questions appropriately and provide emotional support. If possible, stay with him during periods of acute stress and anxiety.
- Keep the patient active and ambulatory to prevent thrombosis. If bed rest is necessary, prescribe a daily program of both active and passive range-of-motion exercises.
- Watch for complications, such as hypervolemia, thrombocytosis, signs of impending CVA (decreased sensation, numbness, transitory paralysis, fleeting blindness, headache, and epistaxis), hypertension, and heart failure (caused by prolonged hyperviscosity).
- Regularly examine the patient for bleeding.
- To compensate for increased uric acid production, give the patient additional fluids, administer allopurinol as ordered, and alkalinize the urine to prevent uric acid calculus formation.
- If the patient has symptomatic splenomegaly, suggest or provide small, frequent meals followed by a rest period to prevent nausea and vomiting.
- If the patient has pruritus, give medications as ordered and provide distractions to help him cope.
- Report acute abdominal pain immediately; it may signal splenic infarction, renal calculus formation, or abdominal organ thrombosis.
- Before phlebotomy, check the patient's blood pressure and pulse and respiratory rates. During phlebotomy, make sure the patient is lying down comfortably to prevent vertigo and syncope. Stay alert for tachycardia, clamminess, and complaints of vertigo. If these effects occur, the procedure should be stopped.
- Immediately after phlebotomy, check the patient's blood pressure and pulse rate. Have the patient sit up for about 5 minutes before allowing him to walk; this prevents vasovagal attack and orthostatic hypotension. Administer 24 oz (710 ml) of juice or water to replenish fluid volume.

During myelosuppressive chemotherapy:

- u Monitor complete blood count (CBC) and platelet count before and during therapy.
- u Watch for and report all adverse effects that occur after administration of an alkylating agent.
- u If nausea and vomiting occur, begin antiemetic therapy and adjust the patient's diet.
- u During treatment with 32P, make sure you have a blood sample for CBC and platelet count before beginning treatment. (*Note:* The health care professional who administers 32P should take radiation precautions to prevent contamination.)
- u Have the patient lie down during I.V. administration (to facilitate the procedure and prevent extravasation) and for 15 to 20 minutes afterward.

Patient teaching

- u Determine what the patient knows about the disease, especially if he has been diagnosed for some time. As necessary, reinforce the doctor's explanation of the disease process, signs and symptoms, and prescribed treatment.
- u Tell the patient to remain as active as possible to help maintain his self-esteem.
- u Instruct the patient to use an electric razor to prevent accidental cuts and to keep his environment free of clutter to minimize falls and contusions.
- u Advise the patient to avoid high altitudes, which may exacerbate polycythemia.
- u If the patient develops thrombocytopenia, tell him the most common bleeding sites (such as the nose, gingiva, and skin) so he can check for bleeding. Advise him to report any abnormal bleeding promptly.
- u If the patient requires phlebotomy, describe the procedure and explain that it will relieve distressing symptoms. Tell the patient to watch for and report any symptoms of iron deficiency (pallor, weight loss, asthenia, glossitis).
- u If the patient requires myelosuppressive therapy, tell him about possible adverse effects (nausea, vomiting, and susceptibility to infection) that may follow administration of an alkylating agent. As appropriate, mention that alopecia may follow use of busulfan, cyclophosphamide, and uracil mustard and that sterile hemorrhagic cystitis may follow use of cyclophospha-mide (forcing fluids can prevent this adverse effect).
- u If an outpatient develops leukopenia, reinforce instructions about preventing infection. Warn the patient that his resistance to infection is low; advise him to avoid crowds and make sure he knows the symptoms of infection.
- u If the patient requires treatment with 32P, explain the procedure. Tell him that he may require repeated phlebotomies until 32 P takes effect.
- u Refer the patient to the social service department and local home health care agencies, as appropriate.

SECONDARY POLYCYTHEMIA

Secondary polycythemia—also called reactive polycythemia—is characterized by excessive production of circulating red blood cells (RBCs) due to hypoxia, tumor, or disease. It occurs in about 2 out of every 100,000 persons who live at or near sea level; incidence increases among people who live at high altitudes.

Causes and pathophysiology

Secondary polycythemia may result from increased production of erythropoietin. This hormone, which is possibly produced and secreted by the kidneys, stimulates bone marrow production of RBCs. The increased production may be an appropriate (compensatory) physiologic response to hypoxemia, which may result from:

- u chronic obstructive pulmonary disease
- u hemoglobin abnormalities (such as carboxyhemoglobinemia, which occurs in heavy smokers)
- u heart failure (causing a decreased ventilation-perfusion ratio)
- u right-to-left shunting of blood in the heart (as in transposition of the great vessels)
- u central or peripheral alveolar hypoventilation (as in barbiturate intoxication or pickwickian syndrome)
- u low oxygen content of air at high altitudes.

Increased production of erythropoietin may also be an inappropriate (pathologic) response to renal disease (such as renovascular impairment, renal cysts, and hydronephrosis), central nervous system disease (such as encephalitis and parkinsonism), neoplasms (such as renal tumors, uterine myomas, and cerebellar hemangiomas), and endocrine disorders (such as Cushing's syndrome and pheochromocytomas). Rarely, secondary polycythemia results from a recessive genetic trait.

Complications

A patient with secondary polycythemia has an increased risk of hemorrhage because of problems with platelet quality, especially during surgery. Thromboemboli secondary to hemoconcentration may occur spontaneously; after prolonged immobility, as may occur with arthritic conditions or decreased mobility; or after surgery.

Assessment findings

The patient's history usually reveals shortness of breath (associated with emphysema). Inspection reveals a ruddy cyanosis of the skin and, possibly, clubbing of the fingers (in underlying cardiac or pulmonary disease). Hypoxemia is found without hepatosplenomegaly or hypertension, which constitutes a major difference between primary (vera) and secondary polycythemia.

Secondary polycythemia that isn't caused by hypoxemia is usually an incidental finding during treatment for an underlying disease.

Diagnostic tests

Laboratory results for secondary polycythemia include:

- u increased RBC mass, with increased hematocrit, hemoglobin levels, mean corpuscular volume, and mean corpuscular hemoglobin
- u elevated urine erythropoietin levels
- u increased histamine levels
- u decreased or normal arterial oxygen saturation.

Bone marrow biopsies reveal hyperplasia confined to the erythroid series. Unlike polycythemia vera, secondary polycythemia isn't associated with leukocytosis or thrombocytosis.

Treatment

The goal of treatment is correction of the underlying disease or environmental condition. In severe secondary polycythemia when altitude is a contributing factor, relocation may be advisable. If secondary polycythemia has produced hazardous hyperviscosity, or if the patient doesn't respond to treatment for the primary disease, reduction of blood volume by phlebotomy or pheresis may be effective.

Emergency phlebotomy is indicated for prevention of impending vascular occlusion and before emergency surgery. In the latter case, removal of excess RBCs and reinfusion of the patient's plasma is usually advisable.

Nursing diagnoses

u Activity intolerance u Altered protection u Anxiety u Fatigue u Fear u Impaired gas exchange u Knowledge deficit u Risk for fluid volume deficit u Risk for infection u Risk for injury

Key outcomes

u The patient will exhibit adequate ventilation.

- u The patient's fluid balance will remain within normal range.
- u The patient will remain free from signs of infection.
- u The patient will express feelings of increased energy.
- u The patient will demonstrate use of protective measures, including conservation of energy, maintenance of balanced diet, and obtainment of adequate rest.
- u The patient will demonstrate effective coping skills.

Nursing interventions

- u Encourage the patient to express any concerns about the disease, its treatments, and the effect that it may have on his life. Answer questions and provide emotional support. If possible, stay with him during periods of severe stress and anxiety.
- u Before phlebotomy or pheresis, check the patient's blood pressure while he's lying down. Also note pulse and respiratory rates. During phlebotomy, make sure the patient is lying down comfortably to prevent vertigo and syncope. Stay alert for tachycardia, clamminess, and complaints of vertigo. If these effects occur, the procedure should be stopped.
- u Immediately after phlebotomy, check the patient's blood pressure and pulse rate while he's lying down. Have the patient sit up for about 5 minutes before allowing him to walk; this prevents vasovagal stimulation and orthostatic hypotension. Administer 24 oz (710 ml) of juice or water to replenish fluid volume.
- u Support the patient's efforts to perform activities.
- u Keep the patient as active as possible to decrease the risk of thrombosis due to increased blood viscosity. Provide rest periods between activities, as needed; the well-rested patient may be more active. If bed rest is necessary, prescribe a daily program of active and passive range-of-motion exercises.
- u Reduce caloric and sodium intake to counteract the tendency to hypertension. Provide meals that meet these requirements.
- u Administer ordered medications, such as analgesics for headaches, as appropriate. Administer oxygen as ordered to maintain adequate tissue perfusion.

Patient teaching

- u Teach the patient and his family about the underlying disorder. Help them understand its relation to polycythemia and the measures to control both. Explain the disease process, its signs and symptoms, prescribed treatments, and complications that may occur.
- u Emphasize the importance of regular blood studies (every 2 to 3 months), even after the disease is controlled.
- u Stress the importance of a low-sodium, reduced-calorie diet. Suggest using herbs and spices to add flavor and removing fat and skin from meat before cooking. Refer the patient to the dietitian for additional teaching, if necessary.
- u Instruct the patient to use an electric razor and to maintain a clutter-free environment to minimize falls and contusions.
- u Caution the patient to avoid high altitudes, which may exacerbate polycythemia.
- u Explain that alternating periods of rest and activity will reduce the body's demand for oxygen and prevent fatigue.
- u Describe the advantages of following a cardiovascular fitness program (affirmed by the doctor), and encourage the patient to participate. If appropriate, suggest walking at a pace of at least 4 mph for 20 to 30 minutes four times per week.
- u Refer the patient to the social service department and local home health care agencies, as appropriate.

SPURIOUS POLYCYTHEMIA

Spurious polycythemia is characterized by increased hematocrit and normal or decreased red blood cell (RBC) total mass. It results from decreasing plasma volume and subsequent hemoconcentration. This disease is also known as relative polycythemia, stress erythrocytosis, stress polycythemia, benign polycythemia, Gaisböck's syndrome, and pseudopolycythemia.

Causes and pathophysiology

Possible causes of spurious polycythemia include the following:

- u dehydration. Conditions that promote severe fluid loss decrease plasma levels and lead to hemoconcentration. Such conditions include persistent vomiting or diarrhea, burns, adrenocortical insufficiency, aggressive diuretic therapy, decreased fluid intake, diabetic ketoacidosis, and renal disease.
- u hemoconcentration due to stress. Nervous stress leads to hemoconcentration by some unknown mechanism, possibly by temporarily decreasing circulating plasma volume or by vascular redistribution of erythrocytes.
- u high normal RBC mass and low normal plasma volume. In many patients, an increased hematocrit merely reflects a normally high RBC mass and low plasma volume.

Other factors that may be associated with spurious polycythemia include hypertension, thromboembolic disease, pregnancy, elevated serum cholesterol and uric acid levels, and familial tendency.

Complications

Spurious polycythemia can be complicated by hypercholesterolemia, hyperlipidemia, and hyperuricemia. Thromboembolic complications may result if the condition goes untreated.

Assessment findings

The patient with spurious polycythemia usually has no specific signs or symptoms but may have vague complaints, such as headache, dizziness, and fatigue. Less commonly, the patient may report diaphoresis, dyspnea, and claudication. The patient's history may reveal existing cardiac or pulmonary disease.

Inspection typically reveals a patient with a ruddy appearance and a short neck. Palpation usually discloses associated hepatosplenomegaly. Auscultation may detect slight hypertension and hypoventilation when the patient is recumbent.

Diagnostic tests

Spurious polycythemia is distinguishable from true polycythemia vera by its characteristic normal or decreased RBC mass, elevated hematocrit, and the absence of leukocytosis.

The results of other commonly performed laboratory tests include:

- u elevated hemoglobin levels and hematocrit
- u elevated RBC count
- u normal arterial oxygen saturation and bone marrow studies
- u normal or decreased plasma volume.

Treatment

The principal goals of treatment are to correct dehydration and to prevent life-threatening thromboembolism. Rehydration with appropriate fluids and electrolytes is the primary therapy for spurious polycythemia secondary to dehydration. Therapy must also include appropriate measures to prevent continuing fluid loss.

Nursing diagnoses

- u Activity intolerance u Altered tissue perfusion (peripheral) u Anxiety u Fatigue u Fluid volume deficit u Ineffective breathing pattern u Pain

Key outcomes

- u The patient will express feelings of comfort and decreased pain.

- u The patient will exhibit adequate ventilation.
- u The patient's fluid volume will remain within range.
- u The patient will express feelings of increased energy.
- u The patient won't develop arrhythmias.

Nursing interventions

- u Focus your care on rehydration, a low-fat diet, exercise regimen, and teaching the patient about the condition and related stress factors.
- u Encourage the patient to discuss his concerns about the disease, its treatments, and the effect it may have on his life. Answer questions appropriately and provide emotional support. If possible, stay with the patient during periods of severe stress and anxiety.
- u Keep the patient active and ambulatory to prevent thrombosis. If he complains of fatigue, alternate periods of rest and activity.
- u Auscultate for breath sounds every 4 hours. If the patient hypoventilates when recumbent, assist him to a comfortable position by elevating the head of the bed.
- u During rehydration, monitor intake and output to maintain fluid balance. Also monitor laboratory studies to maintain electrolyte balance.
- u To prevent thromboembolism in predisposed patients, initiate a cardiovascular exercise program coupled with a reduced dietary cholesterol plan. (Studies show that hypertension and hypercholesterolemia can be reduced by the combination of regular exercise and a diet low in fat and cholesterol.) Antilipemics, such as cholestyramine and gemfibrozil, may be added to the treatment plan when exercise and dietary control are unsuccessful.

Patient teaching

- u Thoroughly explain the disease, including its diagnosis and treatment. The hard-driving person who is predisposed to spurious polycythemia is likely to be more inquisitive and anxious than the average patient. Answer his questions honestly, and reassure him that he can effectively control symptoms by complying with the prescribed treatment.
- u Emphasize the need for follow-up examinations every 3 to 4 months after he is discharged.
- u Advise the patient to follow a doctor-prescribed exercise program and diet. Results should be checked during follow-up examinations.
- u When appropriate, suggest counseling about the patient's work habits and lack of relaxation. If the patient is a smoker, emphasize the importance of stopping. Then refer him to an smoking cessation program, if necessary.
- u Teach the patient to recognize and report signs and symptoms of increasing polycythemia and thromboembolism.
- u Instruct the patient to use an electric razor and to maintain a clutter-free environment to minimize falls and contusions.
- u Refer the patient to the social service department and local home health care agencies, as appropriate.

Hemorrhagic disorders

Characterized by uncontrolled bleeding, hemorrhagic disorders involve a rapid loss of a large amount of blood, either internally or externally. Hemorrhage may be arterial, venous, or capillary. Common hemorrhagic disorders include allergic purpuras, disseminated intravascular coagulation, hemophilia, hereditary hemorrhagic telangiectasia, idiopathic thrombocytopenic purpura, thrombocytopenia, and von Willebrand's disease.

ALLERGIC PURPURAS

Allergic purpura is a nonthrombocytopenic purpura, an acute or a chronic vascular inflammation that affects the skin, joints, and GI and genitourinary (GU) tracts in association with allergy symptoms. When allergic purpura primarily affects the GI tract with accompanying joint pain, it is called Henoch-Schönlein syndrome or anaphylactoid purpura. However, the term allergic purpura applies to purpura associated with many other conditions such as erythema nodosum. An acute attack of allergic purpura can last for several weeks.

Fully developed allergic purpura is persistent and debilitating. This disorder affects males more commonly than females and is most prevalent in children ages 3 to 7 years. The prognosis is more favorable for children than for adults. The course of Henoch-Schönlein syndrome is usually benign and self-limiting, lasting 1 to 6 weeks if renal involvement is not severe.

Causes

The most common identifiable cause of allergic purpura is probably an autoimmune reaction directed against vascular walls and triggered by a bacterial infection (particularly a streptococcal infection, such as scarlet fever). Typically, upper respiratory tract infection occurs 1 to 3 weeks before the onset of signs and symptoms.

Other possible causes include allergic reactions to some drugs and vaccines; allergic reactions to insect bites; and allergic reactions to some foods (such as wheat, eggs, milk, and chocolate).

Complications

Renal disease (renal failure and acute glomerulonephritis) can be fatal. Hypertension and resulting blood loss from renal damage can further complicate the patient's condition.

Assessment findings

An accurate patient allergy history may yield information that helps ensure a positive outcome. The patient history may include pain due to bleeding from the mucosal surfaces of the ureters, bladder, and urethra. In 25% to 50% of patients, allergic purpura is associated with GU symptoms.

Other patient complaints include moderate, transient headaches; fever; anorexia; edema of the hands, feet, or scalp; and skin lesions, accompanied by pruritus, paresthesia and, occasionally, angioneurotic edema.

The patient with Henoch-Schönlein purpura may report a hypersensitivity to aspirin and food and drug additives. Typically, the patient complains of transient or severe colic, tenesmus, constipation, vomiting, and edema. He also may report hematuria and joint pain, mostly affecting the knees and ankles. Other symptoms include bleeding or hemorrhage of the mucous membranes of the bowel, resulting in GI bleeding, occult blood in the stool and, possibly, intussusception. Such GI abnormalities may precede overt, cutaneous signs of purpura.

Inspection findings in allergic purpuras include the characteristic skin lesions. Purple, macular, ecchymotic, and of varying size, these lesions result from vascular leakage into the skin and mucous membranes. The lesions usually appear in symmetrical patterns on the arms and legs. In children, skin lesions are generally urticarial; they expand and become hemorrhagic.

In Henoch-Schönlein purpura, inspection and palpation may disclose localized areas of edema, especially on the dorsal surfaces of the hands.

Diagnostic tests

No laboratory test clearly identifies allergic purpura (although white blood cell count and erythrocyte sedimentation rate are elevated). Diagnosis necessitates careful clinical observation, often during the second or third attack.

These laboratory test results may aid diagnosis of allergic purpura:

- u guaiac-positive stools
- u hematuria identified on urinalysis
- u elevated blood urea nitrogen and serum creatinine levels and proteinuria, indicating glomerular involvement

u normal coagulation and platelet function (with the exception of a positive tourniquet test).

Small-bowel X-rays may reveal areas of transient edema. Diagnosis must rule out other forms of nonthrombocytopenic purpura.

Treatment

In allergic purpura, treatment is usually based on symptoms; for example, severe allergic purpura may require corticosteroids to relieve edema and analgesics to alleviate joint and abdominal pain. Some patients with chronic renal disease may benefit from immunosuppression with azathioprine or corticosteroids, along with identification of the provocative allergen.

Nursing diagnoses

u Altered tissue perfusion (renal, GI) u Anxiety u Body image disturbance u Impaired skin integrity u Pain u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient's input and output will remain within normal limits.
- u The patient will have normal laboratory values.
- u The patient's vital signs will remain stable.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express positive feelings about himself.

Nursing interventions

For allergic purpuras:

- u Monitor skin lesions and level of pain. Provide analgesics, as needed.
- u Watch carefully for complications, including GI and GU tract bleeding, edema, nausea, vomiting, headache, hypertension (with nephritis), abdominal rigidity and tenderness, and absence of stool (with intussusception).
- u To prevent muscle atrophy in the bedridden patient, provide passive or active range-of-motion exercises.
- u Provide emotional support and reassurance, especially if the patient is temporarily disfigured by florid skin lesions.
- u Administer fluids if required to maintain fluid balance. Encourage fluid intake, as appropriate.

For immunosuppressive therapy:

- u Provide an environment that's free from the possibility of secondary infection.
- u If corticosteroid therapy is added, watch for signs of Cushing's syndrome and labile emotional involvement.

Patient teaching

- u Teach the patient about the disease, its symptoms, and treatment.
- u Explain the need to protect against infection. Advise the patient to wash his hands frequently to avoid infecting his skin lesions. Teach him to protect edematous areas because the skin over these areas breaks down easily.
- u After the acute stage, direct the patient to report immediately any recurrence of symptoms (most common about 6 weeks after initial onset). Tell him to return for follow-up urinalysis as scheduled.
- u Encourage maintenance of an elimination diet to help identify specific allergenic foods so that these foods can be eliminated from the patient's diet.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is also known as consumption coagulopathy and defibrination syndrome. DIC complicates diseases and conditions that accelerate clotting, causing occlusion of small blood vessels, organ necrosis, depletion of circulating clotting factors and platelets, and activation of the fibrinolytic system. This, in turn, can provoke severe hemorrhage.

Clotting in the microcirculation usually affects the kidneys and extremities but can occur in the brain, lungs, pituitary and adrenal glands, and G1 mucosa. Other conditions, such as vitamin K deficiency, hepatic disease, and anticoagulant therapy, can cause similar hemorrhage.

DIC is usually acute but can be chronic in cancer patients. The prognosis depends on early detection and treatment, the severity of the hemorrhage, and treatment of the underlying disease or condition.

Causes

DIC may result from:

- u infection—gram-negative or gram-positive septicemia; viral, fungal, or rickettsial infection; protozoal infection
- u obstetric complications—abruptio placentae, amniotic fluid embolism, retained dead fetus, eclampsia, septic abortion, postpartum hemorrhage
- u neoplastic disease—acute leukemia, metastatic carcinoma, lymphomas
- u disorders that produce necrosis—extensive burns and trauma, brain tissue destruction, transplant rejection, hepatic necrosis, anorexia
- u other disorders and conditions—heatstroke, shock, poisonous snakebite, cirrhosis, fat embolism, incompatible blood transfusion, drug reactions, cardiac arrest, surgery necessitating cardiopulmonary bypass, giant hemangioma, severe venous thrombosis, purpura fulminans, adrenal disease, adult respiratory distress syndrome, diabetic ketoacidosis, pulmonary embolism, and sickle cell anemia.

Why such conditions and disorders lead to DIC is unclear, as is whether they lead to DIC through a common mechanism. In many patients, the triggering mechanisms may be the entrance of foreign protein into the circulation and vascular endothelial injury.

Regardless of how DIC begins, the typical accelerated clotting results in generalized activation of prothrombin and a consequent excess of thrombin. Excess thrombin converts fibrinogen to fibrin, producing fibrin clots in the microcirculation. This process consumes exorbitant amounts of coagulation factors (especially platelets, factor V, prothrombin, fibrinogen, and factor VIII), causing thrombocytopenia, deficiencies in factors V and VIII, hypoprothrombinemia, and hypofibrinogenemia.

Circulating thrombin activates the fibrinolytic system, which lyses fibrin clots into fibrinogen degradation products (FDPs). The hemorrhage that occurs may be due largely to the anticoagulant activity of FDPs as well as to depletion of plasma coagulation factors.

Complications

DIC may be complicated by renal failure, hepatic damage, cerebrovascular accident, ischemic bowel, or respiratory distress. Hypoxia and anoxia can occur, lead to severe muscle pain. Shock and coma can also complicate care. Small-vessel occlusion can cause necrosis and gangrene in fingers and toes. After fibrinolysis, severe to fatal hemorrhaging of vital organs can occur suddenly.

Assessment findings

The most significant clinical feature of DIC is abnormal bleeding *without* a history of a serious hemorrhagic disorder. Signs and symptoms are related to bleeding and

thrombosis. Bleeding problems are usually more common than thrombotic problems unless coagulation occurs to a greater extent than fibrinolysis.

The patient history may reveal the presence of one of the causes of DIC. Although bleeding may occur from any site, the patient history may include signs of bleeding into the skin, such as cutaneous oozing, petechiae, ecchymoses, and hematomas. If the patient is receiving treatment for another disorder when this problem occurs, the history may also reveal bleeding from surgical or invasive procedure sites, such as incisions or venipuncture sites.

Other signs and symptoms may include nausea, vomiting, chest pain, hemoptysis, epistaxis, seizures, oliguria, and severe muscle, back, and abdominal pain.

Inspection may reveal petechiae and other signs of bleeding into the skin, acrocyanosis, and dyspnea.

On palpation, you may detect reduced peripheral pulses. Auscultation may disclose decreased blood pressure, and neurologic assessment may reveal mental status changes, including confusion.

Diagnostic tests

Abnormal bleeding in the absence of a known hematologic disorder suggests DIC. The following initial laboratory findings reflect coagulation deficiencies related to their utilization for clotting:

- u decreased platelet count—less than 100,000/μl
- u decreased fibrinogen levels—less than 150 mg/dl
- u prolonged prothrombin time—more than 15 seconds
- u partial thromboplastin time—more than 80 seconds
- u increased FDPs—often greater than 45 mcg/ml, or positive at less than 1:100 dilution
- u positive D-dimer test—specific fibrinogen test for DIC; positive at less than 1:8 dilution.

Other supportive data include prolonged thrombin time, positive fibrin monomers, diminished levels of factors V and VIII, fragmentation of red blood cells (RBCs), and decreased hemoglobin levels (less than 10 g/dl). Assessment of renal status demonstrates decreased urine output (less than 30 ml/hour), and elevated blood urea nitrogen levels (greater than 25 mg/dl) and serum creatinine levels (greater than 1.3 mg/dl).

Final confirmation of the diagnosis may be difficult because many of these test results also occur in other disorders (primary fibrinolysis, for example). The FDP and D-dimer tests are considered specific and diagnostic for DIC. Additional diagnostic measures determine the underlying disorder.

Treatment

Successful management of DIC requires prompt recognition and adequate treatment of the underlying disorder. Treatment may be supportive (when the underlying disorder is self-limiting, for example) or highly specific. If the patient isn't actively bleeding, supportive care alone may reverse DIC. Active bleeding may require administration of blood, fresh frozen plasma, platelets, or packed RBCs to support hemostasis.

Heparin therapy is controversial. It may be used early in the disease to prevent microclotting but may be considered a last resort in the patient who is actively bleeding. If thrombosis does occur, heparin therapy is usually mandatory. In most cases, it's administered in combination with transfusion therapy.

Drugs such as antithrombin III and gabexate are being considered for use as antithrombins to inhibit the clotting cascade.

Nursing diagnoses

u Altered tissue perfusion (GI, cerebral, renal) u Anxiety u Fatigue u Fear u Impaired gas exchange u Impaired physical mobility u Impaired tissue integrity u Pain u Risk for fluid volume deficit u Risk for injury

Key outcomes

- u Intake and output will remain within normal limits.
- u The patient's blood pressure will remain high enough to maintain cerebral perfusion pressure but low enough to prevent intracranial bleeding and cerebral swelling.
- u The patient will perform activities of daily living with the maximum level of mobility and independence.
- u The patient will maintain fluid balance.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will use available support systems to assist in coping with fears.

Nursing interventions

- u Focus on early recognition of signs of abnormal bleeding, prompt treatment of the underlying disorders, and prevention of further bleeding.
- u Keep the family informed of the patient's progress. Prepare them for his appearance (I.V. lines, nasogastric tubes, bruises, dried blood). Give emotional support. Listen to the patient's and family's concerns. When possible, encourage the patient. As needed, enlist the aid of a social worker, chaplain, and other health care team members in providing support.
- u If the patient is unable to tolerate activities because of blood loss, provide rest periods.
- u Administer prescribed analgesics for pain as necessary.
- u Reposition the patient every 2 hours and provide meticulous skin care to prevent skin breakdown.
- u Administer oxygen therapy as ordered.
- u Test stool and urine for occult blood.
- u To prevent clots from dislodging and causing fresh bleeding, don't vigorously rub these areas when washing. Use a 1:1 solution of hydrogen peroxide and water to help remove crusted blood.
- u Protect the patient from injury. Enforce complete bed rest during bleeding episodes. If the patient is agitated, pad the side rails.
- u If bleeding occurs, use pressure and topical hemostatic agents, such as absorbable gelatin sponges (Gelfoam), microfibrillar collagen hemostat (Avitene Hemostat), or thrombin (Thrombinar), to control it.
- u Check all venipuncture sites frequently for bleeding. After injection or removal of I.V. catheters or needles, apply pressure to injection sites for at least 10 minutes. Alert other personnel to the patient's tendency to hemorrhage. Limit venipunctures whenever possible.
- u Monitor intake and output hourly in acute DIC, especially when administering blood products. Watch for transfusion reactions and signs of fluid overload.
- u To measure the amount of blood lost, weigh dressings and linen and record drainage. Weigh the patient daily, particularly in renal involvement.
- u Watch for bleeding from the GI and genitourinary (GU) tracts. If you suspect intra-abdominal bleeding, measure the patient's abdominal girth at least every 4 hours, and monitor closely for signs of shock. Perform bladder irrigations as ordered for GU bleeding.
- u Monitor the results of serial blood studies (particularly hematocrit, hemoglobin levels, and coagulation times).

Patient teaching

- u Explain the disorder to the patient and his family. Teach them about the signs and symptoms of the problem, the diagnostic tests required, and the treatment that the patient is to receive.

HEMOPHILIA

A hereditary bleeding disorder, hemophilia results from deficiency of specific clotting factors. Hemophilia A (classic hemophilia), which affects more than 80% of all hemophiliacs, results from deficiency of factor VIII; hemophilia B (Christmas disease), which affects 15% of hemophiliacs, results from deficiency of factor IX. Other

evidence suggests that hemophilia may result from nonfunctioning factors VIII and IX, rather than from deficiency of these factors.

Hemophilia is the most common X-linked genetic disease and occurs in about 1.25 in 10,000 live male births.

The severity and prognosis of bleeding disorders vary with the degree of deficiency and the site of bleeding. The overall prognosis is best in mild hemophilia, which doesn't cause spontaneous bleeding and joint deformities. Advances in treatment have greatly improved the prognosis, and many hemophiliacs live normal life spans.

Causes and pathophysiology

Hemophilia A and B are inherited as X-linked recessive traits. Therefore, female carriers have a 50% chance of transmitting the gene to each daughter, who would then be a carrier, and a 50% chance of transmitting the gene to each son, who would be born with hemophilia.

Hemophilia produces abnormal bleeding, which may be mild, moderate, or severe, depending on the degree of factor deficiency. After a person with hemophilia forms a platelet plug at a bleeding site, the lack of clotting factors impairs formation of a stable fibrin clot. Immediate hemorrhage is not prevalent, but delayed bleeding is common.

Complications

Bleeding into joints and muscles causes pain, swelling, extreme tenderness and, possibly, permanent deformity. Bleeding near peripheral nerves may cause peripheral neuropathies, pain, paresthesia, and muscle atrophy. If bleeding impairs blood flow through a major vessel, it can cause ischemia and gangrene. Pharyngeal, lingual, intracardial, intracerebral, and intracranial bleeding may all lead to shock and death.

Assessment findings

Varying assessment findings depend on the severity of the patient's condition. A patient with undiagnosed hemophilia typically presents with pain and swelling in a weight-bearing joint, such as the hip, knee, and ankle.

Mild hemophilia frequently goes undiagnosed until adulthood because the patient with a mild deficiency does not bleed spontaneously or after minor trauma but has prolonged bleeding if challenged by major trauma or surgery. Postoperative bleeding continues as a slow ooze or ceases and starts again up to 8 days after surgery.

Moderate hemophilia causes symptoms similar to those of severe hemophilia but produces only occasional spontaneous bleeding episodes.

Severe hemophilia causes spontaneous bleeding. Often, the first sign of severe hemophilia is excessive bleeding after circumcision. Later, spontaneous bleeding or severe bleeding after minor trauma may produce large subcutaneous and deep I.M. hematomas.

The patient history may reveal prolonged bleeding after surgery (including dental extractions), trauma, or joint pain if episodes of spontaneous bleeding into muscles or joints have occurred. The history may disclose signs of internal bleeding, such as abdominal, chest, or flank pain; episodes of hematuria or hematemesis; and tarry stools. It should also reveal activity or movement limitations that the patient has experienced in the past and any need he has for assistive devices, such as splints, canes, or crutches.

Inspection may reveal hematomas on the extremities, the torso, or both and, if bleeding has occurred in joints, joint swelling. Joint range of motion may be limited, and the patient may complain of pain when this assessment is done if bleeding has occurred into the joints.

Diagnostic tests

Specific coagulation factor assays can diagnose the type and severity of hemophilia. A positive family history can also help to diagnose hemophilia.

Characteristic findings in hemophilia A are:

- u factor VIII assay 0% to 25% of normal
- u prolonged activated partial thromboplastin time (APTT)
- u normal platelet count and function, bleeding time, and prothrombin time.

Characteristic findings in hemophilia B are:

- u deficient factor IX assay
- u baseline coagulation results similar to those of hemophilia A, with normal factor VIII.

In hemophilia A or B, the degree of factor deficiency defines severity as follows:

- u mild hemophilia—factor levels 5% to 25% of normal
- u moderate hemophilia—factor levels 1% to 5% of normal
- u severe hemophilia—factor levels less than 1% of normal.

Blood studies are the key diagnostic tool for assessing hemophilia, but additional tests may be ordered periodically to evaluate complications caused by bleeding. For example, a computed tomography scan would be used for suspected intracranial bleeding; arthroscopy or arthrography, for certain joint problems; and endoscopy, for GI bleeding.

Treatment

Hemophilia is not curable, but treatment can prevent crippling deformities and prolong life. Correct treatment quickly stops bleeding by increasing plasma levels of deficient clotting factors to help prevent disabling deformities that result from repeated bleeding into muscles, joints, and organs.

In hemophilia A, cryoprecipitated antihemophilic factor (AHF), lyophilized AHF, or both given in doses large enough to raise clotting factor levels above 25% of normal can permit normal hemostasis. Before surgery, AHF is administered to raise clotting factors to hemostatic levels. Levels are then kept within a normal range until the wound has healed. Fresh frozen plasma can also be given but has some drawbacks.

Inhibitors to factor VIII develop after multiple transfusions in 10% to 20% of patients with severe hemophilia renders the patient resistant to factor VIII infusions. Desmopressin may be given to stimulate the release of stored factor VIII, raising the level in the blood.

In hemophilia B, administration of factor IX concentrate during bleeding episodes increases factor IX levels.

A person with hemophilia who undergoes surgery needs careful management by a hematologist with expertise in hemophilia care. The patient requires deficient factor replacement before and after surgery. Such replacement may be necessary even for minor surgery, such as dental extraction. In addition, amino-caproic acid is commonly used for oral bleeding to inhibit the active fibrinolytic system in oral mucosa.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Anxiety u Impaired physical mobility u Ineffective individual coping u Knowledge deficit u Pain u Powerlessness u Risk for fluid volume deficit u Risk for injury u Social isolation

Key outcomes

- u The patient will show evidence of hemodynamic stability.
- u The patient's peripheral pulses will remain palpable.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will maintain range of motion and joint mobility.
- u The patient's fluid volume will remain within normal range.
- u The patient will demonstrate adequate coping skills.

Nursing interventions

- u Provide emotional support, and listen to the patient's fears and concerns. Reassure him when possible. Remember that people who may have been exposed to the human immunodeficiency virus (HIV) through contaminated blood products need special support and infection control.
- u If the newly diagnosed patient has difficulty adjusting to his diagnosis, reassure him that his feelings are normal. Point out areas of his life in which he can maintain control. Arrange for others with the same problem to speak with the patient and his family.
- u Allow the patient private time with his family and friends to help overcome feelings of social isolation.
- u Watch for signs and symptoms of decreased tissue perfusion, such as restlessness, anxiety, confusion, pallor, cool and clammy skin, chest pain, decreased urine output, hypotension, and tachycardia. Monitor the patient's blood pressure and pulse and respiratory rates. Observe him frequently for bleeding from the skin, mucous membranes, and wounds.

During bleeding episodes:

- u If the patient has surface cuts or epistaxis, apply pressure—often the only treatment needed. With deeper cuts, pressure may stop the bleeding temporarily. Cuts deep enough to require suturing may also require factor infusions to prevent further bleeding. (See [Recognizing and managing bleeding.](#))
- u Give the deficient clotting factor or plasma, as ordered. The body uses up AHF in 48 to 72 hours, so repeat infusions as ordered until the bleeding stops.
- u Watch for adverse reactions to blood products, such as flushing, headache, tingling, fever, chills, urticaria, and anaphylaxis.
- u Apply cold compresses or ice bags and raise the injured part.
- u To prevent recurrence of bleeding, restrict activity for 48 hours after bleeding is under control.
- u Control pain with an analgesic, such as acetaminophen, propoxyphene, codeine, or meperidine, as ordered. Avoid I.M. injections because they may cause hematoma formation at the injection site. Aspirin and aspirin-containing medications are contraindicated because they decrease platelet adherence and may increase the bleeding.
- u If the patient cannot tolerate activities because of blood loss, provide rest periods between activities.

If the patient has bled into a joint:

- u Immediately elevate the joint.
- u To restore joint mobility, if ordered, begin range-of-motion exercises at least 48 hours after the bleeding is controlled. Tell the patient to avoid weight bearing until bleeding stops and swelling subsides.
- u Administer analgesics for the pain associated with hemarthrosis. Also, apply ice packs and elastic bandages to alleviate the pain.

ADVANCED PRACTICE

<div><div>Recognizing and managing bleeding</div></div>		
Bleeding in hemophilia may occur spontaneously or stem from an injury. Inform your patient and his family about possible types of bleeding and their associated signs and symptoms. Accordingly, advise them which actions to take and when to call for medical help.		
BLEEDING SITE	SIGNS AND SYMPTOMS	INTERVENTIONS
Intracranial	Change in personality or wakefulness (level of consciousness), headache, nausea	Instruct the patient or family members to notify the doctor immediately and treat symptoms as an emergency.
Joints (hemarthroses) Most often the knees, followed by elbows, ankles, shoulders, hips, and wrists	Joint pain and swelling, joint tingling and warmth (at onset of hemorrhage)	Tell the patient to begin antihemophilic factor (AHF) infusions and then to notify the doctor.
Muscles	Pain and reduced function of affected muscle; tingling, numbness, or pain in a large area away from the affected site (referred pain)	Urge the patient to notify the doctor and to start an AHF infusion if the patient is reasonably certain that bleeding results from recent injury (otherwise, call the doctor for instructions).
Subcutaneous tissue or skin	Pain, bruising, and swelling at the site (delayed oozing may also occur after an injury)	Show the patient how to apply appropriate topical agents, such as ice packs and absorbable gelatin sponges (Gelfoam), to stop bleeding.
Kidney	Pain in the lower back near the waist, decreased urine output	Instruct the patient to notify the doctor and to start AHF infusion if bleeding results from a known recent injury.
Heart (cardiac tamponade)	Chest tightness, shortness of breath, swelling (usually occurs in hemophiliacs who are very young or who have severe disease)	Instruct the patient to contact the doctor or to go to the nearest emergency department at once.

After bleeding episodes and surgery:

- u Watch closely for signs of further bleeding, such as increased pain and swelling, fever, and symptoms of shock.
- u Closely monitor APTT.

Patient teaching

- u Teach the patient the benefits of regular exercise. Explain that strong muscles help to protect the joints and that this, in turn, reduces the incidence of hemarthrosis. Instruct him to perform isometric exercises. Explain that they can also help to prevent muscle weakness and recurrent joint bleeding.
- u Advise parents to protect their child from injury while avoiding unnecessary restrictions that impair his normal development. For example, for a toddler, padded patches can be sewn into the knees and elbows of clothing to protect these joints during frequent falls. An older child must not participate in contact sports, such as football, but he can be encouraged to swim or play golf.
- u Tell the patient to avoid such activities as heavy lifting and using power tools because they increase the risk of injury that can result in serious bleeding problems.
- u If an injury occurs, direct the parents to apply cold compresses or ice bags and elevate the injured part or to apply light pressure to the bleeding. To prevent recurrence of bleeding after treatment, instruct the parents to restrict the child's activity for 48 hours after bleeding is under control.
- u Advise the parents to notify the doctor immediately after even a minor injury, especially to the head, neck, or abdomen. Such injuries may require special blood factor replacement.
- u Instruct parents to watch for signs of internal bleeding, such as severe pain and swelling in joints or muscles, stiffness, decreased joint movement, severe abdominal pain, blood in urine, tarry stools, and severe headache.
- u Explain to the patient and, if appropriate, his parents the importance of avoiding aspirin, combination medications that contain aspirin, and over-the-counter anti-inflammatory agents, such as ibuprofen compounds. Teach the patient and his parents how to recognize over-the-counter medications that contain aspirin. Tell them to use acetaminophen instead.
- u Stress the importance of good dental care, including regular, careful toothbrushing, to prevent the need for dental surgery. Have the child use a soft toothbrush to avoid gum injury. Emphasize that poor dental hygiene can lead to bleeding from inflamed gums.
- u Tell the parents to check with the doctor before allowing dental extractions or other surgery. Advise them to get the names of other doctors they can contact in case their regular doctor isn't available.
- u Teach the patient the importance of protecting his veins for lifelong therapy.
- u As necessary, encourage the patient to remain independent and be self-sufficient. Refer him for counseling as necessary.
- u Tell the parents to make sure the child wears a medical identification bracelet at all times.
- u Refer new patients to a hemophilia treatment center for evaluation. The center will devise a treatment plan for such patients' primary doctors and is a resource for other medical and school personnel, dentists, and others involved in their care. Explain that these centers also offer carrier testing, prenatal diagnosis, and other genetic counseling services.

For patients receiving blood components:

- u Train the parents to administer blood factor components at home to avoid frequent hospitalization. Teach them proper venipuncture and infusion techniques, and urge them not to delay treatment during bleeding episodes. Tell parents to keep blood factor concentrate and infusion equipment available at all times, even on vacation.
- u Review possible adverse reactions, such as blood-borne infection and factor inhibitor development, that can result from replacement factor procedures.
- u If the patient develops flushing, headache, or tingling from replacement factors, inform him or his parents that these reactions occur most often with freeze-dried concentrate. Slowing the infusion rate may cause symptoms to abate.
- u If fever and chills occur, indicating an allergy to white blood cell antigens, instruct the patient or his parents that this reaction occurs most often with plasma infusions. Acetaminophen may relieve the patient's discomfort.
- u Tell the patient that urticaria is the most common reaction to cryoprecipitate or plasma. This hypersensitivity sign results from an allergy to a plasma protein. The wheals usually subside after administration of diphenhydramine or another antihistamine. Ideally, the patient who develops urticaria frequently should receive an antihistamine about 45 minutes before a clotting factor infusion.
- u Review the signs and symptoms of anaphylaxis: rapid or difficult breathing, wheezing, hoarseness, stridor, and chest tightness. (The same plasma proteins that cause urticaria may cause anaphylaxis.) Teach the patient to administer epinephrine and then to contact the doctor at once.
- u Tell the patient or the parents to watch for early signs of hepatitis: headache, fever, decreased appetite, nausea, vomiting, abdominal tenderness, and pain over the liver. Explain that patients who receive blood components risk hepatitis, which may appear 3 weeks to 6 months after treatment with blood components.
- u Inform the patient that all donated blood and plasma are screened for antibodies to HIV, which causes acquired immunodeficiency syndrome. Also, all freeze-dried products are heat-treated to kill HIV.
- u For more information, refer the patient's family to the National Hemophilia Foundation.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia—also called Osler-Weber-Rendu disease—is an inherited vascular disorder in which venules and capillaries dilate to form fragile masses of thin convoluted vessels (telangiectases), resulting in an abnormal tendency to hemorrhage. This disorder affects both sexes but may cause less severe bleeding in females. A similar inherited disorder, ataxia-telangiectasia, produces some of the same signs and symptoms. (See [Ataxia-telangiectasia](#).)

Ataxia-telangiectasia
<p>Ataxia-telangiectasia is an autosomal recessive disorder characterized by progressively severe ataxia; telangiectasia (visibly red small blood vessels) of the face, earlobes, and conjunctivae; and sinopulmonary infections.</p> <p>Immunodeficiency may result from defective embryonic development, hormonal deficiency, or defective deoxyribonucleic acid repair. Children with ataxia-telangiectasia are vulnerable to lymphomas and other types of cancer. Severe abnormalities cause rapid deterioration and premature death from overwhelming infection or cancer.</p> <p>Ataxia usually appears by age 2 but can develop as late as age 9. About 80% of patients have recurrent or chronic respiratory infections. Signs of cerebellar ataxia (such as involuntary, jerky movements) usually develop by the time infants begin to use motor skills. Signs of telangiectasia usually appear later. Secondary sex characteristics may be absent in adolescents. Eventually, patients may exhibit signs of mental retardation.</p> <p>Diagnosis usually depends on immunologic tests. For example, immunoglobulin (Ig) A may be absent (60% to 80% of patients) or IgA and IgE may be deficient. Computed tomography scans, magnetic resonance imaging, and pneumoencephalography show degenerative neurologic changes.</p> <p>No treatment stops the progression of ataxia-telangiectasia, but aggressive therapy with broad-spectrum antibiotics may prevent or control infections. Immunotherapy to replace missing antibodies and prevent infection helps some patients.</p>

Causes

Hereditary hemorrhagic telangiectasia is transmitted by autosomal dominant inheritance. The disorder seldom skips generations. In its homozygous state, it may be fatal.

Complications

Secondary iron deficiency anemia from chronic bleeding is the most common complication. Rarely, vascular malformation may cause pulmonary arteriovenous fistulas; then, shunting of blood through the fistulas may lead to hypoxemia. Recurring cerebral embolism and brain abscess may also occur. Hemorrhagic shock, although rare, may occur in severe cases, in undiagnosed patients undergoing surgery, and in victims of trauma.

Assessment findings

Although signs of hereditary hemorrhagic telangiectasia may be present in childhood, they increase in severity with age.

The history of a patient with this disorder reveals an established familial pattern of bleeding disorders. The patient may complain of epistaxis, hemoptysis, or tarry

stools, indicating fragile mucous membranes in the nose, mouth, or stomach.

Inspection reveals localized aggregations of dilated capillaries on the skin of the face, ears, scalp, hands, arms, and feet, and under the nails. Characteristic telangiectases are violet, bleed spontaneously, may be flat or raised, blanch on pressure, and are nonpulsatile. They may be associated with vascular malformations, such as arteriovenous fistulas. Although they can't be seen on inspection, visceral telangiectases are common in the liver, bladder, respiratory tract, and stomach. The type and distribution of these lesions are usually similar among family members.

Inspection may also reveal generalized capillary fragility evidenced by spontaneous bleeding, petechiae, ecchymoses, and spider hemangiomas of varying size. These signs of capillary fragility may exist without overt telangiectasia. (See [Typical lesions of hereditary hemorrhagic telangiectasia.](#)) A lesser form of this syndrome leads to clubbing of the digits.

An established familial pattern of bleeding disorders and clinical evidence of telangiectasia and hemorrhage establish the diagnosis.

Diagnostic tests

Bone marrow aspiration showing depleted iron stores confirms secondary iron deficiency anemia. Hypochromic, microcytic anemia is common; abnormal platelet function may also be found. Coagulation tests are essentially irrelevant because hemorrhage in telangiectasia results from vascular wall weakness.

Treatment

Supportive therapy includes blood transfusions and the administration of supplemental iron. Ancillary treatment may consist of applying pressure and topical hemostatic agents to bleeding sites, cauterizing bleeding sites not readily accessible, and protecting the patient from trauma and unnecessary bleeding.

Parenteral administration of supplemental iron enhances absorption to maintain adequate iron stores and prevents gastric irritation. Administering antipyretics or antihistamines before blood transfusion and using saline-washed cells, frozen blood, or other types of leukocyte-poor blood instead of whole blood transfusion may prevent febrile transfusion reactions.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Anxiety u Body image disturbance u Impaired skin integrity u Knowledge deficit u Risk for fluid volume deficit u Risk for infection

Key outcomes

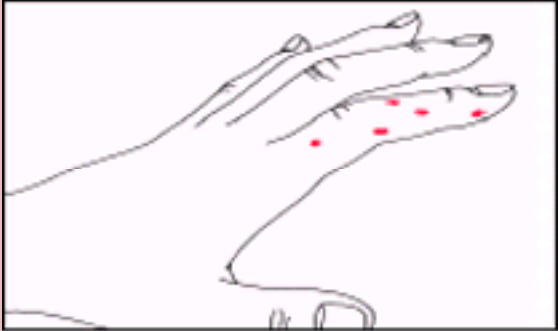

- u The patient's vital signs will remain within normal range.
- u The patient will show evidence of hemodynamic stability.
- u The patient will have normal laboratory values.
- u The patient will express positive feelings about himself.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Provide emotional and psychological support. Encourage the patient to express his concerns about his disease and its treatment. If possible, stay with the patient during periods of severe stress and anxiety. As much as possible, include the patient in care decisions.
- u Administer ordered blood transfusions. Set the flow rate, and observe the patient for tolerance of the infusion and possible adverse reactions. Take the patient's vital signs, and monitor the patient frequently according to facility policy. Check for signs of febrile or allergic transfusion reaction (flushing, shaking chills, fever, headache, rash, tachycardia, hypertension).
- u Encourage fluid intake if the patient is bleeding or hypovolemic. Monitor intake and output.
- u Provide good skin care and hygiene, and use aseptic techniques when caring for the patient. Lesions bleed easily, which may result in infection and skin breakdown.
- u Throughout the patient's hospitalization, observe him for indications of GI bleeding, such as hematemesis and melena.
- u Monitor organ function through routine physical examination; compare with laboratory evaluations to detect possible renal, hepatic, or respiratory failure.

Typical lesions of hereditary hemorrhagic telangiectasia

Dilated capillaries, either flat or raised, appear in localized aggregations, as on the fingers.

On the face, spider hemangiomas reflect capillary fragility.

Patient teaching

- u Teach the patient about the disease, its signs and symptoms, and treatment, reinforcing the doctor's explanation as necessary. Also teach the patient and his family about the hereditary nature of this disorder. Refer the patient for genetic counseling, as appropriate.
- u If the patient requires an iron supplement, stress the importance of following dosage instructions and of taking oral iron with meals to minimize GI irritation. Warn that iron turns stools dark green or black and may cause constipation.
- u Teach the patient and family how to manage minor bleeding episodes, especially recurrent epistaxis, and to recognize major bleeding episodes that require emergency intervention.
- u Encourage routine medical care to monitor for visceral hemorrhage and organ failure.

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Thrombocytopenia that results from immunologic platelet destruction is known as idiopathic thrombocytopenic purpura (ITP). This form of thrombocytopenia may be acute (postviral thrombocytopenia) or chronic (Werlhof's disease, purpura hemorrhagica, essential thrombocytopenia, or autoimmune thrombocytopenia). The acute form usually affects children between ages 2 and 6; the chronic form mainly affects adults under age 50, especially women between ages 20 and 40.

The prognosis for the acute form is excellent; nearly four out of five patients recover completely without specific treatment. The prognosis for the chronic form is good; transient remissions lasting for weeks or even years are common, especially among women.

Causes

ITP is an autoimmune disorder. Antibodies that reduce the life span of platelets have been found in nearly all patients. The spleen probably helps to remove platelets modified by the antibody. The acute form usually follows a viral infection, such as rubella and chickenpox, and can result from immunization with a live vaccine. The chronic form seldom follows infection and is commonly linked with other immunologic disorders, such as systemic lupus erythematosus.

Human immunodeficiency virus (HIV) infection has become a common cause of ITP and should be considered in the differential diagnosis. ITP can be the initial symptom of HIV infection—a symptom indicating AIDS-related complex or a complication of fully developed AIDS. It's also often a precursor to lymphoma.

Complications

As with other purpuric conditions, hemorrhage can severely complicate ITP. A major complication during the initial phase of the disease, cerebral hemorrhage is most likely to occur if the patient's platelet count falls below 500/ μ l. Potentially fatal purpuric lesions may occur in vital organs, such as the brain and kidneys.

Assessment findings

The patient's history usually reveals clinical features common to all forms of thrombocytopenia: epistaxis, oral bleeding, and the development of purpura and petechiae. A female patient may complain of menorrhagia. In the acute form, the sudden onset of bleeding usually follows a recent viral illness, although bleeding can occur up to 21 days after the virus strikes. In the chronic form, the onset of bleeding is insidious.

Inspection typically reveals petechiae or ecchymoses in the skin or bleeding into mucous membranes (GI, urinary, vaginal, or respiratory). Palpation may reveal splenomegaly.

The patient's platelet count determines the type of abnormal bleeding she experiences. For example, a platelet count between 30,000 and 50,000/ μ l causes bruising with minor trauma. A platelet count between 15,000 and 30,000/ μ l produces spontaneous bruising and petechiae, mostly on the arms and legs. A platelet count below 15,000/ μ l triggers spontaneous bruising or, after minor trauma, mucosal bleeding, generalized purpura, epistaxis, hematuria, and GI or intracranial bleeding.

Diagnostic tests

A platelet count less than 20,000/ μ l and prolonged bleeding time suggest ITP. Platelet size and morphologic appearance may be abnormal; anemia may be present if bleeding has occurred.

As in thrombocytopenia, bone marrow studies show an abundance of megakaryocytes (platelet precursors) and a shortened circulating platelet survival time (several hours or days rather than the usual 7 to 10 days).

Highly sensitive tests that quantitate platelet-associated immunoglobulin (Ig) G may help to establish the diagnosis; because these tests are nonspecific, their usefulness is limited. Half of all patients with thrombocytopenia show an increased IgG level on the platelet.

Treatment

Acute ITP may be allowed to run its course without intervention, or it may be treated with glucocorticoids or immune globulin. Treatment with plasmapheresis or plateletpheresis with transfusion has been attempted with limited success.

For chronic ITP, corticosteroids are the treatment of choice to suppress phagocytic activity, promote capillary integrity, and enhance platelet production. Patients who fail to respond spontaneously within 1 to 4 months or who require high doses of corticosteroids to maintain platelet counts require splenectomy,

Splenectomy may be up to 85% successful in adults when splenomegaly accompanies the initial thrombocytopenia. Before splenectomy, the patient may require blood, blood components, and vitamin K to correct anemia and coagulation defects. After splenectomy, she may need blood and component replacement and platelet concentrate. Normally, platelets multiply spontaneously after splenectomy.

Alternative treatments include immunosuppressants (cytoxan or vincristine sulfate, for example) and high-dose I.V. immune globulin in adults (85% effective).

The use of immunosuppressants requires weighing the risks against the benefits. Immune globulin treatment has a rapid effect, raising platelet counts within 1 to 5 days, but the beneficial effect lasts only 1 to 2 weeks. Immune globulin is usually administered to prepare severely thrombocytic patients for emergency surgery.

Nursing diagnoses

u Activity intolerance u Altered protection u Anxiety u Body image disturbance u Fatigue u Impaired skin integrity u Knowledge deficit u Risk for fluid volume deficit

Key outcomes

- u The patient won't experience fever, chills, and other signs of infection.
- u The patient will demonstrate the use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- u The patient will demonstrate effective coping mechanisms.
- u The patient will express positive feelings about herself.
- u The patient will express feelings of increased energy.
- u The patient's fluid volume will remain within normal range.

Nursing interventions

- u Patient care for ITP is essentially the same as that for thrombocytopenia, but a key difference is the use of platelet support. Thrombocytopenia responds well to treatment with platelet replacement, but ITP isn't usually treated with platelets because the body often rejects them.
- u Provide emotional support, and encourage the patient to discuss any concerns. Reassure her that any petechiae and ecchymoses will heal as the disease resolves.
- u Protect all areas of petechiae and ecchymoses from further injury.
- u Watch for signs of bleeding. Identify the amount of bleeding or the size of ecchymoses at least every 24 hours. Test stool, urine, and vomitus for blood.
- u Provide rest periods between activities, if needed.
- u Guard against bleeding by protecting the patient from trauma. Keep the bed's side rails raised and pad them, if possible. Promote the use of an electric razor and a soft toothbrush. Avoid invasive procedures, such as venipuncture and urinary catheterization, if possible. When venipuncture is unavoidable, exert pressure on the puncture site for at least 20 minutes or until the bleeding stops.
- u Monitor the patient's platelet count daily, and check for adverse reactions to platelet transfusions, such as fever, allergic responses, and alloimmunization.

- u During active bleeding, maintain strict bed rest. Elevate the head of the bed to prevent gravity-related pressure increases, possibly leading to intracranial bleeding.
- u If the patient is receiving corticosteroid therapy, monitor her fluid and electrolyte balance and watch for infection, pathologic fractures, and mood changes.
- u Before splenectomy, administer transfusions as ordered and according to facility protocol. Take the patient's vital signs immediately before the transfusion; then monitor them closely after the transfusion has begun.
- u After splenectomy, monitor the patient's vital signs and intake and output. Administer analgesics, I.V. infusions, and transfusions, as necessary.
- u Closely monitor the patient receiving immunosuppressants (commonly given before splenectomy) for signs of bone marrow depression, infection, mucositis, GI tract ulceration, and severe diarrhea or vomiting.

Patient teaching

- u Teach the patient about ITP. For a home care patient, explain how to cope with it. (See [Living with ITP.](#))
- u Warn the patient not to strain during defecation and coughing; both can lead to increased intracranial pressure, possibly causing cerebral hemorrhage. Provide a stool softener, if needed, because constipation and passage of hard stools can tear the rectal mucosa, causing bleeding.
- u Explain the purpose of diagnostic tests and the function of platelets. Tell the patient how the results of platelet counts can help to identify abnormal bleeding.
- u Warn the patient that the lower her platelet count falls, the more precautions she will need to take. In severe ITP, even minor bumps or scrapes can result in bleeding.
- u Advise the patient to carry medical identification to alert others that she has ITP.

HOME CARE

Living with ITP

When teaching a patient how to live safely at home with idiopathic thrombocytopenic purpura (ITP), include the following points:

- u Caution the patient to avoid aspirin and other drugs that impair coagulation. Teach him how to recognize aspirin compounds and nonsteroidal anti-inflammatory drugs listed on labels of over-the-counter drugs.
- u Instruct the patient to use a humidifier at night if he experiences frequent nosebleeds. Also suggest that he moisten his inner nostrils twice a day with an anti-infective ointment.
- u Teach the patient how to examine his skin for ecchymoses and petechiae and how to test his stools for occult blood.
- u Explain the importance of reporting signs of bleeding, such as tarry stools, coffee-ground vomitus, and gum or urinary tract bleeding.

THROMBOCYTOPENIA

Thrombocytopenia is the most common cause of hemorrhagic disorders. It's characterized by a deficient number of circulating platelets. Because platelets play a vital role in coagulation, this disease poses a serious threat to hemostasis. Platelet dysfunction rather than platelet deficiency results in hemorrhagic disorders resembling thrombocytopenia. (See [Platelet function disorders.](#)) The prognosis is excellent in drug-induced thrombocytopenia if the offending drug is withdrawn; in such cases, recovery may be immediate. Otherwise, the prognosis depends on the patient's response to treatment of the underlying cause.

Causes and pathophysiology

Thrombocytopenia may be congenital or acquired; the acquired form is more common. In either case, it usually results from decreased or defective production of platelets in the marrow (for example, in leukemia, aplastic anemia, and toxicity with certain drugs) or from increased destruction outside the marrow caused by an underlying disorder (such as cirrhosis of the liver, disseminated intravascular coagulation, and severe infection).

Less commonly, thrombocytopenia results from sequestration (hypersplenism, hypothermia) or platelet loss. Acquired thrombocytopenia may result from the use of certain drugs, such as quinine, quinidine, rifampin, heparin, nonsteroidal anti-inflammatory agents, histamine blockers, most chemotherapeutic agents, allopurinol, and alcohol.

Thrombocytopenia may also occur transiently after a viral infection (such as Epstein-Barr) or infectious mononucleosis. (See [Causes of decreased circulating platelets.](#)) An idiopathic form of thrombocytopenia also occurs. (For more information, refer to "Idiopathic thrombocytopenic purpura" in this chapter.)

Complications

Complications of thrombocytopenia are usually related to bleeding. Severe thrombocytopenia can cause acute hemorrhage, which may be fatal without immediate therapy. The most common sites of severe bleeding include the brain and GI tract, although intrapulmonary bleeding and cardiac tamponade can also occur.

Assessment findings

Typically, a patient with thrombocytopenia reports sudden onset of petechiae and ecchymoses from bleeding into mucous membranes (GI, urinary, vaginal, or respiratory). He may also complain of malaise, fatigue, and general weakness (with or without accompanying blood loss). In acquired thrombocytopenia, the patient's history may include the use of one or several offending drugs.

Inspection typically reveals evidence of bleeding (petechiae, ecchymoses), along with slow, continuous bleeding from any injuries or wounds. Painless, round, and as tiny as pinpoints (1 to 3 mm in diameter), petechiae usually occur on dependent portions of the body, appearing and fading in crops and sometimes grouping to form ecchymoses. Another form of blood leakage and larger than petechiae, ecchymoses are purple, blue, or yellow-green bruises that vary in size and shape. They can occur anywhere on the body from traumatic injury. In patients with bleeding disorders, they usually appear on the arms and legs. In adults, inspection may reveal large, blood-filled bullae in the mouth. Gentle palpation of edematous ecchymotic areas may cause pain, indicating that these areas are actually hematomas. Superficial hematomas are red; deep hematomas are blue. They typically exceed 1 cm in diameter.

If the patient's platelet count is between 30,000 and 50,000/μl, expect bruising with minor trauma; if it's between 15,000 and 30,000/μl, expect spontaneous bruising and petechiae, mostly on the arms and legs. With a platelet count below 15,000/μl, expect spontaneous bruising or, after minor trauma, mucosal bleeding, generalized purpura, epistaxis, hematuria, and GI or intracranial bleeding. Female patients may report menorrhagia. Remember to look for both obvious and insidious sources of bleeding.

Diagnostic tests

- The following laboratory findings help to establish a diagnosis of thrombocytopenia:
- u diminished platelet count (in adults, less than 100,000/μl)
 - u prolonged bleeding time (although this doesn't always indicate platelet quality)
 - u normal prothrombin and partial thromboplastin times.

Platelet antibody studies can help to determine why the platelet count is low and help to direct treatment. Platelet survival studies help to differentiate between ineffective platelet production and inappropriate platelet destruction. (Platelet production disorders may occur after radiation exposure, medication ingestion, or an infectious disease. They may also occur idiopathically. Inappropriate platelet destruction may occur with splenic disease and platelet antibody disorders.)

In severe thrombocytopenia, a bone marrow study determines the number, size, and cytoplasmic maturity of the megakaryocytes (the bone marrow cells that release mature platelets). This information may identify ineffective platelet production as the cause of thrombocytopenia and rule out a malignant disease process at the same

time.

Treatment

Removal of the offending agents in drug-induced thrombocytopenia or proper treatment of the underlying cause, when possible, is essential. Corticosteroids may be used to increase platelet production or immune globulin.

Platelet transfusions may be used to stop episodic abnormal bleeding caused by a low platelet count. If platelet destruction results from an immune disorder, platelet infusions may have only a minimal effect and may be reserved for life-threatening bleeding.

Splenectomy may be necessary to correct thrombocytopenia caused by platelet destruction. A splenectomy should significantly reduce platelet destruction because the spleen acts as the primary site of platelet removal and antibody production.

Platelet function disorders
<p>Platelet function disorders resemble thrombocytopenia but stem from platelet dysfunction (poor platelet adhesion or fibrin clot formation), not platelet deficiency. Hemorrhage is the most serious complication.</p> <p>Disorders may be inherited (the bone marrow produces ineffectively clotting platelets) or acquired (resulting from the effects of drugs, such as aspirin and carbenicillin; from systemic diseases, such as uremia; and from other hematologic disorders).</p> <p>Sudden, excessive bruising and nasal and gingival bleeding is characteristic. Petechiae, purpura, and external hemorrhage may be present. Vital signs are usually normal, but with hemorrhage, pulse and respiratory rate increase and blood pressure decreases. Occasionally, excessive bleeding during surgery is the first sign of internal hemorrhage.</p> <p>The diagnosis is suggested by prolonged bleeding time despite normal platelet count and clotting factors. A blood film and platelet function test reveal the defective mechanism. Other findings include poor clot retraction, decreased prothrombin conversion, and normal prothrombin, activated partial thromboplastin, and thrombin times. Complete blood count and differential and determination of hemorrhage sites are needed.</p> <p>Platelet replacement is the only satisfactory treatment for inherited platelet dysfunction. Acquired dysfunctions require treatment for the underlying disease or discontinuation of damaging drug therapy. Cryoprecipitate infusions aid uremia-induced platelet dysfunction. Plasmapheresis controls bleeding caused by a plasma element that inhibits platelet function.</p>

Nursing diagnoses

- u Activity intolerance
- u Altered protection
- u Anxiety
- u Body image disturbance
- u Fatigue
- u Impaired skin integrity
- u Knowledge deficit
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient won't incur an injury.
- u The patient won't experience fever, chills, and other signs or symptoms of illness.
- u The patient will demonstrate use of protective measures, including conserving energy, maintaining a balanced diet, and getting plenty of rest.
- u The patient will demonstrate effective coping skills.
- u The patient will express positive feelings about himself.

Causes of decreased circulating platelets
<p>Thrombocytopenia usually results from insufficient production or increased peripheral destruction of platelets. Less commonly, it results from sequestration or platelet loss.</p> <p>Diminished or defective platelet production <i>Congenital</i></p> <ul style="list-style-type: none">u Wiskott-Aldrich syndromeu Maternal ingestion of thiazidesu Neonatal rubellau Polycythemia <p><i>Acquired</i></p> <ul style="list-style-type: none">u Aplastic anemiau Marrow infiltration (acute and chronic leukemias, tumor)u Nutritional deficiency (vitamin B₁₂, folic acid)u Myelosuppressive agentsu Drugs that directly influence platelet production (thiazides, alcohol, hormones)u Radiationu Viral infections (measles, dengue) <p>Increased peripheral destruction (outside marrow) <i>Congenital</i></p> <ul style="list-style-type: none">u Nonimmune (prematurity, erythroblastosis fetalis, infection)u Immune (drug sensitivity, maternal idiopathic thrombocytopenic purpura [ITP]) <p><i>Acquired</i></p> <ul style="list-style-type: none">u Nonimmune (infection, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura)u Immune (drug-induced, especially with quinine and quinidine; posttransfusion purpura; acute and chronic ITP; sepsis; alcohol)u Invasive lines or devices (intra-aortic balloon pump, prosthetic cardiac valves) <p>Sequestration of platelets</p> <ul style="list-style-type: none">u Hypersplenismu Hypothermia <p>Platelet loss</p> <ul style="list-style-type: none">u Hemorrhageu Extracorporeal perfusion

Nursing interventions

- u Provide emotional support as necessary. Encourage the patient to discuss his concerns about his condition. Reassure him that the ecchymoses and petechiae heal as the disease resolves.
- u Provide rest periods between activities if the patient tires easily.
- u If the patient has painful hematomas, handle the area gently. Protect all areas of ecchymosis and petechiae from further injury.
- u Take every possible precaution against bleeding. Protect the patient from trauma. Keep the bed's side rails raised and pad them, if possible. Promote the use of an electric razor and a soft toothbrush. Avoid invasive procedures, such as venipuncture and urinary catheterization, if possible. When venipuncture is unavoidable, exert pressure on the puncture site for at least 20 minutes or until the bleeding stops.
- u Monitor platelet count daily.
- u Watch for bleeding (petechiae, ecchymoses, surgical or GI bleeding, menorrhagia). Identify the amount of bleeding or the size of ecchymoses at least every 24 hours. Test stool, urine, and emesis for blood.
- u During active bleeding, maintain the patient on strict bed rest. Keep the head of the bed elevated to prevent gravity-related pressure increases, possibly leading to intracranial bleeding.
- u When administering platelet concentrate, remember that platelets are extremely fragile, so infuse them quickly using the administration set recommended by the blood bank.

ALERT During platelet transfusion, monitor for a febrile reaction (flushing, chills, fever, headache, tachycardia, or hypertension). Such reactions are common, and a fever will destroy the blood products. Human leukocyte antigen (HLA)-typed platelets may be ordered to prevent febrile reaction. If the patient has a history of minor reactions, he may benefit from acetaminophen and diphenhydramine before the transfusion.

- u One to 2 hours after administering platelet concentrate, monitor the patient's platelet count to assess his response to the infusion. A lack of platelet level increase indicates that the patient is making platelet antibodies and should receive HLA-matched platelets.

Patient teaching

- u Teach the patient about his disorder and its cause, if known. If appropriate, reassure him that thrombocytopenia often resolves spontaneously.
- u Teach the patient to recognize and report signs of intracranial bleeding (persistent headache, mood change, nausea, vomiting, and drowsiness) and other signs of bleeding (tarry stools, coffee-ground vomitus, epistaxis, menorrhagia, and gingival or urinary tract bleeding).
- u Advise the patient to avoid straining while defecating and coughing; both can lead to increased intracranial pressure, possibly causing cerebral hemorrhage. Provide a stool softener, if necessary, because constipation and passage of hard stools are likely to tear the rectal mucosa and cause bleeding.
- u Discuss the diagnostic tests that may be performed throughout the course of the disease.
- u Explain the function of platelets. Warn the patient that the lower his platelet count falls, the more cautious he'll have to be in his activities. Make sure he understands that in severe thrombocytopenia, even minor bumps or scrapes may result in bleeding.
- u Teach the patient how to control local bleeding. (See [Controlling local bleeding](#).)
- u If thrombocytopenia is drug-induced, stress the importance of avoiding the offending drug.
- u If the patient must receive long-term steroid therapy, teach him to watch for and report cushingoid symptoms. Emphasize that corticosteroids must be discontinued gradually. While the patient is receiving corticosteroid therapy, monitor his fluid and electrolyte balance and watch for infection, pathologic fractures, and mood changes.
- u Warn the patient to avoid taking aspirin in any form as well as other drugs that impair coagulation. Teach him how to recognize aspirin compounds and nonsteroidal anti-inflammatory drugs listed on labels of over-the-counter remedies.
- u If the patient experiences frequent nosebleeds, recommend that he use a humidifier at night. Also suggest that he moisten his inner nostrils twice a day with an anti-infective ointment.
- u Teach the patient to monitor his condition by examining his skin for ecchymoses and petechiae. Instruct him how to test his stools for occult blood.
- u Advise the patient to carry medical identification to alert others that he has thrombocytopenia.

Controlling local bleeding

The following agents may be used at home and in the hospital to control local bleeding and capillary oozing.

Agents for home use

Let your patient know about preparations that may be used at home, such as absorbable gelatin sponges (Gelfoam), ice packs, and dicresulene polymer (Negatan).

If the doctor recommends Gelfoam to stop the bleeding, from a puncture wound (venipuncture) or tooth extraction, for example, tell the patient to saturate this foamlike wafer with an isotonic saline or a thrombin solution. Instruct him to place the sponge on the bleeding site and apply pressure for 10 to 15 seconds. Advise him to keep the sponge in place after the bleeding stops. Explain that this agent, which holds many times its weight in blood, can be systemically absorbed.

If the patient bleeds from a blood vessel or into a joint (hemarthrosis), instruct him to elevate the bleeding part and apply an ice pack to the site until the bleeding subsides.

Inform the patient that Negatan, an astringent and protein denaturant, may be applied to oral ulcers. Tell him to clean and dry the ulcer first and then to apply the preparation for 1 minute. Next, he should neutralize the area with large amounts of water. Because the agent may burn or sting, a topical anesthetic may be applied first.

Agents for hospital use

Inform the surgical patient that bleeding can be controlled with such agents as oxidized cellulose (Surgicel), microfibrillar collagen hemostat (Avitene), or thrombin (Thrombinar).

Surgicel, for instance, helps to control surgical bleeding or external bleeding at open wounds. This agent may remain in place until hemostasis occurs. The caregiver then irrigates it (to prevent fresh bleeding) and removes it with sterile forceps.

Another agent, Thrombinar, may be used during surgery or for GI bleeding. The caregiver mixes Thrombinar with sterile isotonic saline solution or sterile distilled water and applies it to the wound, or the agent may be mixed with milk, which the patient drinks to control GI bleeding. Some patients react to Thrombinar with hypersensitivity and fever.

VON WILLEBRAND'S DISEASE

Also known as angiohemophilia, pseudohemophilia, or vascular hemophilia, von Willebrand's disease is a hereditary bleeding disorder characterized by prolonged bleeding time, moderate deficiency of clotting factor VIII (antihemophilic factor [AHF]), and impaired platelet function.

Von Willebrand's disease commonly causes bleeding from the skin or mucosal surfaces and, in females, excessive uterine bleeding. Bleeding may range from mild and asymptomatic to severe hemorrhage. The prognosis is usually good because most cases are mild. Severe forms may cause hemorrhage after laceration or surgery as well as GI bleeding. Excessive postpartum bleeding is uncommon because factor VIII levels and bleeding time abnormalities become less pronounced during pregnancy. Massive soft-tissue hemorrhage and bleeding into joints seldom occur. Bleeding episodes occur sporadically; a patient may bleed excessively after one dental extraction but not after another. The severity of bleeding may lessen with age.

Causes and pathophysiology

Unlike hemophilia, von Willebrand's disease is inherited as an autosomal dominant trait, affecting both males and females. Scientists have identified an acquired form of this disease in patients with cancer and immune disorders.

One theory is that mild to moderate deficiency of factor VIII and defective platelet adhesion prolong coagulation time. This results from a deficiency of von Willebrand's factor (factor VIII_{VWF}), which appears to occupy the factor VIII molecule and may be necessary for factor VIII production and proper platelet function.

Defective platelet function is characterized by:

- u decreased agglutination and adhesion at the bleeding site
- u reduced platelet retention when filtered through a column of packed glass beads
- u diminished ristocetin-induced platelet aggregation.

Complications

Severe, potentially life-threatening hemorrhage is the major complication of von Willebrand's disease.

Assessment findings

The patient history may reveal a positive family history of von Willebrand's disease. Typically, the patient complains of easy bruising and frequent bleeding from the nose or gums. A female patient may report menorrhagia. If a patient has a severe form of the disease, he may report hemorrhage after a laceration or surgery and may have experienced episodes of GI bleeding. Inspection may reveal bruises.

Diagnostic tests

Symptoms are usually mild, so laboratory values are borderline and factor VIII levels fluctuate, making diagnosis difficult. Typical laboratory findings include:

- u prolonged bleeding time (more than 6 minutes)
- u slightly prolonged partial thromboplastin time (more than 45 seconds)
- u absent or reduced levels of factor VIII–related antigens and low factor VIII activity level
- u defective in vitro platelet aggregation (using the ristocetin coagulation factor assay test)
- u normal platelet count and clot retraction.

Treatment

The objectives of treatment are to shorten bleeding time by local measures and to replace factor VIII (and, consequently, factor VIII_{VWF}) by infusion of cryoprecipitate or blood fractions that are rich in factor VIII.

In many cases, the disorder is so mild that unless surgical or dental procedures are needed, no treatment may be required other than having the patient avoid taking aspirin. However, preparation is necessary for these procedures even for patients with mild forms of the disease.

During bleeding episodes and before even minor surgery, I.V. infusion of cryoprecipitate or fresh plasma (in quantities sufficient to raise factor VIII levels to 50% of normal) shortens bleeding time. Desmopressin may be effective in mild disease because it enhances cellular release of stored factor VIII.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fatigue u Ineffective family coping: Disabling u Ineffective individual coping u Knowledge deficit u Risk for fluid volume deficit u Risk for injury

Key outcomes

- u The patient will show evidence of hemodynamic stability.
- u The patient's peripheral pulses will remain palpable.
- u The patient's fluid volume will remain within normal range.
- u The patient will remain free from injury.
- u The patient and family members will exhibit adequate coping skills.

Nursing interventions

- u Focus on measures to control bleeding and on patient teaching to prevent bleeding, unnecessary trauma, and complications.
- u Provide emotional support, as necessary. Listen to the patient's fears and concerns. If the newly diagnosed patient has difficulty adjusting to his diagnosis, reassure him that his feelings are normal. Arrange for others with the same problem to speak with the patient and his family.
- u Watch for signs and symptoms of decreased tissue perfusion, such as restlessness, anxiety, confusion, pallor, cool and clammy skin, chest pain, decreased urine output, hypotension, and tachycardia. Monitor the patient's blood pressure and pulse and respiratory rates. Observe the patient frequently for bleeding from the skin, mucous membranes, and wounds.
- u After surgery, monitor bleeding time or other clotting procedure for 24 to 48 hours and watch for signs of new bleeding.
- u During a bleeding episode, elevate the area, if possible, and apply cold compresses and gentle pressure to the bleeding site. (Pressure is often the only treatment necessary.) Monitor the patient's vital signs for tachypnea, tachycardia, and hypotensive changes.
- u Give AHF or plasma, as ordered. The body uses up AHF in 48 to 72 hours, so repeat infusions as ordered until bleeding stops.
- u Watch for adverse reactions to blood products, such as flushing, headache, tingling, fever, chills, urticaria, and anaphylaxis.
- u After bleeding episodes and surgery, be alert for signs of further bleeding, such as increased pain and swelling, fever, and shock.
- u If the patient is fatigued after a bleeding episode, alternate activities and rest periods.
- u Prevent potential injury by using an electric razor, keeping the room free from clutter, and providing a cushioned sitting and sleeping surface (such as a convoluted foam mattress).

Patient teaching

- u Advise the patient to notify the doctor after even minor trauma and before all surgery, including dental procedures, to determine if replacement of blood components is necessary.
- u Warn against using aspirin and other drugs that impair platelet function. Explain to the patient and, if appropriate, his parents the importance of not taking aspirin, combination medications that contain aspirin, and over-the-counter anti-inflammatory agents, such as ibuprofen compounds. Teach the patient and his parents how to recognize over-the-counter medications that contain aspirin.
- u If the patient has a severe form of this disease, teach the patient and his parents special precautions to prevent bleeding episodes. Explain to them that all contact sports and activities must be avoided because they increase the risk of bleeding. Tell the patient to avoid such activities as heavy lifting and using power tools because they increase the risk of injury that can result in serious bleeding problems.
- u Urge the patient to wear a medical identification bracelet.
- u Refer the parents of affected children for genetic counseling.

Miscellaneous disorders

Granulocytopenia and lymphocytopenia, hemolytic disease of the newborn (erythroblastosis fetalis), and hyperbilirubinemia are included in this section.

GRANULOCYTOPENIA AND LYMPHOCYTOPENIA

Granulocytopenia is characterized by a marked reduction in the number of circulating granulocytes. Although this implies that all granulocytes (neutrophils, basophils, and eosinophils) are reduced, granulocytopenia usually refers to decreased neutrophils, a condition known as neutropenia. This disorder, which can occur at any age, is associated with infections and ulcerative lesions of the throat, GI tract, other mucous membranes, and skin. Its severest form is known as agranulocytosis.

A rare disorder, lymphocytopenia (lymphopenia) is a deficiency of circulating lymphocytes (leukocytes produced mainly in lymph nodes).

In granulocytopenia and lymphocytopenia, the white blood cell (WBC) count may reach dangerously low levels, leaving the body unprotected against infection. The prognosis in both disorders depends on the underlying cause and whether it can be treated. Untreated, severe granulocytopenia can be fatal in 3 to 6 days.

Causes

Granulocytopenia may result from diminished production of granulocytes in bone marrow, increased peripheral destruction of granulocytes, or greater use of granulocytes. Diminished production of granulocytes in bone marrow generally stems from radiation therapy or drug therapy, is a common adverse effect of antimetabolites and alkylating agents, and can occur in the patient who is hypersensitive to phenothiazines, sulfonamides (and some sulfonamide derivatives, such as chlorothiazide), antibiotics, or antiarrhythmics. Drug-induced granulocytopenia usually develops slowly and typically correlates with the dosage and duration of therapy. Granulocyte production also decreases in such conditions as aplastic anemia and malignant bone marrow diseases and in some hereditary disorders (infantile genetic agranulocytosis).

The growing loss of peripheral granulocytes results from increased splenic sequestration, diseases that destroy peripheral blood cells (viral and bacterial infections), and drugs that act as haptens (carriers of antigens that attack blood cells, causing acute idiosyncratic or non–dose-related drug reactions). Infections such as mononucleosis may cause granulocytopenia because of the increased use of granulocytes.

Similarly, lymphocytopenia may result from decreased production, increased destruction, or loss of lymphocytes. Decreased lymphocyte production may result from a genetic or thymic abnormality or from an immunodeficiency disorder, such as thymic dysplasia or ataxia-telangiectasia. Increased lymphocyte destruction may be caused by radiation therapy, chemotherapy, or human immunodeficiency virus infection. Loss of lymphocytes may follow postoperative thoracic duct drainage, intestinal lymphangiectasia, and impaired intestinal lymphatic drainage (as in Whipple's disease). Lymphocyte depletion can also result from elevated plasma corticoid levels (due to stress, corticotropin or steroid therapy, or heart failure). Other disorders associated with lymphocyte depletion include Hodgkin's disease, leukemia, aplastic anemia, sarcoidosis, myasthenia gravis, lupus erythematosus, protein-calorie malnutrition, renal failure, terminal cancer, tuberculosis and, in infants, severe combined immunodeficiency disease (SCID).

Complications

Localized infection can quickly become systemic (as in bacteremia) or can spread throughout an organ (as in pneumonia). All patients should be evaluated carefully to detect even subtle signs of infection because untreated infection can lead to septic shock in 8 to 24 hours.

Assessment findings

Typically, patients with granulocytopenia experience slowly progressive fatigue and weakness. If they develop an infection, they can exhibit sudden onset of fever, chills, and mental status changes. Overt signs of infection (pus formation) are usually absent. If granulocytopenia results from an idiosyncratic drug reaction, signs of infection develop abruptly, without causing slowly progressive fatigue and weakness.

In a patient with lymphocytopenia, palpation may reveal enlarged lymph nodes, spleen, and tonsils and signs of an associated disease.

Diagnostic tests

Diagnosis of granulocytopenia necessitates a thorough patient history to check for precipitating factors. Physical examination for clinical effects of underlying disorders is also essential.

Marked reduction in neutrophils (less than 500/ μ l leads to severe bacterial infections) and a WBC count below 2,000/ μ l, with few observable granulocytes on the complete blood count (CBC), confirm granulocytopenia.

Bone marrow examination shows a scarcity of granulocytic precursor cells beyond the most immature forms, but this may vary, depending on the cause.

A lymphocyte count below 1,500/ μ l in adults or below 3,000/ μ l in children indicates lymphocytopenia. Evaluation of the patient's clinical status, bone marrow and lymph node biopsies, or other appropriate diagnostic tests can help to identify the cause and establish the diagnosis.

Treatment

Effective management of granulocytopenia must include identifying and eliminating the cause and controlling infection until the bone marrow can generate more leukocytes. This often means that drug or radiation therapy must be stopped and antibiotic treatment begun immediately, even before test results are known. Treatment may also include antifungal preparations. Administration of granulocyte- or granulocyte-macrophage colony-stimulating factor (G-CSF or GM-CSF) is another treatment used to stimulate bone marrow production of neutrophils. Spontaneous restoration of leukocyte production in bone marrow generally occurs within 1 to 3 weeks.

Treatment of lymphocytopenia includes eliminating the cause and managing the underlying disorder. For an infant with SCID, therapy may include bone marrow transplantation.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Fatigue u Impaired tissue integrity u Risk for infection u Risk for fluid volume deficit

Key outcomes

- u The patient will show no evidence of infection.
- u The patient's fluid volume will remain within normal range.
- u The patient's vital signs will remain within normal limits.
- u The patient will express feelings of increased energy.
- u The patient won't develop complications.

Nursing interventions

- u Monitor vital signs frequently. Obtain cultures from blood, throat, urine, mouth, nose, rectum, vagina, and sputum, as ordered. Give antibiotics, as scheduled.
- u Explain the necessity of infection-prevention procedures to the patient and his caregivers. Teach proper hand-washing technique and correct use of gowns and masks. Prevent patient contact with staff or visitors who have respiratory tract infections.
- u Maintain adequate nutrition and hydration because malnutrition aggravates immunosuppression. Make sure the patient with mouth ulcerations receives a high-calorie liquid diet. Offer a straw to make drinking less painful.
- u Provide warm saline water gargles and rinses as well as analgesics and anesthetic lozenges. Good oral hygiene promotes comfort and healing.

- u Ensure adequate rest, which helps to mobilize the body's defenses against infection. Provide good skin and perineal care.
- u Monitor the CBC and differential count, blood culture results, serum electrolyte levels, fluid intake and output, and daily weight.
- u To help detect granulocytopenia and lymphocytopenia in the early, most treatable stages, monitor the WBC count of any patient receiving radiation therapy or chemotherapy. After the patient has developed bone marrow depression, he must zealously avoid exposure to infection.
- u Advise a patient with known or suspected sensitivity to a drug that can cause granulocytopenia or lymphocytopenia to alert medical personnel to this sensitivity in the future.

Patient teaching

- u Reinforce the doctor's explanation of the disease. Answer any questions the patient may have.
- u Teach effective personal hygiene and the importance of proper hand washing.
- u Instruct the patient to use a soft toothbrush and to maintain good oral hygiene.
- u Teach the patient and family members how to institute and maintain infection precautions.

HEMOLYTIC DISEASE OF THE NEWBORN

Hemolytic disease of the newborn, formerly known as erythroblastosis fetalis, affects the fetus and neonate. It stems from an incompatibility of fetal and maternal blood, resulting in maternal antibody activity against fetal red blood cells (RBCs).

Intrauterine transfusions can save 40% of fetuses with this problem. In severe, untreated hemolytic disease of the newborn, the prognosis is poor, especially if kernicterus develops. About 70% of these infants die, usually within the first week of life; survivors inevitably develop pronounced neurologic damage.

ABO incompatibility, another form of fetomaternal incompatibility, can also occur and can lead to hemolytic disease of the newborn. (See [Understanding ABO incompatibility.](#))

Causes and pathophysiology

Although more than 60 RBC antigens can stimulate antibody formation, hemolytic disease of the newborn usually results from Rh isoimmunization, a condition that develops in about 7% of all pregnancies in the United States.

During her first pregnancy (whether it ends in delivery or abortion), an Rh-negative female becomes sensitized by exposure to Rh-positive fetal blood antigens inherited from the father. A female may also become sensitized by receiving blood transfusions with alien Rh antigens, causing agglutinins to develop. This sensitization is the result of inadequate doses of Rh_o(D) immune globulin (human) or from failure to receive Rh_o(D) immune globulin after significant fetal-maternal leakage from abruptio placentae.

Subsequent pregnancy with an Rh-positive fetus causes increasing amounts of maternal agglutinating antibodies to cross the placental barrier, attach to Rh-positive cells in the fetus, and cause hemolysis and anemia in the fetus. To compensate for this, the fetus produces more RBCs and erythroblasts (immature RBCs) appear in the fetal circulation. Extensive hemolysis results in the release of large amounts of unconjugated bilirubin, which the liver is unable to conjugate and excrete, causing hyperbilirubinemia and hemolytic anemia in the fetus. Before the development of Rh_o(D) immune globulin, this condition was a major cause of kernicterus and neonatal death.

Complications

Untreated hemolytic disease of the newborn can lead to kernicterus, which produces pronounced neurologic defects, such as cerebral palsy, sensory impairment, and mental deficiencies.

Severely affected fetuses who develop hydrops fetalis—the most severe form of this disorder, associated with profound anemia and edema—are commonly stillborn. Even if they're delivered alive, they seldom survive longer than a few hours.

Understanding ABO incompatibility			
ABO incompatibility, a form of fetomaternal incompatibility, occurs between mother and fetus in about 25% of all pregnancies, with the highest incidence occurring among blacks. In about 1% of this number, it leads to hemolytic disease of the newborn. Although ABO incompatibility is more common than Rh isoimmunization, it is less severe. Low antigenicity of fetal or neonatal ABO factors may account for the milder clinical effects.			
Each blood group has specific antigens on red blood cells and specific antibodies in serum. Maternal antibodies form against fetal cells when blood groups differ. Infants with group A blood born of group O mothers account for about 50% of all ABO incompatibilities. Unlike Rh isoimmunization, which always follows sensitization during a previous pregnancy, ABO incompatibility is likely to develop in a firstborn infant.			
Clinical effects of ABO incompatibility include jaundice (which usually appears in the neonate in 24 to 48 hours), mild anemia, and mild hepatosplenomegaly.			
Diagnosis is based on clinical signs in the neonate, the presence of ABO incompatibility, a weak to moderate positive Coombs' test, and elevated serum bilirubin levels. Cord hemoglobin and indirect bilirubin levels indicate the need for exchange transfusion. An exchange transfusion is done with blood of the same group and Rh type as those of the mother. Because infants with ABO incompatibility respond so well to phototherapy, exchange transfusion is seldom necessary.			
BLOOD GROUP	ANTIGENS ON RBCs	ANTIBODIES IN SERUM	MOST COMMON INCOMPATIBLE GROUPS
A	A	Anti-B	Mother A, infant B or AB
B	B	Anti-A	Mother B, infant A or AB
AB	A and B	No antibodies	No incompatibility
O	No antigens	Anti-A and anti-B	Mother O, infant A or B

Assessment findings

The mother's history may reveal that the infant's father is Rh-positive and the mother is Rh-negative, or that the mother has had a previous pregnancy in which she developed the antigen-antibody response. Previous pregnancies include stillbirths and abortions as well as any live births. The maternal history may also reveal previous blood transfusions.

Inspection of the mildly affected neonate reveals pallor and, 30 minutes to 24 hours after birth, jaundice. Palpation may uncover mild to moderate hepatosplenomegaly.

In severely affected neonates who survive birth, inspection usually reveals pallor, edema, petechiae, a bile-stained umbilical cord, and yellow or meconium-stained

amniotic fluid. Grunting respirations are obvious. Palpation reveals hepatosplenomegaly; auscultation discloses pulmonary crackles and, possibly, heart murmurs. On neurologic examination, you'll note poor muscle tone and, in some cases, unresponsiveness.

In the 10% of untreated neonates who develop kernicterus, neurologic assessment may reveal lethargy, poor sucking ability, retracted head, stiff extremities, squinting, a high-pitched cry, and seizures. Infants with kernicterus also commonly have anemia.

If the neonate with hydrops fetalis is born alive, inspection reveals signs of extreme hemolysis: marked pallor, edema (ranging from mild peripheral edema to anasarca), petechiae, and widespread ecchymosis in severe cases (indicating the presence of disseminated intravascular coagulation). Inspection also discloses smaller body size than that of infants of comparable gestational age and an enlarged placenta. (This disorder retards intrauterine growth. The neonate's lungs, kidneys, brain, and thymus are also small.)

Palpation and percussion may reveal hepatosplenomegaly, cardiomegaly, and ascites. Auscultation may reveal dyspnea and pulmonary crackles (signs of peritoneal and pleural effusions). In addition, the neonate may have fetal hypoxia and heart failure (with possible pericardial effusion and circulatory collapse).

Note: Identification of green- or brown-tinged amniotic fluid before birth usually indicates that the infant will be stillborn.

Diagnostic tests

Diagnostic tests are performed on the mother and the neonate. The father may also be tested for blood group, Rh factor, and Rh zygosity.

Diagnostic tests performed on the *mother* to help identify hemolytic disease of the newborn and determine treatment include blood typing and screening, antibody titer tests to determine changes in the degree of maternal immunization, and amniotic fluid analysis, which may show increased bilirubin levels (indicating possible hemolysis) and elevations in Rh titers. Radiologic studies, which may show edema and, in hydrops fetalis, the halo sign (edematous, elevated subcutaneous fat layers) and Buddha position (fetus's legs are crossed) are also performed.

Diagnostic tests performed on the *neonate* to help identify hemolytic disease of the newborn include a direct Coombs' test of umbilical cord blood to measure RBC (Rh-positive) antibodies in the neonate (positive only when the mother is Rh-negative and the fetus is Rh-positive; a cord hemoglobin count, which signals severe disease if hemoglobin levels are low (less than 10 g/dl); and stained RBC examination (many nucleated peripheral RBCs).

Treatment

The choice of treatment depends on the degree of maternal sensitization and hemolytic effects on the fetus or neonate.

Intrauterine transfusion is performed on a fetus when amniotic fluid analysis suggests that the fetus is severely affected and delivery is inappropriate because of fetal immaturity. The mother is admitted to the labor and delivery area and monitored closely. She is given a tocolytic agent I.V. to inhibit contractions, and ultrasonography is performed to locate the umbilical vein of the fetus. Then, using a procedure called percutaneous umbilical blood sampling, a needle is inserted into the umbilical vein and a blood sample is taken to identify fetal blood type, measure hemoglobin levels and hematocrit, and obtain other pertinent information. If the fetal blood sample verifies anemia, a blood transfusion of O-negative blood in utero can take place through the sampling needle. This procedure may be repeated periodically (about every 2 weeks) until the fetus is mature enough for delivery.

Planned delivery usually is done 2 to 4 weeks before term date, depending on maternal history, serologic tests, and amniocentesis; labor may be induced from the 34th to 38th week of gestation. During labor, the fetus should be monitored electronically; capillary blood sampling (from the scalp) determines acid-base balance. Any indication of fetal distress necessitates immediate cesarean delivery.

Phenobarbital administered during the last 5 to 6 weeks of gestation may lower serum bilirubin levels in the neonate.

An exchange transfusion removes antibody-coated RBCs and prevents hyperbilirubinemia through removal of the infant's blood and replacement with fresh group O Rh-negative blood. Albumin infusion binds bilirubin, reducing the risk of hyperbilirubinemia. Phototherapy by exposure to ultraviolet light reduces bilirubin levels.

Administration of gamma globulin that contains anti-Rh-positive antibody (Rh₀[D]) can provide passive immunization, which prevents maternal Rh isoimmunization in Rh-negative females. However, it's ineffective if sensitization has already resulted from a previous pregnancy, abortion, or transfusion.

Neonatal therapy for hydrops fetalis consists of maintaining ventilation by intubation, oxygenation, and mechanical assistance, when necessary, and removing excess fluid to relieve ascites and respiratory distress. Other appropriate measures include an exchange transfusion and maintenance of the neonate's body temperature.

Administration of Rh₀(D) immune globulin (human) to an unsensitized Rh-negative mother as soon as possible after the birth of an Rh-positive infant or after a spontaneous or elective abortion prevents complications in subsequent pregnancies.

The following patients should be screened for Rh isoimmunization or irregular antibodies:

- all Rh-negative mothers during their first prenatal visit and at 24, 28, 32, and 36 weeks' gestation
- all Rh-positive mothers with histories of transfusion, a jaundiced baby, stillbirth, cesarean birth, induced abortion, placenta previa, or abruptio placentae.

Nursing diagnoses

▫ Altered parenting ▫ Altered tissue perfusion (cardiopulmonary) ▫ Impaired gas exchange ▫ Impaired tissue integrity ▫ Ineffective breathing pattern ▫ Risk for altered body temperature ▫ Risk for fluid volume deficit ▫ Risk for impaired skin integrity

Key outcomes

- The patient will exhibit adequate ventilation.
- The patient will be hemodynamically stable.
- The patient's fluid balance will remain within normal limits.
- The patient's airway will remain patent.
- The patient's temperature will remain within normal limits.
- The patient will demonstrate eye, voice, and touch contact with the infant.
- The patient's complications will be minimized.

Nursing interventions

▫ Administer Rh₀(D) immune globulin I.M., as ordered, to all Rh-negative, antibody-negative females after transfusion reaction or ectopic pregnancy or during the second and third trimesters to patients with abruptio placentae, placenta previa, or amniocentesis.

For intrauterine transfusion:

▫ Before intrauterine transfusion, obtain a baseline fetal heart rate through electronic monitoring. Afterward, carefully observe the mother for uterine contractions and fluid leakage from the puncture site. Monitor fetal heart rate for tachycardia or bradycardia.

For exchange transfusions:

- Prepare the infant warmer and tray before the transfusion. Try to keep the infant quiet. Obtain a baseline fetal heart rate.
- Check the type, Rh, and age of the blood to be used for the exchange. Keep emergency equipment (oxygen and resuscitative and intubation equipment) available.

- ⌞ During an exchange transfusion, maintain the infant's body temperature by placing him under a heat lamp or overhead radiant warmer. Monitor his respiratory and heart rates every 15 minutes; check his temperature every 30 minutes. Keep resuscitative and monitoring equipment handy, and warm blood before transfusion.
- ⌞ Watch for complications of transfusion, such as lethargy, muscle twitching, seizures, dark urine, edema, and change in vital signs. Watch for postexchange serum bilirubin levels that are usually 50% of preexchange levels (although these levels may increase to 70% to 80% of preexchange levels because of the rebound effect). Within 30 minutes of transfusion, bilirubin may rebound, requiring repeated exchange transfusions.
- ⌞ After the exchange transfusion, continue to monitor the infant's vital signs every 15 to 30 minutes for 2 hours. Measure intake and output. Observe for umbilical cord bleeding and complications, such as hemorrhage, hypocalcemia, sepsis, and shock. Report serum bilirubin and hemoglobin levels.

For phototherapy:

- ⌞ Keep a record of how long each bilirubin light bulb is in use because these bulbs require frequent changing for optimum effectiveness.
- ⌞ Undress the infant so that his entire body surface is exposed to the light rays. Keep him 18" to 30" (46 to 76 cm) from the light source. Protect his eyes with shields that filter the light to prevent retinal damage. Remove the eye patches at least every 8 hours to provide visual stimulation.
- ⌞ Monitor and maintain the infant's body temperature; high and low temperatures predispose him to kernicterus. Remove the infant from the light source every 3 to 4 hours, and take off the eye shields. Turn the infant every 2 hours to provide maximum skin exposure for photodecomposition.
- ⌞ Promote normal parental bonding. Encourage the parents to visit the nursery and help care for their infant as often as possible.
- ⌞ Provide the infant with 2 oz (57 g) of dextrose 5% in water or sterile water between feedings to help avoid fluid volume deficit, resulting from insensible fluid loss from the heat of the phototherapy lamp.

For all infants:

- ⌞ Provide emotional support to the infant's parents, as appropriate. Reassure them that they're not at fault for having a child with this disorder. Encourage them to express their fears concerning possible complications of treatment.
- ⌞ Organize nursing care to allow for extended periods of rest for the infant who is hemolyzing RBCs and is anemic and jaundiced.
- ⌞ Keep the infant in an incubator to help reduce his energy expenditures until his condition stabilizes.
- ⌞ Monitor vital signs frequently. Remember that tachycardia may occur in severe anemia.
- ⌞ If the infant has hydrops fetalis, also administer oxygen as ordered, maintain the airway and mechanical ventilation as required, and assist in the removal of excess fluids to relieve ascites and respiratory distress.

Patient teaching

- ⌞ Reinforce the doctor's explanation of the disease and its complications as necessary. Explain diagnostic tests and the prescribed treatment to the parents. Be sure they understand the care that the infant will receive.
- ⌞ Explain any medications, drug routes, and administration.
- ⌞ Encourage follow-up appointments with the pediatrician and explain the importance of preventive measures.

HYPERBILIRUBINEMIA

Elevated serum bilirubin levels and mild jaundice are hallmarks of hyperbilirubinemia, also known as neonatal jaundice. The disorder can be physiologic (with jaundice the only symptom) or pathologic (resulting from an underlying disease). Physiologic jaundice is widespread and is more common and severe in certain ethnic groups (Chinese, Japanese, Koreans, Native Americans) whose mean peak of unconjugated bilirubin is about twice that of the rest of the population.

Physiologic jaundice is self-limiting; the prognosis for pathologic jaundice varies, depending on the cause. Untreated, severe hyperbilirubinemia may cause kernicterus, a neurologic syndrome resulting from deposition of unconjugated bilirubin in the brain cells and characterized by severe neural symptoms.

Causes and pathophysiology

Hyperbilirubinemia may develop when:

- ⌞ factors that disrupt conjugation and usurp albumin-binding sites are present, including drugs such as aspirin, tranquilizers, and sulfonamides and conditions such as hypothermia, anoxia, hypoglycemia, and hypoalbuminemia
- ⌞ decreased hepatic function results in reduced bilirubin conjugation
- ⌞ increased erythrocyte production or breakdown results from hemolytic disorders or from Rh or ABO incompatibility
- ⌞ biliary obstruction or hepatitis results in blockage of normal bile flow
- ⌞ maternal enzymes present in breast milk inhibit the infant's glucuronyl-transferase conjugating activity. (See [Causes of hyperbilirubinemia.](#))

Hyperbilirubinemia stems from hemolytic processes in the neonate. As erythrocytes break down at the end of the neonatal life cycle, the hemoglobin separates into globin (protein) and heme (iron) fragments. Heme fragments form unconjugated (indirect) bilirubin, which binds with albumin for transport to liver cells to conjugate with glucuronide, forming direct bilirubin. Because unconjugated bilirubin is fat-soluble and can't be excreted in urine or bile, it may escape to extravascular tissue, especially fatty tissue and the brain, resulting in hyperbilirubinemia.

Causes of hyperbilirubinemia

The infant's age at onset of hyperbilirubinemia may provide clues to the sources of this jaundice-causing disorder.

Day 1

- Blood type incompatibility (Rh, ABO, other minor blood groups)
- Intrauterine infection (rubella, cytomegalic inclusion body disease, toxoplasmosis, syphilis and, occasionally, bacteria such as *Escherichia coli*, staphylococci, *Pseudomonas*, *Klebsiella*, *Proteus*, and streptococci)

Day 2 or 3

- Abnormal red blood cell (RBC) morphology
- Blood group incompatibilities
- Enclosed hemorrhage (skin bruises, subdural hematoma)
- Heinz-body anemia from drugs and toxins (vitamin K₃, sodium nitrate)
- Infection (usually from gram-negative bacteria)
- Physiologic jaundice
- Polycythemia
- RBC enzyme deficiencies (glucose-6-phosphatedehydrogenase, hexokinase)
- Respiratory distress syndrome (hyaline membrane disease)

Days 4, 5, or 6

- Breast-feeding, maternal diabetes
- Crigler-Najjar syndrome (congenital nonhemolytic icterus)
- Gilbert syndrome
- Respiratory distress syndrome

Day 7 and later

- Bile duct atresia
- Choledochal cyst
- Herpes simplex
- Galactosemia
- Hypothyroidism
- Infection (usually acquired in neonatal period)
- Neonatal giant cell hepatitis
- Pyloric stenosis

Complications

Kernicterus (bilirubin encephalopathy) is the most dangerous complication of hyperbilirubinemia. It can be fatal or cause profound neurologic disorders. Survivors may develop cerebral palsy, epilepsy, or mental retardation or have only minor sequelae, such as perceptual-motor handicaps and learning disorders.

Assessment findings

Identifying the underlying cause of hyperbilirubinemia requires a detailed patient history, including prenatal history and family history for paternal Rh factor and red blood cell defects.

PREVENTION

Preventing hyperbilirubinemia

- Here are some steps to take to prevent hyperbilirubinemia:
- Maintain oral intake. Stress the importance of this to the infant's mother. Tell her not to skip any feedings because fasting stimulates the conversion of heme to bilirubin.
 - Supplement breast-feeding with the administration of glucose water.
 - If indicated, administer Rh_o(D) immune globulin (human) as ordered:
 - to an Rh-negative patient after amniocentesis
 - to an Rh-negative patient during the third trimester of pregnancy (if she previously gave birth to an Rh-positive infant)
 - to an Rh-negative patient after spontaneous or elective abortion.

Inspection of the face and sclera in fair-skinned infants in a well-lighted room (without yellow or gold lighting) reveals a yellowish skin coloration (jaundice), particularly in the sclera. In dark-skinned infants, inspection of the oral mucosa and sclera reveals jaundice. Begin inspection with the head and face because jaundice first appears over the head and face area and then spreads, occurring in the lower extremities last. Jaundice can be verified by pressing the skin on the cheek or abdomen lightly with one finger and then releasing pressure and observing the skin color immediately. Keep in mind that jaundice does not become clinically apparent until serum bilirubin levels reach about 7 mg/dl.

Diagnostic tests

Jaundice and elevated levels of serum bilirubin confirm hyperbilirubinemia.

Signs of jaundice necessitate measuring and charting serum bilirubin levels every 4 hours. Testing may include direct and indirect bilirubin levels, particularly for pathologic jaundice.

Physiologic jaundice develops 24 hours after delivery in 50% of term infants (usually day 2 to day 3) and 48 hours after delivery in 80% of premature infants (usually day 3 to day 5). It usually disappears by day 7 in term infants and by day 9 or 10 in premature infants. Throughout physiologic jaundice, serum unconjugated bilirubin levels don't exceed 12 mg/dl.

Pathologic jaundice can appear anytime after the first day of life and persist beyond 7 days with serum bilirubin levels greater than 12 mg/dl in a term infant, greater than 15 mg/dl in a premature infant, or increasing more than 5 mg/dl in 24 hours. Bilirubin levels that are excessively elevated or that vary daily suggest a pathologic process.

Both mother and infant should be tested for blood group incompatibilities, and their hemoglobin levels and hematocrit should be measured. The direct Coombs' test also should be performed on both mother and infant.

Treatment

Depending on the underlying cause, treatment may include phototherapy, exchange transfusions, albumin infusion and, possibly, drug therapy. Phototherapy is the treatment of choice for physiologic jaundice and pathologic jaundice due to hemolytic disease of the newborn (after the initial exchange transfusion). Phototherapy uses fluorescent light to decompose bilirubin in the skin by oxidation. It usually is discontinued after bilirubin levels fall below 10 mg/dl and continue to decrease for 24 hours. Phototherapy seldom is the only treatment for jaundice due to a pathologic cause.

An exchange transfusion, replacing the infant's blood with fresh blood (less than 48 hours old), thus removing some of the unconjugated bilirubin in serum, may be performed for severe hyperbilirubinemia.

Other therapy for excessive bilirubin levels includes albumin administration (1 g/kg of 25% salt-poor albumin), which provides additional albumin for binding unconjugated bilirubin. This can be done 1 to 2 hours before exchange or as a substitute for a portion of the plasma in the transfused blood.

Drug therapy, which is rare, usually consists of phenobarbital administered to the mother before delivery and to the infant several days after delivery. This drug stimulates the hepatic glucuronide-conjugating system.

Nursing diagnoses

u Altered parenting u Anxiety u Knowledge deficit u Risk for altered body temperature u Risk for fluid volume deficit u Risk for impaired skin integrity

Key outcomes

- u Family members will demonstrate understanding of the neonate's special needs.
- u The neonate will exhibit normal body temperature.
- u The neonate's fluid balance will be maintained.
- u The neonate's skin integrity will be intact.
- u The parents will maintain eye, verbal, and physical contact with the neonate.

Nursing interventions

- u Observe the infant for jaundice. Identify the body areas affected, and note the time that you first noticed jaundice. Also, immediately note and report the jaundice and serum bilirubin levels.
- u Provide emotional support and, as appropriate, reassurance to the infant's parents.
- u Observe the infant's eye color every 4 to 8 hours, and check the infant for lethargy, a sign of neurologic complications.

For the infant receiving phototherapy:

- u Keep a record of how long each bilirubin light bulb is in use because these bulbs require frequent changing for optimum effectiveness.
- u Undress the infant so that his entire body surface is exposed to the light rays. Keep him about 18" to 30" (about 46 to 76 cm) from the light source. Protect his eyes with shields that filter the light to prevent retinal damage. Remove the eye patches at least every 8 hours to provide visual stimulation.
- u Monitor and maintain the infant's body temperature; high and low temperatures predispose him to kernicterus. Remove the infant from the light source every 3 to 4 hours, and take off the eye shields. Turn the infant every 2 hours to provide maximum skin exposure for photodecomposition.
- u Encourage the parents to visit the nursery and sit by the infant as often as they desire. Allow the parents to feed him.
- u Provide the infant with 2 oz of dextrose 5% in water or sterile water between feedings to help avoid fluid volume deficit, resulting from insensible fluid loss from the heat of the phototherapy lamp.
- u The infant usually shows a decrease in serum bilirubin level 1 to 12 hours after the start of phototherapy. When the infant's bilirubin level is less than 10 mg/dl and has been decreasing for 24 hours, discontinue phototherapy as ordered. Resume therapy as ordered if the serum bilirubin level increases several milligrams per 100 ml, as it often does, because of a rebound effect.

For the infant receiving exchange transfusions:

- u Prepare the infant warmer and tray before the transfusion. Try to keep the infant quiet. Give him nothing by mouth for 3 to 4 hours before the procedure to reduce the risk of aspiration.
- u Check the type, Rh, and age of the blood to be used for the exchange. Keep emergency equipment (oxygen and resuscitation and intubation equipment) available.
- u During the procedure, monitor respiratory and heart rates every 15 minutes; check the infant's temperature every 30 minutes. Continue to monitor vital signs every 15 to 30 minutes for 2 hours.
- u Measure intake and output. Observe for umbilical cord bleeding and complications, such as hemorrhage at the cannulization site, hypokalemia, hypoglycemia, infection at the catheterization site, thrombosis, and cardiac failure from fluid volume excess, sepsis, and shock. Report serum bilirubin and hemoglobin levels. Bilirubin levels may increase because of a rebound effect within 30 minutes after transfusion, necessitating repeat transfusions.

Patient teaching

- u Teach parents how to prevent hyperbilirubinemia. (See [Preventing hyperbilirubinemia](#).)
- u Reassure parents that most infants experience some degree of jaundice. Explain hyperbilirubinemia, its causes, diagnostic tests, and treatment. If possible, provide them with printed information about hyperbilirubinemia.
- u Explain the prescribed treatment to the parents and the care that their infant will receive during the prescribed therapy.
- u Inform the parents that their infant's stool contains some bile and may be greenish.
- u Emphasize the importance of follow-up doctor visits.

CARDIOVASCULAR DISORDERS

[Introduction](#)
[Congenital Defects](#)
[Cardiac Disorders](#)
[Vascular Disorders](#)
[Selected References](#)

INTRODUCTION

The cardiovascular system begins its activity when the fetus is barely 4 weeks old and is the last system to cease activity at the end of life. This system is so vital that its activity helps define the presence of life.

Life-giving transport system

The heart, arteries, veins, and lymphatics form the cardiovascular network, which serves as the body's transport system. This system brings life-supporting oxygen and nutrients to cells, removes metabolic waste products, and carries hormones from one part of the body to another.

The cardiovascular system, often called the circulatory system, is divided into two branches: *pulmonic circulation* and *systemic circulation*. In pulmonic circulation, blood picks up oxygen and releases the waste product carbon dioxide. In systemic circulation (which includes coronary circulation), blood carries oxygen and nutrients to all active cells while transporting waste products to the kidneys, liver, and skin for excretion.

Circulation requires normal function of the heart, which propels blood through the system by continuous rhythmic contractions. The heart is a muscular organ the size of a man's fist that is located behind the sternum. It has three layers:

- the *endocardium* — the smooth inner layer
- the *myocardium* — the thick, muscular middle layer that contracts in rhythmic beats
- the *epicardium* — the thin, serous membrane, or outer surface of the heart.

A saclike membrane called the pericardium covers the entire heart. This membrane has two layers: a *visceral* layer that is in contact with the heart and a *parietal*, or outer, layer. The pericardial space between these two layers contains a small amount of fluid, which is secreted by the serous membrane. This pericardial fluid lubricates the parietal pericardium when the heart moves against this layer during contraction, preventing irritation.

The heart has four chambers: two thin-walled chambers called *atria* and two thick-walled chambers called *ventricles*. The atria serve as reservoirs during ventricular contraction (systole) and as booster pumps during ventricular relaxation (diastole). The left ventricle propels blood through the systemic circulation. The right ventricle, which forces blood through the pulmonic circulation, is much thinner than the left ventricle because it meets only one-sixth the resistance.

Heart valves

Two kinds of valves work inside the heart: *atrioventricular* and *semilunar*. The atrioventricular valve between the right atrium and the right ventricle has three leaflets, or cusps, and three papillary muscles; hence, it's called the tricuspid valve. The atrioventricular valve between the left atrium and the left ventricle consists of two cusps shaped like a bishop's miter and two papillary muscles and is called the mitral valve. The tricuspid and mitral valves prevent blood backflow from the ventricles to the atria during ventricular contraction.

The leaflets of both valves are attached to the papillary muscles of the ventricle by thin, fibrous bands called chordae tendineae. These leaflets separate and descend funnel-like into the ventricles during diastole and are pushed upward and together during systole to occlude the tricuspid and mitral orifices. The valves' action isn't entirely passive; papillary muscles contract during systole and prevent the leaflets from prolapsing into the atria during ventricular contraction.

The two semilunar valves, which resemble half moons, prevent blood backflow from the aorta and the pulmonary artery into the ventricles when those chambers relax and fill with blood from the atria. These semilunar valves are referred to as aortic and pulmonic for their respective arteries.

Cardiac cycle

Diastole is the phase of ventricular relaxation and filling. As diastole begins, ventricular pressure falls below atrial pressure, and the aortic and pulmonic valves close. As ventricular pressure continues to fall below atrial pressure, the mitral and tricuspid valves open, and blood flows rapidly into the ventricles. Atrial contraction then increases the volume of ventricular filling by pumping up to 20% more blood into the ventricles.

When systole begins, the ventricles contract, raising ventricular pressure above atrial pressure and closing the mitral and tricuspid valves. When ventricular pressure finally becomes greater than that in the aorta and the pulmonary artery, the aortic and pulmonic valves open and the ventricles eject blood. Ventricular pressure continues to increase as blood is expelled from the heart. As systole ends, the ventricles relax and stop ejecting blood, and ventricular pressure decreases, closing the aortic and pulmonic valves.

S₁ (the first heart sound) is heard as the ventricles contract and the atrioventricular valves close. S₁ is loudest at the apex of the heart, over the mitral area. S₂ (the second heart sound), which is normally rapid and sharp, occurs when the aortic and pulmonic valves close. S₂ is loudest at the base of the heart (second intercostal space on both sides of the sternum).

Interpreting pulse character

Peripheral pulse rhythm should correspond exactly to the auscultatory heart rhythm. You can palpate it most easily where the artery crosses a bone or other firm surface (at the wrist, for example).

The character of the pulse offers useful information. For example, *pulsus alternans* is a strong beat followed by a weak one and can mean left-sided heart failure. A *water-hammer* (or Corrigan's) *pulse* is forceful and bounding. It's best felt in the carotid arteries or in the forearm and accompanies increased pulse pressure — commonly with capillary pulsations of the fingernails (Quincke's sign). This pulse usually indicates patent ductus arteriosus or aortic insufficiency.

Pulsus biferiens, a double peripheral pulse for every apical beat, can signal aortic stenosis, hyperthyroidism, or another disease. *Pulsus bigeminus* is a coupled rhythm; you feel its beat in pairs. The second beat, indicating a premature ventricular contraction after each regular beat, sometimes occurs after myocardial infarction.

Pulsus paradoxus is exaggerated waxing and waning of the arterial pressure (a 15 mm Hg or greater decrease in systolic blood pressure during inspiration), which is seen in cardiac tamponade.

Normally, the right heart valves close a fraction of a second later than the left heart valves because of lower pressures in the right ventricle and pulmonary artery. Identifying these components during auscultation is usually difficult, except when inspiration coincides with the end of systole or when a right bundle-branch block exists. Either can cause a slightly prolonged right ventricular ejection time, when the delayed closing of the pulmonic valve is heard as a split S₂.

Ventricular distention during diastole, which can occur in heart failure, creates low-frequency vibrations that may be heard in early diastole as a third heart sound (S₃), or ventricular gallop. An atrial gallop (S₄) may appear at the end of diastole, just before S₁ if atrial filling is forced into a ventricle that has become less compliant or overdistended, or has a decreased ability to contract. A ventricular pressure increase and ventricular vibrations cause this sound.

Cardiac conduction

The heart's conduction system consists of specialized cells that are capable of generating and conducting rhythmic electrical impulses to stimulate heart contraction. This system includes the sinoatrial (SA) node, the atrioventricular (AV) junction, the bundle of His and its bundle branches, and the ventricular conduction tissue and Purkinje's fibers.

Normally, the SA node controls the heart rate and rhythm at 60 to 100 beats/minute. Because the SA node has the lowest resting potential, it's the heart's pacemaker. If it defaults, another part of the system takes over. The AV junction may emerge at 40 to 60 beats/minute; the bundle of His and its bundle branches at 30 to 40 beats/minute; and ventricular conduction tissue and Purkinje's fibers at 20 to 30 beats/minute.

As the myocardium of the aging heart becomes more irritated, extra systoles may occur along with sinus arrhythmias and sinus bradycardias. In addition, the increased fibrous tissue infiltrates the SA nodes and intercostal atrial nodes, which may cause atrial fibrillation and flutter.

Cardiac output

The amount of blood pumped by the left ventricle into the aorta each minute (cardiac output) is calculated by multiplying the stroke volume (the amount of blood the left ventricle ejects during each contraction) by the heart rate (number of beats per minute). When cellular demands increase, the stroke volume or heart rate must increase.

Stroke volume depends on the ventricle's blood volume and pressure at the end of diastole (preload), resistance to ejection (afterload), and the myocardium's contractile strength. Changes in preload, afterload, or contractile strength can alter the stroke volume. Cardiac output declines slightly with age and by age 70, cardiac output may diminish by 30% to 35%.

Many factors affect the heart rate, such as exercise, pregnancy, and stress. When the sympathetic nervous system releases norepinephrine, the heart rate increases; when the parasympathetic system releases acetylcholine, the heart rate slows. As a person ages, the heart rate takes longer to return to normal after exercise.

Circulation and pulses

Blood circulates through three types of vessels: *arteries*, *veins*, and *capillaries*. The sturdy, pliable walls of the arteries adjust to the volume of blood leaving the heart. The major artery arching out of the left ventricle is the aorta. Its segments and subbranches ultimately divide into minute, thin-walled (one-cell thick) capillaries. Capillaries pass the blood to the veins, which return it to the heart. In the veins, valves prevent blood backflow.

Characterizing chest pain			
PERICARDITIS	ANGINA	MYOCARDIAL INFARCTION	
Onset and duration			
Sudden onset, continuous pain lasting for days, residual soreness	Gradual or sudden onset, pain usually lasting less than 15 minutes and not more than 30 minutes (average: 3 minutes)	Sudden onset, pain lasting 30 minutes to 2 hours, residual soreness for 1 to 3 days	
Location and radiation			
Substernal pain to left of midline, radiation to back or subclavicular area	Substernal or anterior chest pain or pressure; not sharply localized; radiation to back, neck, arms, jaws, also upper abdomen or fingers	Substernal, midline, or anterior chest pain; radiation to jaws, neck, back, shoulders, and one or both arms	
Quality and intensity			
Mild ache to severe pain, deep or superficial, “stabbing” and “knifelike”	Mild to moderate pressure; deep sensation; varied pattern of attacks; “tightness,” “squeezing,” or “crushing”	Persistent, severe pressure; deep sensation; “crushing,” “squeezing,” “heavy,” or “oppressive”; sudden death	
Signs and symptoms			
Pericardial friction rub; increased pain with movement, inspiration, laughing, coughing; increased pain with sitting or leaning forward (sitting up pulls the heart away from the diaphragm)	Dyspnea, diaphoresis, nausea, desire to void, belching, or apprehension	Nausea, vomiting, apprehension, dyspnea, diaphoresis, increased or decreased blood pressure; gallop heart sound, “sensation of impending doom”; chest pressure may fluctuate initially and then become persistent	
Precipitating factors			
Myocardial infarction or upper respiratory tract infection; no relation to effort; cardiac surgery, cardiac tumor, or penetrating chest wound	Exertion, stress, eating, cold or hot and humid weather	Physical exertion or emotional stress; may also occur when person is at rest	

Pulses are best felt where an artery runs near the skin surface and over a hard structure. (See [Interpreting pulse character.](#)) Easily found pulses are the:

- u *radial artery* — at the anterolateral aspect of the wrist
- u *temporal artery* — in front of the ear, above and lateral to the eye
- u *common carotid artery* — at the side of the neck
- u *femoral artery* — in the groin.

The lymphatic system also plays a role in the cardiovascular network. The lymphatic system originates in tissue spaces. It drains fluid and other plasma components that build up in extravascular spaces and reroutes them back to the circulatory system as lymph, a plasmalike fluid. Lymphatics also extract bacteria and foreign bodies.

Cardiovascular assessment

The patient history and physical assessment provide vital information about cardiovascular status. (See [Characterizing chest pain.](#)) When performing the assessment, follow these guidelines:

- u First, observe for general signs of cardiovascular disorders, such as central cyanosis (due to disturbance in gas exchange), edema (due to heart failure or valvular disease), and clubbing (due to congenital cardiovascular disease).
- u Next, palpate the peripheral pulses bilaterally and evaluate their rate, equality, and quality on a scale from 0 (absent) to +4 (bounding). (See [Determining pulse amplitude.](#))
- u Inspect the carotid arteries for distention. Palpate them individually for thrills (fine vibrations due to irregular blood flow), and listen for bruits.

- u Check for pulsations in the jugular veins (more easily seen than felt with tangential light). Watch for jugular vein distention—a possible sign of right-sided heart failure, valvular stenosis, cardiac tamponade, or pulmonary embolism. Take blood pressure readings in both arms while the patient is lying, sitting, and standing.
- u Systematically auscultate the anterior chest wall for each of the four heart sounds in the aortic area (second intercostal space at the right sternal border), pulmonary area (second intercostal space at the left sternal border), right ventricular area (lower half of the left sternal border), and mitral area (fifth intercostal space at the midclavicular line). For low-pitched sounds, use the bell of the stethoscope; for high-pitched sounds, the diaphragm. Inspect for pulsations, and palpate for thrills. Check the location of apical pulsation for deviations in normal size ($\frac{1}{8}$ " to $\frac{1}{4}$ " [1 to 2 cm]) and position (in the mitral area), which are possible signs of left ventricular hypertrophy, left-sided valvular disease, or right ventricular disease.
- u Auscultate for murmurs, the vibrating sound of turbulent blood flow through a stenotic or incompetent valve. Time the murmur to determine where it occurs in the cardiac cycle—between S₁ and S₂ (systolic), between S₂ and the next S₁ (diastolic), or throughout systole (holosystolic). Finally, listen for the scratching or squeaking of a pericardial friction rub.
- u If you hear a rub, determine if it's a pericardial or a pleural friction rub. Have the patient hold his breath while auscultating the anterior chest. If a rub persists while he is holding his breath, the rub is pericardial.

Determining pulse amplitude

To record your patient's pulse amplitude, use this standard scale:

- 0: Pulse isn't palpable.
- +1: Pulse is thready, weak, difficult to find, may fade in and out, and disappears easily with pressure.
- +2: Pulse is constant but not strong; light pressure must be applied or pulse will disappear.
- +3: Pulse considered normal. It's easily palpable and doesn't disappear with pressure.
- +4: Pulse is strong, bounding, and doesn't disappear with pressure.

Special cardiovascular tests

After a thorough history, physical examination, and clinical observation, special tests provide valuable diagnostic information.

Electrocardiography (ECG) is a primary tool for evaluating cardiac status through electrodes placed on the patient's limbs and over the precordium. (See [Positioning chest electrodes](#).) An ECG measures electrical activity by recording currents transmitted by the heart. It's used to detect ischemia, conduction delay, chamber enlargement, injury, necrosis, bundle-branch blocks, fascicular blocks, and arrhythmias. In ambulatory ECG, or Holter monitoring, a tape recording tracks as many as 100,000 cardiac cycles over a 12- or 24-hour period. Sometimes this test is used to determine cardiac status after myocardial infarction (MI), to assess the effectiveness of antiarrhythmic drugs, and to determine if arrhythmias are the cause of particular symptoms.

Chest X-rays may reveal an enlarged heart and aortic dilation. They also are used to assess pulmonary circulation. When pulmonary venous and arterial pressures increase, characteristic changes appear such as dilation of the pulmonary venous shadows. When pulmonary venous pressure exceeds oncotic pressure of the blood, capillary fluid leaks into lung tissues causing pulmonary edema. This fluid may settle in the alveoli, producing a butterfly pattern, or the lungs may appear cloudy or hazy; in the interlobular septa, sharp linear densities (Kerley's lines) may appear.

Exercise testing using a bicycle ergometer, treadmill, or a short flight of stairs can determine cardiac response to physical stress. This type of test is used to measure blood pressure and ECG changes during increasingly rigorous exercises. Myocardial ischemia, abnormal blood pressure response, or arrhythmias indicate failure of the circulatory system to adapt to exercise.

Cardiac catheterization is used to evaluate chest pain, the need for coronary artery surgery or angioplasty, congenital heart defects, and valvular heart disease, and to determine the extent of heart failure.

Right ventricular catheterization involves threading a catheter through a vein into the right ventricle, pulmonary artery, and its branches in the lungs to measure right atrial, right ventricular, pulmonary artery, and pulmonary artery wedge pressures. A pulmonary arterial thermodilution catheter can measure cardiac output.

Left ventricular catheterization entails inserting a catheter into an artery and threading it retrogradely through the aorta into the left ventricle. Ventriculography during left ventricular catheterization involves injecting radiopaque dye into the left ventricle to measure ejection fraction (portion of ventricular volume ejected per beat) and to disclose abnormal heart wall motion or mitral valve incompetence.

In coronary arteriography, radiopaque material injected into coronary arteries allows cineangiocardigraphic visualization of coronary arterial narrowing or occlusion.

Digital subtraction angiography is used to evaluate the coronary arteries, using X-ray images that are digitally subtracted by computer. Time-based color enhancement shows blood flow in nearby areas.

In echocardiography, echoes from pulsed high-frequency sound waves (ultrasound) are used to evaluate structures of the heart. A small transducer placed on the chest wall in various positions and angles acts as both a transmitter and a receiver. It provides information about valve leaflets, sizes and dimensions of heart chambers, and thicknesses and motions of the septum and the ventricular walls.

Echocardiography can also show intracardiac masses (for example, atrial tumors and thrombi), is used to detect pericardial effusion, diagnose hypertrophic cardiomyopathy (also known as idiopathic hypertrophic subaortic stenosis), and estimate cardiac output and ejection fraction. Echocardiography can also be used to evaluate possible aortic dissection when it involves the ascending aorta. Both M-mode and two-dimensional echocardiography exist, but the latter has greater diagnostic abilities.

Doppler echocardiography records blood flow within the cardiovascular system. Color Doppler echocardiography shows the direction of blood flow, which provides information about the degree of valvular insufficiency. Transesophageal echocardiography combines ultrasound with endoscopy to better view the heart's structures. This position allows images to be taken from the heart's posterior aspect.

In multiple-gated acquisition scanning, a radioactive isotope remains in the intravascular compartment, allowing measurement of stroke volume, ventricular ejection fraction, and wall motion. Myocardial imaging uses radioactive agents (most commonly thallium-201) to detect abnormalities in coronary artery perfusion. These agents concentrate in normally perfused myocardium but not in ischemic areas. Nonperfused areas, or “cold spots,” may be permanent (scar tissue after MI) or temporary (induced by transient ischemia). Thallium scanning with exercise tests is used to identify exercise-induced ischemia and evaluate abnormal findings on a stress ECG.

Positioning chest electrodes

To record the 12-lead electrocardiogram, place electrodes on the patient's arms and legs (with the ground lead on the patient's right leg). The three standard limb leads (I, I, and III) and the three augmented leads (aV_R, aV_L, and aV_F) are recorded using these electrodes.

To record the precordial chest leads, place the electrodes as follows:

- u V₁ — fourth intercostal space (ICS), right sternal border
- u V₂ — fourth ICS, left sternal border
- u V₃ — midway between V₂ and V₄
- u V₄ — fifth ICS, left midclavicular line
- u V₅ — fifth ICS, left anterior axillary line
- u V₆ — fifth ICS, left midaxillary line.

Acute infarct imagery or technetium pyrophosphate scanning can be used to document muscle viability (not perfusion). Unlike thallium, technetium accumulates only in irreversibly damaged myocardial tissue. Areas of necrosis appear as “hot spots” and can be detected only with acute infarction. This test can be used to determine the size and location of infarction but can produce false results.

Cardiac enzyme assays confirm acute MI or severe cardiac trauma because these cellular proteins are released into the blood as a result of cell membrane injury. All cardiac enzymes—creatine kinase (CK), lactate dehydrogenase, and aspartate aminotransferase, for example—are also found in other cells, but their numbers peak in the presence of transmural MI. Total CK levels peak 6 to 30 hours after the onset of symptoms. Fractionation of enzymes can be used to determine the source of damaged cells. For example, three fractions of CK are isolated, one of which (an isoenzyme called CK-MB) is found only in myocardial cells. CK-MB in the blood indicates injury to these cells and generally peaks 21 hours after insult.

Peripheral arteriography consists of fluoroscopic imaging after arterial injection of contrast media. Similarly, phlebography defines the venous system after injection of contrast media into a vein. Impedance plethysmography is used to evaluate the venous system by detecting pressure changes transmitted to lower leg veins.

Doppler ultrasonography is used to evaluate the peripheral vascular system and assess arterial occlusive disease.

Endomyocardial biopsy can disclose cardiomyopathy, infiltrative myocardial diseases, and rejection of transplants. Under fluoroscopic control, a right ventricular biopsy is done by way of the right internal jugular vein. Less commonly, a left ventricular biopsy is done by retrograde arterial catheterization.

Electrophysiologic studies are used to help diagnose conduction system disease and serious arrhythmias. Electronic induction and termination of arrhythmias aid drug selection. Endocardial mapping is used to detect an arrhythmia's focus using a finger electrode. Epicardial mapping uses a computer and a fabric sock with electrodes that is slipped over the heart.

Magnetic resonance imaging can be used to evaluate cardiac structure and function. Position emission tomography and magnetic resonance spectroscopy are used to assess myocardial metabolism.

Congenital Defects

Abnormalities during fetal development may cause structural defects of the heart and great arteries. These defects may be acyanotic or cyanotic. Acyanotic defects include atrial and ventricular septal defects, coarctation of the aorta, and patent ductus arteriosus. Cyanotic defects include tetralogy of Fallot and transposition of the great arteries.

ATRIAL SEPTAL DEFECT

In an atrial septal defect, an opening between the left atrium and the right atrium allows blood to shunt between the chambers. (See [Types of atrial septal defects.](#)) Because atrial pressure normally is slightly higher in the left atrium than in the right, blood typically shunts from left to right. The pressure difference may force large amounts of blood through the defect during diastole. If the hole is more than 1⁄8" (1 cm) in diameter, the atria act as a single chamber.

Most infants with an atrial septal defect have no significant left-to-right shunt and no symptoms because during diastole, blood flows toward the ventricular chamber (usually the right), which has thinner, more compliant walls.

Symptoms of left-to-right shunt typically develop in adolescents and young adults because the left ventricle becomes thicker over the years from increased left ventricular end-diastolic pressure. This increased ventricular resistance forces blood through the defect rather than into the ventricles.

An atrial septal defect is found in about 10% of children who have congenital heart disease and who have survived past their first birthday. The disorder is almost twice as common in females as in males and has a strong familial tendency.

Although an atrial septal defect is benign during infancy and childhood, delayed development of signs and symptoms and complications makes it one of the most common congenital heart defects diagnosed in adolescence and adulthood. The prognosis is excellent in asymptomatic people, but poor in those with cyanosis caused by large, untreated defects.

Causes and pathophysiology

The cause of an atrial septal defect is unknown. In this disorder, left-to-right shunt results in right ventricular volume overload, which affects the right atrium, right ventricle, and pulmonary arteries. Eventually, the right atrium enlarges and the right ventricle dilates to accommodate the increased blood volume.

Complications

In some adult patients, fixed (irreversible) pulmonary hypertension causes the shunt to reverse direction; unoxygenated blood enters the systemic circulation, causing cyanosis. Right and left ventricular hypertrophies become significant. Atrial arrhythmias, heart failure, and emboli may occur.

PATHOPHYSIOLOGY

Types of atrial septal defects

Experts recognize three types of atrial septal defects, as shown. These defects can vary in size, but sinus venosus defects tend to be smaller than the others.

Sinus venosus

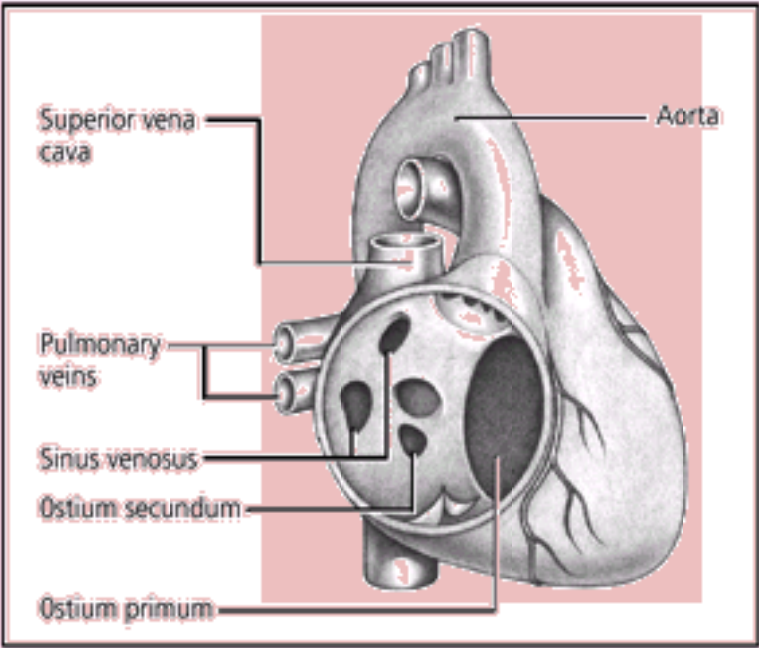

Usually located in the superior-posterior portion of the atrial septum, this defect sometimes extends into the superior vena cava and almost always is associated with abnormalities of the pulmonary veins as they enter the superior vena cava and the right atrium.

Ostium secundum

This defect, which may be single or multiple, is associated with the fossa ovalis and occasionally extends down close to the superior vena cava.

Ostium primum

A defect of the primitive septum, ostium primum occurs in the inferior portion of the septum primum and usually is associated with atrioventricular valve abnormalities (cleft mitral valve) and conduction defects.

Children with an atrial septal defect seldom develop heart failure, pulmonary hypertension, infective endocarditis, or other complications.

Assessment findings

Small defects typically go undetected in a preschooler, although the child may have a history of fatigue, shortness of breath after extreme exertion, and frequent respiratory tract infections.

A large defect may retard a child's growth. Cyanosis may develop, especially if right ventricular outflow is obstructed. Inspection of the jugular vein may reveal a strong pulse preceded by a systolic collapse. Inspection of the chest wall may reveal left chest prominence. An impulse may be palpable in that area.

In children, auscultation may reveal an early to midsystolic murmur, superficial in quality, heard at the second or third left intercostal space. If the patient has a large shunt—the result of increased tricuspid valve flow—you hear a low-pitched diastolic murmur at the lower left sternal border. The murmur becomes more pronounced on inspiration. The intensity of the murmur is a rough indicator of left-to-right shunt size, but its low pitch can make it difficult to hear.

The most diagnostic sounds are a fixed, widely split S₁, (caused by delayed closure of the pulmonic valve) and a systolic click or late systolic murmur at the apex (resulting from mitral valve prolapse, which occasionally affects older children with atrial septal defects).

As adults, many patients with atrial septal defect complain of more pronounced symptoms, such as fatigue and dyspnea on exertion. Symptoms may become severe enough to sharply limit the patient's activities, especially after age 40.

If the patient has a large, uncorrected defect and fixed pulmonary hypertension, auscultation reveals an accentuated S₂ and, possibly, a pulmonary ejection click and an audible S₄. The patient becomes cyanotic and develops clubbed nails; severe pulmonary vascular disease may lead to syncope and hemoptysis.

Diagnostic tests

Chest X-rays show an enlarged right atrium and right ventricle, a prominent pulmonary artery, and increased pulmonary vascular markings. The sinus venosus defect is characterized by an absent right superior vena cava shadow and entrance of the horizontal pulmonary vein into the upper right cardiac shadow.

Electrocardiography results may be normal but usually show right axis deviation, a prolonged PR interval, varying degrees of right bundle-branch block, right ventricular hypertrophy, atrial fibrillation (particularly in severe cases after age 30) and, in ostium primum, left axis deviation.

Echocardiography shows a volume overload on the right side of the heart and is used to measure the right ventricular enlargement. It also may be used to locate the defect and estimate the size and direction of the shunt. (Other causes of right ventricular enlargement must be ruled out.)

Cardiac catheterization can be used to confirm an atrial septal defect by demonstrating that right atrial blood is more oxygenated than superior vena cava blood, which indicates a left-to-right shunt. Catheterization also can be used to determine the degree of shunting and pulmonary vascular disease. Pulmonary artery systolic pressures are usually positive. Dye injection shows the defect's size and location, the location of pulmonary venous drainage, and atrioventricular valve competence. Cardiac catheterization is performed only when the patient's doctor strongly suspects an atrial septal defect but the patient has unusual symptoms.

Treatment

Because an atrial septal defect seldom produces complications in infants and toddlers, surgery may be delayed until they reach preschool or early school age. A large defect may need immediate surgical closure with sutures or a patch graft.

Nursing diagnoses

- u Activity intolerance
- u Decreased cardiac output
- u Fatigue
- u Impaired gas exchange
- u Knowledge deficit
- u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u Cardiac output will remain adequate.
- u The patient will have no arrhythmias.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain hemodynamic stability.
- u The patient will maintain adequate ventilation.

Nursing interventions

- u Encourage the child to engage in any activity he can tolerate. Living as normally as possible is important to avoid illness-dependent behavior patterns.

After surgery:

- u Closely monitor vital signs, central venous and intra-arterial pressures, and intake and output.
- u Watch for atrial arrhythmias.
- u Give antibiotics and analgesics, as ordered.
- u Provide range-of-motion exercises and coughing and deep-breathing exercises.

Patient teaching

- u Before cardiac catheterization, explain pretest and posttest procedures to the patient (and parents, if the patient is a child). If possible, use drawings or other visual aids to help a child understand.
- u If surgery is scheduled, teach the child and his parents about the intensive care unit, and introduce them to the staff. Show parents where they can wait during the operation. Explain postoperative procedures, tubes, dressings, and monitoring equipment.
- u As needed, teach the patient or his family about the importance of antibiotic prophylaxis—especially before routine dental procedures—to prevent infective endocarditis.

COARCTATION OF THE AORTA

This disorder involves a narrowing (coarctation) of the aorta, usually just below the left subclavian artery and near the site where the ligamentum arteriosum joins the pulmonary artery to the aorta. (See [Understanding coarctation of the aorta.](#)) The ligamentum arteriosum is a remnant of a fetal blood vessel called the ductus arteriosus.

Coarctation may be associated with mitral or aortic valve lesions (usually the bicuspid aortic valve) and with severe cases of hypoplasia of the aortic arch, patent ductus arteriosus, or a ventricular septal defect.

This disorder accounts for about 8% of all congenital heart defects in children and is more common in males than in females. When it occurs in females, it commonly is associated with Turner's syndrome, a chromosomal disorder that causes ovarian dysgenesis.

The prognosis for coarctation of the aorta depends on the severity of associated cardiac anomalies. The prognosis is good if the condition can be surgically corrected before it induces severe systemic hypertension or degenerative changes in the aorta.

Causes

Coarctation of the aorta may develop as a result of smooth-muscle spasm and constriction as the ductus arteriosus closes. Contractile tissue may reach into the aortic wall, causing it to narrow.

Complications

Infective endocarditis represents the most common complication. Rarely, patients may develop vascular complications such as cerebrovascular accident, ruptured aorta, and cerebral thrombosis. Untreated, coarctation may lead to left-sided heart failure.

If the patient has a ventricular septal defect and coarctation, blood shunts left to right, straining the right ventricle. This leads to pulmonary hypertension and, eventually, right ventricular hypertrophy and right-sided heart failure.

Assessment findings

An infant with coarctation may appear normal for up to 3 weeks after birth before signs and symptoms of left-sided heart failure begin to surface. The infant may develop tachypnea, dyspnea, tachycardia, and pallor tinged with cyanosis. He also may exhibit signs of failure to thrive, such as inadequate weight gain.

Palpation may reveal an enlarged heart and liver and absent or diminished femoral pulses.

Auscultation may disclose normal heart sounds or a narrowly split second sound with a loud pulmonary component. You may hear a third heart sound at the apex, possibly prolonged into a diastolic rumble. You may also hear an apical systolic blowing murmur that results from mitral incompetence. You may also hear a loud stenotic murmur over the spine (from the coarctation), or at the second right intercostal space or suprasternal notch (from associated aortic valve disease).

Patients with coarctation may remain asymptomatic until adolescence because collateral circulation develops to bypass the narrowed segment. During adolescence, however, the defect may cause signs and symptoms despite the collateral circulation. Signs and symptoms include dyspnea, muscle cramps after exercise, coolness in the lower extremities, headaches, epistaxis, and hypertension in the upper extremities.

Patients typically have resting systolic hypertension and wide pulse pressure. You find high diastolic pressure readings that are the same in both the arms and the legs. Coarctation may also produce a visible aortic pulsation in the suprasternal notch, a continuous systolic murmur, an accentuated S₂, and an S₄.

Diagnostic tests

Chest X-rays may show left ventricular hypertrophy, left-sided heart failure, a wide ascending and descending aorta, and notching of the undersurfaces of the ribs, caused by extensive collateral circulation.

PREVENTION

Understanding coarctation of the aorta

Normal fetal circulation includes three shunts that bypass the fetus's liver and lungs. One of these shunts is called the ductus arteriosus; it connects the pulmonary artery with the aorta.

Most of the blood entering the main pulmonary artery bypasses the lungs and flows directly into the aorta through the ductus arteriosus.

After birth, when the neonate's lungs must function on their own, the ductus arteriosus closes, and the right ventricular output enters the left ventricle through the pulmonary capillaries, as it does in normal adult circulation.

If the ductus arteriosus closes improperly, coarctation may be the result.

By restricting blood flow, this abnormal constriction increases pressure on the left ventricle so much that it may fail, causing increased end-diastolic and pulmonary artery pressures, pulmonary edema, a low output state and, possibly, sudden circulatory collapse. Restricted flow also increases the pressure load on the left ventricle, dilates the proximal aorta, and causes ventricular hypertrophy.

To compensate for the increased pressure, collateral circulation may develop to circumvent the narrowed aorta.

Magnetic resonance imaging or digital angiography allows visualization of the length and severity of the obstruction and the extent of collateral circulation.

Electrocardiography may initially show right ventricular hypertrophy and left-sided heart failure. If the coarctation isn't repaired, this test eventually shows left ventricular hypertrophy and a right axis deviation.

Echocardiography may disclose increased left ventricular muscle thickness, coexisting abnormalities, and the coarctation site.

Cardiac catheterization allows evaluation of collateral circulation and measurement of pressure in the right and left ventricles and the ascending and descending aortas (on both sides of the obstruction). When combined with aortography, catheterization can be used to locate the site and extent of coarctation. This procedure is performed only to identify associated abnormalities in infants with left-sided heart failure.

Treatment

For an infant with left-sided heart failure caused by coarctation of the aorta, treatment consists of medical management with prostaglandins, diuretics, and digoxin. Although most patients require surgery, the timing may be debatable. Most doctors recommend that surgery be done early. The procedure may involve end-to-end anastomosis or subclavian flap angioplasty. If the narrowed segment is long, the doctor may use a tubular graft, patch, or bypass conduit.

Nursing diagnoses

u Activity intolerance u Altered parenting u Decreased cardiac output u Fatigue u Knowledge deficit u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will maintain hemodynamic stability.
- u Cardiac output will remain adequate.
- u The patient will have no arrhythmias.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u When coarctation in an infant requires rapid digitalization, monitor his vital signs closely, and watch for signs of digitalis toxicity (such as poor feeding and vomiting).
- u Balance intake and output carefully, especially if the infant is receiving diuretics and restricted fluids.
- u If the infant can't maintain the proper body temperature, regulate environmental temperature with an overbed warmer.
- u Monitor blood glucose levels to detect possible hypoglycemia, which may develop as glycogen stores decline.

After corrective surgery:

- u Monitor blood pressure closely, using an intra-arterial line. Take pressures on all extremities.
- u Monitor fluid intake and output.
- u If the patient develops hypertension and requires nitroprusside or trimethaphan, administer it as ordered by continuous I.V. infusion. Use an infusion pump. Watch for severe hypotension, and regulate the dosage carefully.
- u Check blood cyanide levels if the patient requires sustained nitroprusside therapy.
- u Provide pain relief, and encourage a gradual increase in activity.
- u Offer the parents emotional support.

Patient teaching

- u Explain the disorder and appropriate diagnostic procedures and treatments. Tell parents what to expect after the surgery.

- u For an older child, assess blood pressure in his extremities regularly, explain any exercise restrictions, and teach the family how to use blood pressure equipment for home monitoring.
- u If an older child needs to continue antihypertensives after surgery, teach him and his parents about them. Stress the need to take medications properly and to watch for adverse reactions.
- u Stress the importance of continued endocarditis prophylaxis.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a blood vessel that connects the pulmonary artery to the descending aorta during fetal development. Normally, the ductus closes within days or weeks after birth. Its closure routes oxygenated blood to the body and unoxygenated blood to the lungs.

In patent ductus arteriosus, the lumen of the ductus remains open after birth. (See [Understanding patent ductus arteriosus.](#)) This abnormal opening allows blood to shunt left to right from the aorta to the pulmonary artery. The result is recirculation of oxygenated arterial blood through the lungs.

The amount of blood shunted through the ductus depends on the relative resistances of pulmonary and systemic vasculature and on the size of the ductus itself. The left atrium and left ventricle must accommodate increased pulmonary venous return, which increases the left ventricular filling pressure and work load and could lead to left-sided heart failure.

Patent ductus arteriosus typically affects twice as many females as males. When it occurs with rubella, however, it affects both sexes in equal numbers. It's the most common congenital heart defect in adults; symptoms of pulmonary vascular disease appear by age 40. The prognosis is good if the shunt is small or can be surgically repaired.

Causes

Failure of the ductus to close—most prevalent in premature infants and those born at high altitudes—probably stems from abnormal oxygenation or from the relaxant action of prostaglandin E, which prevents the ductal spasm and contracture needed for closure. Patent ductus arteriosus may be familial or have no known cause. It commonly accompanies rubella syndrome and may be associated with other congenital defects, such as coarctation of the aorta, a ventricular septal defect, and pulmonic and aortic stenoses.

Complications

In its final stages, untreated patent ductus arteriosus may advance to intractable—possibly fatal—left-sided heart failure. The left-to-right shunt leads to chronic pulmonary artery hypertension that becomes fixed and unresponsive. Children typically experience respiratory distress.

Assessment findings

Inspection may reveal a very slender infant, possibly with signs of failure to thrive, slow motor development, and a left chest deformity. An infant with a large shunt (especially a premature infant) may have dyspnea, tachycardia, edema, and other signs of left-sided heart failure from the large volume of blood shunted to the lungs and the increased left ventricular workload.

Most children with patent ductus arteriosus have only cardiac signs and symptoms. However, some may be physically underdeveloped, tire easily, and have a history of frequent respiratory tract infections.

An adult with undetected patent ductus arteriosus typically presents with signs and symptoms of pulmonary vascular disease and, by age 40, may tire easily and complain of dyspnea on exertion. About 1 in 10 adults may have signs of infective endocarditis.

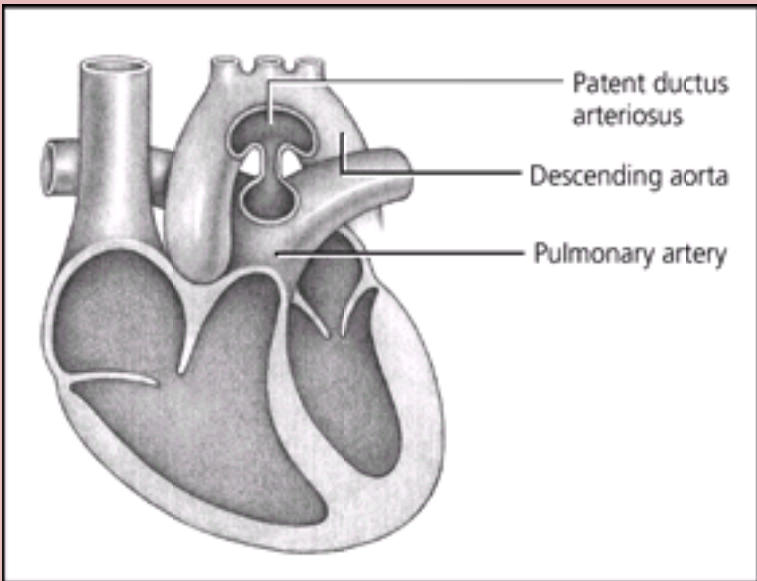

In nearly all children with this anomaly, auscultation reveals the classic machinery murmur (Gibson murmur), best heard at the base of the heart, second left intercostal space under the left clavicle. (See [Auscultating for patent ductus arteriosus.](#))

PATHOPHYSIOLOGY

Understanding patent ductus arteriosus

This anomaly occurs when the ductus arteriosus—a tubular connection that shunts blood away from the fetus's pulmonary circulation—fails to close after birth. Blood then shunts from the aorta to the pulmonary artery.

Patent ductus arteriosus
Descending aorta
Pulmonary artery

Palpation may reveal a thrill at the left sternal border and a prominent left ventricular impulse. Peripheral arterial pulses are bounding (Corrigan's pulse). Pulse pressure widens from an increase in systolic blood pressure and also from a drop in diastolic pressure.

Diagnostic tests

Chest X-rays show increased pulmonary vascular markings, prominent pulmonary arteries, and enlargement of the left ventricle and the aorta. Results vary with the size of the shunt.

Electrocardiography (ECG) results may be normal or may indicate left ventricular hypertrophy, left atrial enlargement and, in pulmonary vascular disease, biventricular hypertrophy.

Echocardiography can be used to detect and estimate the size of a shunt. It also reveals an enlarged left atrium and left ventricle, or right ventricular hypertrophy from

pulmonary vascular disease.

Cardiac catheterization shows pulmonary arterial oxygen content greater than the right ventricular content because of the influx of aortic blood. Increased pulmonary artery pressure indicates a large shunt or, if it exceeds systemic arterial pressure, severe pulmonary vascular disease. Catheterization allows calculation of the blood volume crossing the ductus and can be used to rule out associated cardiac defects. Dye injection definitively demonstrates patent ductus arteriosus. This test isn't used routinely to diagnose this disorder because of the risk involved.

Auscultating for patent ductus arteriosus

To detect patent ductus arteriosus, auscultate the base of the heart at the second left intercostal space under the left clavicle. You hear systolic clicks (C) and a continuous murmur during systole and diastole, not necessarily through the entire cycle but through the second sound in a crescendo-decrescendo manner, as shown below.

NORMAL

PATENT DUCTUS ARTERIOSUS

Treatment

Asymptomatic infants require no immediate treatment. Those with left-sided heart failure require fluid restriction, diuretics, and digitalis glycosides until surgery can be performed. If signs and symptoms are mild, surgical correction is usually delayed until the infant is 1 year old. Before surgery, the child requires antibiotics to protect against infective endocarditis. Experimental treatments include cardiac catheterization to deposit a plug or umbrella in the ductus, or administration of indomethacin I.V. to induce the ductus to spasm and close.

Nursing diagnoses

- u Activity intolerance
- u Altered growth and development
- u Altered parenting
- u Altered tissue perfusion (cardiopulmonary)
- u Decreased cardiac output
- u Fatigue
- u Impaired gas exchange
- u Ineffective breathing pattern
- u Knowledge deficit
- u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.
- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to ensure adaptive coping behaviors.
- u The patient will maintain hemodynamic stability.
- u Cardiac output will remain adequate.
- u The patient will have no arrhythmias.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will exhibit no further weight loss.

Nursing interventions

- u Watch carefully for signs of patent ductus arteriosus in all premature infants. Be alert for respiratory distress symptoms that stem from left-sided heart failure; they may develop rapidly in a premature infant.
- u Frequently assess vital signs, ECG tracings, serum electrolyte levels, and fluid intake and output. Record the infant's response to diuretics and other therapy. Watch for signs of digitalis toxicity (such as poor feeding and vomiting).
- u Ensure that the infant receives adequate nutrition to optimize growth and development.
- u If the infant receives indomethacin to help close the ductus, watch for possible adverse reactions to the drug, such as diarrhea, jaundice, bleeding, and renal dysfunction.
- u Before surgery, carefully explain all treatments and tests to the parents. Include the child in your explanations, if possible. Arrange for the child and the parents to meet the intensive care unit staff. Tell them about expected I.V. lines, monitoring equipment, and postoperative procedures.
- u Immediately after surgery, the child may have a central venous pressure catheter and an arterial line in place. Carefully assess vital signs, fluid intake and output, and arterial and venous pressures. Provide pain relief as needed.

Patient teaching

- u Before discharge, review what you've told the parents about activity restrictions based on the child's tolerance and energy levels. Advise parents not to become overprotective as their child's tolerance for physical activity increases.
- u Stress the need for regular medical follow-up examinations. Tell the parents to inform any doctor who treats their child about his history of surgery for patent ductus arteriosus—even if the child is being treated for an unrelated medical problem.
- u Teach the parents the importance of prophylactic antibiotics to reduce the child's risk of bacterial endocarditis.
- u Urge the parents to seek medical attention whenever their child develops signs of infection, such as a sore throat, a cold, the flu, or an earache.

TETRALOGY OF FALLOT

This cardiac defect is really four defects that occur together: a ventricular septal defect, infundibular stenosis (possibly with pulmonic valve stenosis), right ventricular hypertrophy, and dextroposition of the aorta, which overrides the ventricular septal defect. (See [Defects in tetralogy of Fallot.](#))

The degree of pulmonic stenosis and the size and location of the ventricular septal defect determine the clinical and hemodynamic effects of this complex anomaly. Blood may shunt left to right or right to left, depending on the defect's configuration.

Usually, the ventricular septal defect lies in the outflow tract of the right ventricle and is large enough to equalize right and left ventricular pressures. However, the ratio of systemic vascular resistance to pulmonic stenosis affects how much blood flows across the defect and the direction in which it flows.

When blood shunts right to left through the ventricular septal defect, unoxygenated blood mixes with oxygenated blood, which leads to cyanosis.

When right ventricular outflow is severely obstructed, blood flows right to left, which decreases arterial oxygen saturation (S_{aO_2}) and leads to cyanosis, reduced pulmonary blood flow, and hypoplasia of all the pulmonary vessels. Increased right ventricular pressure causes right ventricular hypertrophy.

Milder forms of pulmonic stenosis result in a left-to-right shunt or no shunt at all.

About 15% of infants born with a congenital heart defect have tetralogy of Fallot. It's equally common in males and females. Sometimes it coexists with other congenital heart defects, such as patent ductus arteriosus or an atrial septal defect. Before surgical techniques were available to correct this defect, about one-third of affected children died in infancy.

PATHOPHYSIOLOGY

Defects in tetralogy of Fallot

This four-part complex includes a ventricular septal defect, an overriding (dextroposition of) aorta, infundibular pulmonic stenosis, and right ventricular hypertrophy. The severity of these defects influences hemodynamic changes. Milder defects may produce a left-to-right shunt. More severe defects produce a right-to-left shunt, through which unoxygenated blood directly enters the aorta.

Causes

Tetralogy of Fallot stems from embryonic hypoplasia of the right ventricle's outflow tract. No one knows what causes that hypoplasia. However, the defect has been associated with fetal alcohol syndrome and maternal ingestion of thalidomide during pregnancy.

Complications

Patients with tetralogy of Fallot risk developing cerebral abscess, pulmonary thrombosis, venous thrombosis or cerebral embolism, and infective endocarditis.

Affected females who live to childbearing age face an increased incidence of spontaneous abortion and premature birth and are more likely to have infants with low birth weights.

Assessment findings

Cyanosis is a hallmark of this defect. It usually becomes evident within a few months after birth, but it may be present at birth if the infant has severe pulmonic stenosis.

Infants who normally appear pink may have hypercyanotic spells when they cry. They also may have tachycardia, tachypnea, dyspnea and, possibly, a period of unconsciousness or seizures.

After about age 3 months, inspection may reveal clubbing of the fingers and toes.

Older children may experience varying degrees of exercise intolerance and cyanosis, dyspnea on exertion, growth retardation, and eating difficulties. They commonly assume a squatting position after exercise such as walking or running. Signs and symptoms probably result from increased right-to-left shunting caused by spasm of the right ventricular outflow tract, increased systemic venous return, or decreased systemic arterial resistance.

Auscultation may detect an apical click, a loud (grade 4 to 6) systolic murmur (best heard along the left sternal border), which may diminish or obscure the pulmonary component of S_2 . In a patient who also has a large patent ductus, the continuous murmur of the ductus obscures the systolic murmur.

Palpation may reveal an obvious right ventricular impulse and a systolic thrill at the left sternal border that transmits to the suprasternal notch but not usually to the carotids. The inferior sternum appears prominent.

Diagnostic tests

Chest X-rays may demonstrate normal or decreased pulmonary vascular markings, depending on the severity of the pulmonary obstruction. They also may reveal a large aorta and a normal-sized heart with right ventricular enlargement in the lateral view. This configuration gives the cardiac silhouette a boot-shaped appearance. The main pulmonary artery segment on the left border of the heart may be diminished or have a concave appearance.

Electrocardiography shows right ventricular hypertrophy with upright T waves in the right chest leads. These results are commonly associated with peaked P waves, right axis deviation and, possibly, right atrial hypertrophy.

Echocardiography identifies a septal override of the aorta, the ventricular septal defect, and infundibular pulmonic stenosis. It also reveals the right ventricle's hypertrophied walls.

Laboratory tests reveal diminished Sao₂ and polycythemia (hematocrit may be more than 60%) if the cyanosis is severe and long-standing. This condition predisposes the patient to thrombosis.

Cardiac catheterization can be used to confirm the diagnosis by displaying pulmonic stenosis, the ventricular septal defect, and the overriding aorta. It also can be used to rule out other cyanotic heart defects and to measure the degree of oxygen saturation in aortic blood.

Treatment

During cyanotic spells, oxygenation improves if the patient assumes the knee-chest position and receives oxygen and morphine. Propranolol may prevent cyanotic episodes. Surgery that joins the subclavian artery to the pulmonary artery (Blalock-Taussig operation) may enhance blood flow to the lungs, reducing hypoxia.

Supportive measures include antibiotics administered before, during, and after dental treatments or surgery. Phlebotomy may also be needed in children with polycythemia.

Surgery to relieve pulmonic stenosis and close the ventricular septal defect requires cardiopulmonary bypass with hypothermia (to decrease oxygen utilization during surgery, especially in young children). Surgery is necessary when progressive hypoxia and polycythemia impair the patient's quality of life, usually before age 2.

Nursing diagnoses

- u Altered growth and development
- u Altered parenting
- u Decreased cardiac output
- u Impaired gas exchange
- u Ineffective family coping: Disabling

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient will maintain hemodynamic stability and adequate cardiac output and will exhibit no arrhythmias.

Nursing interventions

- u Because of the right-to-left shunt through the ventricular septal defect, treat I.V. lines like arterial lines. A clot dislodged from a catheter tip in a vein can cross the shunt and cause cerebral embolism. The same thing can happen if air enters the venous lines.
- u Allow parents time to grieve when they learn of their child's diagnosis. Encourage them to discuss their concerns and feelings. Help them to deal with guilt if they experience it.
- u Encourage parent-child bonding as much as possible.

After surgery:

- u If the child has undergone the Blalock-Taussig operation, don't use the arm on the operative side for measuring blood pressure, inserting I.V. lines, or drawing blood samples. Blood perfusion on that side diminishes greatly until collateral circulation develops. Note this restriction on the child's chart and at his bedside.
- u Watch for right bundle-branch block or more serious disturbances of atrioventricular (AV) conduction and for ventricular ectopic beats.
- u Be alert for other postoperative complications, such as bleeding, left-sided heart failure, and respiratory failure. Transient left-sided heart failure is common and may require treatment with digoxin and diuretics.
- u Monitor left atrial pressure directly. A pulmonary artery catheter may be used to check central venous and pulmonary artery pressures.
- u Check color and vital signs frequently. Obtain arterial blood gas measurements regularly to assess oxygenation. Suction as needed to prevent atelectasis and pneumonia. Monitor mechanical ventilation.
- u Monitor and record intake and output accurately.
- u If AV block develops with a low heart rate, a temporary external pacemaker may be necessary.
- u For inadequate blood pressure or cardiac output, administer catecholamines as ordered by continuous I.V. infusion.
- u To decrease left ventricular workload, administer nitroprusside as ordered.
- u Provide analgesics as needed.
- u Keep the parents informed about their child's progress.

Patient teaching

- u Explain tetralogy of Fallot to the parents. Inform them that their child will set his own exercise limits and know when to rest. Make sure they understand that their child can engage in physical activity. Advise them not to be overprotective.
- u Repeat your teaching information, if necessary, because learning is difficult in times of great stress.
- u Teach the parents to recognize serious hypoxic spells, which can cause dramatically increased cyanosis; deep, sighing respirations; and loss of consciousness. Tell them to report such spells immediately. Emergency treatment may be necessary
- u After discharge, the child may require digoxin, diuretics, and other drugs. Stress the importance of complying with the prescribed regimen, and make sure the parents know how and when to administer the medications.
- u Teach the parents to watch for signs of digitalis toxicity (such as anorexia, nausea, or vomiting).
- u To prevent infective endocarditis and other infections, warn the parents to keep their child away from people with known infections. Urge them to encourage good dental hygiene, and tell them to watch for ear, nose, and throat infections and dental caries, all of which necessitate immediate treatment. The child requires prophylactic antibiotics, so tell parents to make sure that the child completes the prescribed regimen.
- u If the child requires medical attention for an unrelated problem, tell parents to inform the doctor immediately of the child's history of tetralogy of Fallot. This defect must be taken into consideration before any treatment is initiated.

TRANSPOSITION OF THE GREAT ARTERIES

In this congenital heart defect, the aorta and the pulmonary artery—known as the great vessels—are reversed from their normal positions. (See [Understanding transposition of the great arteries](#).) The aorta arises from the right ventricle, and the pulmonary artery from the left ventricle. This arrangement produces two circulatory systems (pulmonary and systemic). Oxygenated blood entering the left side of the heart returns to the lungs by the transposed pulmonary artery. Unxygenated blood entering the right side of the heart returns to systemic circulation by the transposed aorta.

The two circulatory systems communicate somewhat only because of additional cardiac defects. In infants who have a condition called isolated transposition, oxygenated and unxygenated blood mix slightly at the patent foramen ovale and the patent ductus arteriosus. In infants with other cardiac defects, blood may mix to a greater degree.

Transposition accounts for up to 5% of all congenital heart defects and commonly coexists with other congenital heart defects, such as a ventricular septal defect with or without pulmonic stenosis, an atrial septal defect, and patent ductus arteriosus. Transposition is two to three times more common in males than in females.

PATHOPHYSIOLOGY

Understanding transposition of the great arteries

In this anomaly, the aorta arises from the right ventricle and the pulmonary artery from the left ventricle, preventing the pulmonary and systemic circulations from mixing. Without associated defects that allow these circulatory systems to mix—such as patent ductus arteriosus or a septal defect—the neonate dies.

Causes

Transposition of the great arteries results from faulty embryonic development, but the cause is unknown.

Complications

Serious complications may include chronic heart failure, poor oxygenation, arrhythmias, and right-sided heart failure.

Assessment findings

Within a few hours of birth, neonates with transposition of the great arteries and no other heart defects typically develop cyanosis and tachypnea that worsen with crying. After several days or weeks, such infants usually develop signs of heart failure (gallop rhythm, tachycardia, dyspnea, hepatomegaly, and cardiomegaly).

S₂ is louder than normal because the aorta is transposed in an anterior direction and lies just behind the sternum. Usually, however, no murmur can be heard during the first few days after birth. Associated defects (a ventricular septal defect, an atrial septal defect, or patent ductus arteriosus) cause their typical murmurs and may reduce cyanosis. However, they may cause other complications (especially severe heart failure). A ventricular septal defect with pulmonic stenosis produces a characteristic murmur and severe cyanosis.

As infants with this defect mature, cyanosis becomes their most prominent abnormality. However, they also develop exercise intolerance, fatigue, coughing, clubbing of the fingers, and—if they have a septal defect, patent ductus arteriosus, or pulmonic stenosis—more pronounced murmurs.

Diagnostic tests

Chest X-rays are normal in the first days after birth. Within days or weeks, however, right atrial and right ventricular enlargement cause the heart to take on a characteristic egg shape. X-rays also reveal a narrow mediastinum and increased pulmonary vascular markings except when the infant also has pulmonic stenosis.

Electrocardiography typically reveals right axis deviation and right ventricular hypertrophy, but results may be normal in a neonate.

Echocardiography displays the reversed positions of the aorta and the pulmonary artery. Because of aortic valve displacement, it also records simultaneous echoes from the semilunar valves. It may also reveal other cardiac defects.

Cardiac catheterization reveals decreased oxygen saturation in left ventricular blood and aortic blood; increased right atrial, right ventricular, and pulmonary artery oxygen saturation; and right ventricular systolic pressure equal to systemic pressure. Dye injection shows the transposed arteries and any other cardiac defects.

Arterial blood gas (ABG) measurements indicate hypoxia and secondary metabolic acidosis.

Treatment

An infant with transposition of the great arteries may undergo atrial balloon septostomy (Rashkind procedure) during cardiac catheterization. This procedure enlarges the patent foramen ovale, which improves oxygenation by allowing more of the pulmonary and systemic blood to mix. Afterward, digoxin and diuretics can reduce the degree of heart failure until the infant can withstand corrective surgery (usually before age 1).

The most effective way to correct transposition is through surgery. In the *Mustard procedure* the atrial septum is replaced with a Dacron or pericardial partition or baffle that channels systemic venous blood to the pulmonary artery. The pulmonary artery then carries the blood to the lungs for oxygenation. Oxygenated blood returning to the heart is channeled into the aorta. In the *Senning procedure*, the same result is accomplished by using the atrial septum to create partitions that redirect blood flow. In the arterial switch, or *Jantene procedure*, the transposed arteries are anastomosed to the correct ventricles.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.
- u The patient will maintain hemodynamic stability.
- u Cardiac output will remain adequate.
- u The patient will have no arrhythmias.
- u The patient will avoid complications of excess fluid.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Explain cardiac catheterization and all necessary procedures to the parents. Offer them emotional support.

- u Monitor the patient's vital signs, ABG measurements, urine output, and central venous pressure. Watch for signs of heart failure. Give digoxin and I.V. fluids as ordered, being careful to avoid fluid overload.
- u Before corrective surgery, monitor ABG measurements, acid-base balance, intake and output, and vital signs.

After corrective surgery:

- u Monitor cardiac output by checking blood pressure, skin color, heart rate, urine output, central venous and left atrial pressures, and level of consciousness. Notify the doctor of abnormalities or changes.
- u Monitor ABG measurements.
- u Monitor the patient closely for supraventricular conduction blocks and arrhythmias. Watch for signs of atrioventricular blocks, atrial arrhythmias, and faulty sinoatrial function.
- u After the Mustard or Senning procedure, watch for signs of baffle obstruction, such as marked facial edema.

Patient teaching

- u Teach the parents to recognize signs of heart failure and digoxin toxicity (such as poor feeding and vomiting). Stress the importance of regular checkups to monitor cardiovascular status.
- u Teach the parents to protect their infant from infection and to give prophylactic antibiotics.
- u Tell the parents to let their child develop normally. They need not restrict activities; he'll set his own limits.
- u If the patient is scheduled for surgery, explain the procedure to the parents (and the child, if he is old enough). Teach them about the intensive care unit, and introduce them to the staff. Also explain postoperative care.
- u Encourage the parents to help their child assume new activity levels and become independent. Teach them about postoperative antibiotic prophylaxis for infective endocarditis.

VENTRICULAR SEPTAL DEFECT

Ventricular septal defect—the most common congenital heart disorder—is an abnormal opening in the ventricular septum that allows blood to escape from the left ventricle into the right. The result is that oxygenated blood returns to the lungs instead of moving into the aortic arch, as it should.

A ventricular septal defect may be large or small and may involve one hole or several holes in any part of the septum. Sometimes, the entire septum may be missing, which creates a single chamber. The amount of blood shunted between ventricles depends on the size of the defect and the amount of pulmonary and systemic resistance. (See [Types of ventricular septal defects.](#))

Up to 30% of smaller defects and 12% of larger ones close without treatment within a year after birth. Those that do—or those that are corrected surgically—have a good prognosis. Untreated defects that don't close on their own can be fatal during the first year after birth, usually due to secondary complications.

PATHOPHYSIOLOGY

Types of ventricular septal defects

The names for ventricular septal defects correspond to their anatomic locations, as shown. Defects of different types may appear together or converge.

Subpulmonic defects

These defects are located in the right ventricular outflow. Viewed from the left ventricle, they appear just below the aortic valve.

Membranous or perimembranous defects

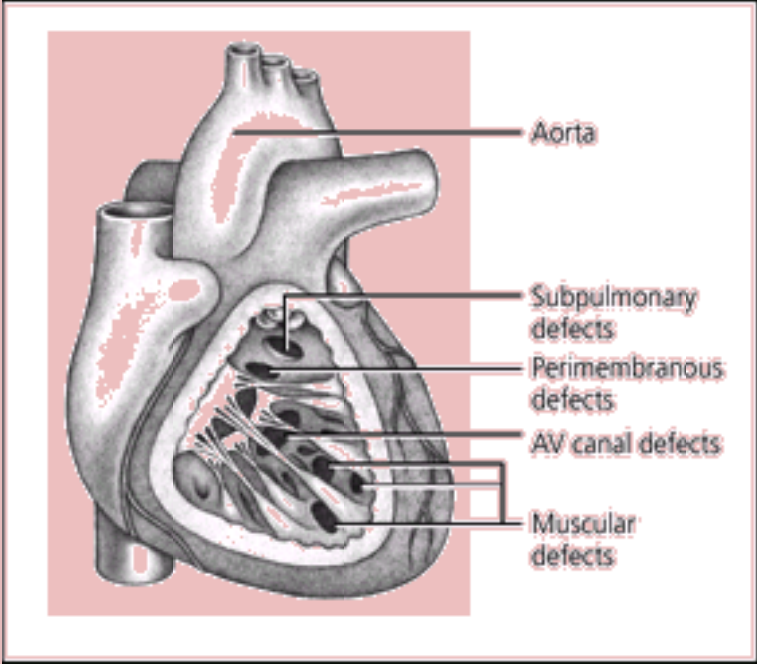

When viewed from either ventricle, these defects involve the subaortic region of the membranous septum. Some experts use the term perimembranous because this type of defect may not be confined to the membranous septum.

Atrioventricular (AV) canal defects

These defects appear in the inflow of the right ventricle.

Muscular defects

Defects in the lower trabecular septum are known as muscular defects and more specifically as apical, midmuscular, anterior, and posterior defects. A large apical muscular defect may look like a single hole when viewed from the left ventricle but have a “swiss cheese” appearance when viewed from the right ventricle. Right ventricular trabeculations cause this defect by partially covering the defect.

Causes and pathophysiology

Normally, the ventricular septum closes by the 6th week of gestation. However, in about 200 of 100,000 neonates, the septum fails to close, resulting in a ventricular septal defect. The condition may not be obvious right away because right and left ventricular pressures are nearly equal at birth (so blood doesn't shunt through the defect). However, 4 to 8 weeks after birth, pulmonary vessels gradually relax and right ventricular pressure decreases. Blood begins to shunt and symptoms arise.

Although no one knows what causes a ventricular septal defect, genetic and environmental factors may influence its development. Fetal alcohol syndrome may play a role. Although most children with congenital heart defects are otherwise normal, those with a ventricular septal defect may have other birth defects. These include Down syndrome and other autosomal trisomies, renal anomalies, and such cardiac defects as patent ductus arteriosus and coarctation of the aorta.

Complications

Pulmonary resistance increases because of the increased volume of blood being pumped to the lungs. Left-to-right shunting and increased pressure in the right ventricle cause hypertrophy, which causes the right atrium to enlarge as it works against the right ventricular resistance. The patient may develop heart failure and pulmonary hypertension.

Assessment findings

The clinical features of a ventricular septal defect vary with the defect's size, the effect of shunting on pulmonary vasculature, and the patient's age.

An infant with a small defect usually appears normal and has no sternal or costal retractions because a small defect allows little shunting, so pulmonary artery pressure and heart size remain normal. Auscultation reveals a loud murmur, usually loudest at the lower left sternal border and occurring within the first week after birth. Tachypnea of more than 60 breaths/minute may indicate mild heart failure.

An infant with a large defect typically appears thin, small, restless, and irritable. He gains weight slowly and may have a history of feeding problems. With a moderate or large defect, auscultation typically reveals a pansystolic murmur—loudest at the lower left sternal border, fourth intercostal space—and usually produces a thrill. Also, the pulmonary component of S₂ sounds loud and is widely split.

An untreated ventricular septal defect that has progressed to heart failure reveal tachycardia and an S₃ gallop rhythm that can be heard at the apex. An infant with heart failure appears dusky and diaphoretic. You may see sternal and costal retractions during inspiration (particularly if the infant has pneumonia or atelectasis, or if he's aspirated something). The respiratory rate is rapid, and the infant has grunting respirations. Auscultation of the lung fields reveals crackles and gurgles. Palpation reveals that the point of maximal impulse has been displaced to the left. The liver, heart, and spleen enlarge as a result of systemic venous congestion.

With advanced heart failure and cardiac hypertrophy, you see cyanosis and, possibly, anterior chest wall prominence.

The older patient may display signs of fixed pulmonary hypertension, which can occur much later in life with right-to-left shunt (a condition called Eisenmenger's complex). These signs include cyanosis and clubbing of the nail beds. Auscultation may reveal a diastolic murmur, a quieter systolic murmur, and a greatly accentuated S₂.

Diagnostic tests

Chest X-ray results are normal if the patient has a small defect; for a large defect, chest X-rays reveal cardiomegaly, left atrial and left ventricular enlargement, and prominent pulmonary vascular markings.

Electrocardiography results are normal for a small defect but show left and right ventricular hypertrophy (which suggests pulmonary hypertension) for a large defect. Large defects generate a right axis shift.

Echocardiography may reveal a large defect and its location in the septum, estimate the degree of a left-to-right shunt, suggest pulmonary hypertension, and identify associated lesions and complications.

Cardiac catheterization may be used to determine the size and location of the defect, to calculate the degree of shunting by comparing blood oxygen saturation between ventricles, to determine the extent of pulmonary hypertension, and to detect associated defects.

Treatment

Only about 15% of small defects in infants require surgical correction. Infants who don't require surgery may receive an antibiotic to prevent bacterial endocarditis.

For an infant with a large defect, treatment focuses on managing heart failure and improving growth. Specifically, the infant may receive digoxin, diuretics, a sodium-restricted diet, and nutritional supplements. If this regimen is effective, surgery may be delayed to give the defect time to shrink or close on its own. Surgery for large defects usually requires insertion of a patch graft, usually through the tricuspid valve, with the patient on cardiopulmonary bypass. If the child has other defects and may benefit from delaying surgery, the doctor may band the pulmonary artery. This procedure normalizes pressures and blood flow distal to the band and prevents pulmonary vascular disease.

Usually, postoperative treatment includes mechanical ventilation, analgesics, diuretics to increase urine output, continuous infusion of nitroprusside or adrenergic agents to regulate blood pressure and cardiac output and, in rare cases, a temporary pacemaker.

Nursing diagnoses

u Activity intolerance u Altered growth and development u Altered nutrition: Less than body requirements u Altered parenting u Decreased cardiac output u Impaired gas exchange u Ineffective family coping: Disabling u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.
- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will maintain hemodynamic status.
- u Cardiac output will remain adequate.
- u The patient will have no arrhythmias.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will exhibit no further weight loss.

Nursing interventions

- u Administer ordered medications to the infant and monitor for adverse effects.
- u Provide adequate nutrition. If the infant tires easily during feeding, he may need to be fed through a nasogastric tube.
- u Monitor for signs of heart failure, and administer symptomatic treatment as ordered.
- u Encourage activity as tolerated.
- u Recognize that the parents may have difficulty coping with the child's illness because of anxiety or economic problems. Assist the parents in identifying areas of concern and refer them to social service agencies as needed.

After surgery:

- u Monitor vital signs and intake and output. Maintain the infant's body temperature with an overbed warmer. Give catecholamines, nitroprusside, and diuretics as ordered. Give analgesics as needed. Record the effectiveness of all medications given.
- u Monitor central venous pressure, intra-arterial blood pressure, and left atrial or pulmonary artery pressure readings. Check heart rate and rhythm for signs of conduction block.
- u Assess oxygenation, particularly in a child who requires mechanical ventilation. Suction as needed to maintain a patent airway and to prevent atelectasis and pneumonia.
- u Monitor pacemaker effectiveness, if needed. Watch for signs of failure, such as bradycardia and hypotension.

Patient teaching

- u Explain all tests thoroughly.
- u Instruct the parents to watch for signs of heart failure, such as poor feeding, sweating, and heavy breathing.
- u If the child is receiving digoxin or other medications, teach the parents how to give them and how to recognize adverse reactions. Caution them to keep medications out of the reach of all children.
- u Teach the parents to recognize and report early signs of infection and to avoid exposing the child to people with obvious infections.
- u Encourage the parents to let the child engage in normal activities as much as possible.
- u Stress the importance of prophylactic antibiotics before and after surgery.
- u Reassure the parents, and allow them to participate in their child's care.

Cardiac Disorders

Cardiac disorders include inflammatory, valvular, and degenerative conditions and cardiac complications. In inflammatory conditions (such as endocarditis, myocarditis, pericarditis, and rheumatic heart disease), scar formation and otherwise normal healing processes can cause debilitating structural damage. Valvular disorders result in stenosis (tissue thickening that narrows the valvular opening) or insufficiency (incomplete valve closure). Degenerative disorders (cardiomyopathies, coronary artery disease, heart failure, hypertension, and myocardial infarction) are the most common cardiovascular ailments. Cardiac complications include arrhythmias, cardiac tamponade, shock, and ventricular aneurysm.

AORTIC INSUFFICIENCY

In aortic insufficiency (also called aortic regurgitation), blood flows back into the left ventricle during diastole. The ventricle becomes overloaded, dilated, and eventually hypertrophies. The excess fluid volume also overloads the left atrium and, eventually, the pulmonary system.

Aortic insufficiency by itself occurs most commonly among males. When associated with mitral valve disease, however, it's more common among females. This disorder also may be associated with Marfan syndrome, ankylosing spondylitis, syphilis, essential hypertension, and a ventricular septal defect, even after surgical closure.

Causes

Aortic insufficiency results from rheumatic fever, syphilis, hypertension, endocarditis, or trauma. In some patients, it may be idiopathic.

Complications

Left-sided heart failure usually occurs. The patient may develop fatal pulmonary edema if a fever, an infection, or a cardiac arrhythmia develops. The patient also risks myocardial ischemia because left ventricular dilation and elevated left ventricular systolic pressure alter myocardial oxygen requirements.

Assessment findings

In chronic severe aortic insufficiency, the patient may complain that he has an uncomfortable awareness of his heartbeat, especially when lying down on his left side. He may report palpitations along with a pounding head.

Dyspnea may occur with exertion, and the patient may experience paroxysmal nocturnal dyspnea with diaphoresis, orthopnea, and cough. He may become fatigued and syncopal with exertion or emotion. He may also have a history of anginal chest pain unrelieved by sublingual nitroglycerin.

On inspection, you may note that each heartbeat seems to jar the patient's entire body and that his head bobs with each systole. Inspection of arterial pulsations shows a rapidly rising pulse that collapses suddenly as arterial pressure falls late in systole. This is called a water-hammer pulse.

The patient's nail beds may appear to be pulsating. If you apply pressure at the nail tip, the root will alternately flush and pale (called Quincke's sign). Inspection of the chest may reveal a visible apical impulse. In left-sided heart failure, the patient may have ankle edema and ascites.

In palpating the peripheral pulses, you may note rapidly rising and collapsing pulses (called pulsus biferiens). If the patient has cardiac arrhythmias, pulses may be irregular. You'll be able to feel the apical impulse. (The apex is displaced laterally and inferiorly.) A diastolic thrill probably is palpable along the left sternal border, and you may be able to feel a prominent systolic thrill in the jugular notch and along the carotid arteries.

Auscultation may reveal an S₃, occasionally an S₄, and a loud systolic ejection sound. A high-pitched, blowing, decrescendo diastolic murmur is best heard at the left sternal border, third intercostal space. Use the diaphragm of the stethoscope to hear it, and have the patient sit up, lean forward, and hold his breath in forced expiration. (See [Identifying the murmur of aortic insufficiency.](#))

You also may hear a midsystolic ejection murmur at the base of the heart. It may be a grade 5 or 6 and typically is higher pitched, shorter, and less rasping than the murmur heard in aortic stenosis. Another murmur that may occur is a soft, low-pitched, rumbling, middiastolic or presystolic bruit (Austin Flint murmur). This murmur is best heard at the base of the heart.

ASSESSMENT TIP Place the stethoscope lightly over the femoral artery to hear a booming, pistol-shot sound and a to-and-fro murmur (Duroziez's sign). Arterial pulse pressure is widened. Auscultating blood pressure may be difficult because you can auscultate the patient's pulse without inflating the cuff. To determine systolic pressure, note when Korotkoff's sounds begin to muffle.

Identifying the murmur of aortic insufficiency

A high-pitched, blowing decrescendo murmur that radiates from the aortic valve area to the left sternal border characterizes aortic insufficiency.

Diagnostic tests

Cardiac catheterization shows reduction in arterial diastolic pressures, aortic insufficiency, other valvular abnormalities, and increased left ventricular end-diastolic pressure.

Chest X-rays display left ventricular enlargement and pulmonary vein congestion.

Echocardiography reveals left ventricular enlargement, dilation of the aortic annulus and left atrium, and thickening of the aortic valve. It also reveals a rapid, high-frequency fluttering of the anterior mitral leaflet that results from the impact of aortic insufficiency.

Electrocardiography shows sinus tachycardia, left ventricular hypertrophy, and left atrial hypertrophy in severe disease. ST-segment depressions and T-wave inversions appear in leads I, aV_L, V₅, and V₆ and indicate left ventricular strain.

Treatment

Valve replacement is the treatment of choice and should be performed before significant ventricular dysfunction occurs. This may not be possible, however, because signs and symptoms seldom occur until after myocardial dysfunction develops.

Digitalis glycosides, a low-sodium diet, diuretics, vasodilators, and especially angiotensin-converting enzyme inhibitors are used to treat patients with left-sided heart failure. In acute episodes, supplemental oxygen may be necessary.

Nursing diagnoses

u Activity intolerance u Altered role performance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Diversional activity deficit u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping

Key outcomes

- u The patient will carry out activities of daily living without excess fatigue or decreased energy.
- u The patient will maintain cardiac output, will demonstrate hemodynamic stability, and won't develop arrhythmias.
- u The patient won't develop complications of fluid volume excess.
- u The patient will maintain adequate ventilation.
- u The patient will maintain joint mobility and range of motion.

Nursing interventions

- u If the patient needs bed rest, stress its importance. Assist with bathing if necessary. Provide a bedside commode because using a commode puts less stress on the heart than using a bedpan. Offer diversional activities that are physically undemanding.
- u Alternate periods of activity and rest to prevent extreme fatigue and dyspnea.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u Keep the patient's legs elevated while he sits in a chair to improve venous return to the heart.
- u Place the patient in an upright position to relieve dyspnea, if necessary, and administer oxygen to prevent tissue hypoxia.
- u Keep the patient on a low-sodium diet. Consult a dietitian to ensure that the patient receives foods that he likes while adhering to the diet restrictions.
- u Monitor for signs of heart failure, pulmonary edema, and adverse reactions to drug therapy.

ALERT If the patient undergoes surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor his vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.

Patient teaching

- u Advise the patient to plan for periodic rest in his daily routine to prevent undue fatigue.
- u Teach the patient about diet restrictions, medications, symptoms that should be reported, and the importance of consistent follow-up care.
- u Tell the patient to elevate his legs whenever he sits.

AORTIC STENOSIS

In aortic stenosis, the opening of the aortic valve becomes narrowed, and the left ventricle exerts increased pressure to drive blood through the opening. The added workload increases the demand for oxygen, while diminished cardiac output reduces coronary artery perfusion, causes ischemia of the left ventricle, and leads to heart failure.

Signs and symptoms of aortic stenosis may not appear until the patient reaches ages 50 to 70, even though the lesion has been present since childhood. Incidence increases with age. Aortic stenosis is the most significant valvular lesion seen among elderly people. About 80% of patients with aortic stenosis are male.

Causes

Aortic stenosis may result from congenital aortic bicuspid valve (associated with coarctation of the aorta), congenital stenosis of pulmonic valve cusps, rheumatic fever or, in elderly patients, atherosclerosis.

Complications

Aortic stenosis leads to left-sided heart failure, usually after age 70. It typically occurs within 4 years after the onset of signs and symptoms and is fatal in up to two-thirds of patients.

Sudden death, possibly caused by an arrhythmia, occurs in up to 20% of patients, usually around age 60.

Assessment findings

Even with severe aortic stenosis (narrowing to about one-third of the normal opening), the patient may be asymptomatic. Eventually, the patient complains of dyspnea on exertion, fatigue, exertional syncope, angina, and palpitations. If left-sided heart failure develops, the patient may complain of orthopnea and paroxysmal nocturnal dyspnea.

Inspection may reveal peripheral edema if the patient has left-sided heart failure.

Palpation may detect diminished carotid pulses and pulsus alternans. If the patient has left-sided heart failure, the apex of the heart may be displaced inferiorly and laterally. If the patient has pulmonary hypertension, you may be able to palpate a systolic thrill at the base of the heart, at the jugular notch, and along the carotid arteries. Occasionally, it may be palpable only during expiration and when the patient leans forward.

Auscultation may uncover an early systolic ejection murmur in children and adolescents who have noncalcified valves. The murmur begins shortly after S₁ and increases in intensity to reach a peak toward the middle of the ejection period. It diminishes just before the aortic valve closes. (See [Identifying the murmur of aortic stenosis.](#))

The murmur is low-pitched, rough, and rasping and is loudest at the base in the second intercostal space. In stenosis, the murmur is at least grade 3 or 4. It disappears when the valve calcifies. A split S₂ develops as aortic stenosis becomes more severe. An S₄ reflects left ventricular hypertrophy and may be heard at the apex in many patients with severe aortic stenosis.

Diagnostic tests

Cardiac catheterization reveals the pressure gradient across the valve (indicating the severity of the obstruction), increased left ventricular end-diastolic pressures (indicating left ventricular function), and the location of the left ventricular outflow obstruction.

Chest X-rays show valvular calcification, left ventricular enlargement, pulmonary vein congestion and, in later stages, left atrial, pulmonary artery, right atrial, and right ventricular enlargement.

Echocardiography demonstrates a thickened aortic valve and left ventricular wall and, possibly, coexistent mitral valve stenosis.

Electrocardiography reveals left ventricular hypertrophy. In advanced stages, the patient exhibits ST-segment depression and T-wave inversion in standard leads I and aV_L and in the left precordial leads. Up to 10% of patients have atrioventricular and intraventricular conduction defects.

Treatment

Digitalis glycosides, a low-sodium diet, diuretics and, in acute cases, oxygen are used to treat patients with heart failure. Nitroglycerin helps to relieve angina.

In children who don't have calcified valves, simple commissurotomy under direct visualization is usually effective. Adults with calcified valves need valve replacement when they become symptomatic or are at risk for developing left-sided heart failure.

Identifying the murmur of aortic stenosis

A low-pitched, harsh crescendo-decrescendo murmur that radiates from the aortic valve area to the carotid artery characterizes aortic stenosis.

SYSTOLE

DIASTOLE

SYSTOLE

S₁

S₂

S₁

S₂

Percutaneous balloon aortic valvuloplasty is useful in children and young adults who have congenital aortic stenosis and in elderly patients with severe calcifications. This procedure may improve left ventricular function so that the patient can tolerate valve replacement surgery.

A Ross procedure may be performed in patients under age 55. In this procedure, the pulmonic valve is used to replace the aortic valve and a cadaver pulmonic valve is inserted. This allows longer valve life and anticoagulant therapy isn't necessary.

Nursing diagnoses

- u Activity intolerance
- u Altered role performance
- u Altered tissue perfusion (cardiopulmonary)
- u Decreased cardiac output
- u Diversional activity deficit
- u Fatigue
- u Fluid volume excess
- u Impaired gas exchange
- u Impaired physical mobility
- u Ineffective individual coping

Key outcomes

- u The patient will perform activities of daily living without excess fatigue or exhaustion.
- u The patient won't develop arrhythmias, will maintain cardiac output, and will demonstrate hemodynamic stability.
- u The patient won't develop complications from fluid volume excess.
- u The patient will maintain ventilation.
- u The patient will maintain joint mobility and range of motion.
- u The patient will develop and demonstrate adequate coping skills.

Nursing interventions

- u If the patient needs bed rest, stress its importance. Assist the patient with bathing if necessary; provide a bedside commode because using a commode puts less stress on the heart than using a bedpan. Offer diversional activities that are physically undemanding.
- u Alternate periods of activity and rest to prevent extreme fatigue and dyspnea.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u Keep the patient's legs elevated while he sits in a chair to improve venous return to the heart.
- u Place the patient in an upright position to relieve dyspnea, if needed. Administer oxygen to prevent tissue hypoxia, as needed.

- u Keep the patient on a low-sodium diet. Consult with a dietitian to ensure that the patient receives foods that he likes while adhering to the diet restrictions.
- u Monitor for signs of heart failure, pulmonary edema, and adverse reactions to drug therapy.
- u Allow the patient to express his fears and concerns about the disorder, its impact on his life, and any impending surgery. Reassure him as needed.
- u After cardiac catheterization, apply firm pressure to the catheter insertion site, usually in the groin. Monitor the site every 15 minutes for at least 6 hours for signs of bleeding. If the site bleeds, remove the pressure dressing and apply firm pressure.
- u Notify the doctor of any changes in peripheral pulses distal to the insertion site, changes in cardiac rhythm and vital signs, and complaints of chest pain.
- u If the patient has surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor his vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.

Patient teaching

- u Advise the patient to plan for periodic rest in his daily routine to prevent undue fatigue.
- u Teach the patient about diet restrictions, medications, symptoms that should be reported, and the importance of consistent follow-up care.
- u Tell the patient to elevate his legs whenever he sits.

CARDIAC ARRHYTHMIAS

Arrhythmias result from abnormal electrical conduction or automaticity that changes heart rate and rhythm. They vary in severity, from those that are mild, asymptomatic, and require no treatment (such as sinus arrhythmia, in which heart rate increases and decreases with respiration) to catastrophic ventricular fibrillation, which requires immediate resuscitation.

Arrhythmias are classified according to their origin as ventricular, atrial (supraventricular), or junctional. Their effect on cardiac output and blood pressure, partially influenced by the site of origin, can be used to determine their clinical significance.

Causes

Arrhythmias may be congenital or may result from myocardial ischemia or infarction, organic heart disease, drug toxicity, or degeneration of conductive tissue necessary to maintain normal heart rhythm (sick sinus syndrome).

Complications

In a patient with a normal heart, arrhythmias typically produce few symptoms. However, even in a normal heart, persistently rapid or highly irregular rhythms can strain the myocardium and impair cardiac output.

Assessment findings

Depending on the arrhythmia, the patient may exhibit symptoms ranging from pallor, cold and clammy extremities, reduced urine output, palpitations, and weakness to chest pains, dizziness and, if cerebral circulation is severely impaired, syncope.

Diagnostic tests

Electrocardiography (ECG) allows detection and identification of arrhythmias. (See [Types of cardiac arrhythmias.](#))

Treatment

Effective treatment aims to return pacer function to the sinus node, increase or decrease ventricular rate to normal, regain atrioventricular synchrony, and maintain normal sinus rhythm. Such treatment corrects abnormal rhythms through therapy with antiarrhythmic drugs; electrical conversion with precordial shock (defibrillation and cardioversion); physical maneuvers, such as carotid massage and Valsalva's maneuver; temporary or permanent placement of a pacemaker to maintain heart rate; and surgical removal or cryotherapy of an irritable ectopic focus to prevent recurring arrhythmias.

Types of cardiac arrhythmias			
The table below describes common cardiac arrhythmias and outlines their causes, characteristics, and treatments. Use a normal electrocardiography strip, if available, to compare normal cardiac rhythm configurations with the rhythm strips below. Characteristics of normal rhythm include:			
<ul style="list-style-type: none">u ventricular and atrial rates of 60 to 100 beats/minuteu regular and uniform QRS complexes and P wavesu PR interval of 0.12 to 0.2 secondu QRS duration less than 0.12 secondu identical atrial and ventricular rates, with constant PR interval.			
ARRHYTHMIA	CAUSES	CHARACTERISTICS	TREATMENT
Sinus arrhythmia 	<ul style="list-style-type: none">u A normal variation of normal sinus rhythm in athletes, children, and elderly peopleu Also seen in digitalis toxicity and inferior wall myocardial infarction (MI)	<ul style="list-style-type: none">u Irregular atrial and ventricular rhythmsu Normal P wave preceding each QRS complex	<ul style="list-style-type: none">u Atropine if rate decreases below 40 beats/minute and the patient becomes symptomatic
Sinus tachycardia 	<ul style="list-style-type: none">u Normal physiologic response to fever, exercise, anxiety, pain, dehydration; may also accompany shock, left-sided heart failure, cardiac tamponade, hyperthyroidism, anemia, hypovolemia, pulmonary embolism, anterior wall MIu May also occur with anticholinesterase, epinephrine, isoproterenol, quinidine, caffeine, alcohol, and nicotine use		<ul style="list-style-type: none">u Atrial and ventricular rates regularu Rate > 100 beats/minute; rarely, > 160 beats/minuteu Normal P wave preceding each QRS complexu Correction of underlying causeu Propranolol for symptomatic patients
Sinus bradycardia 	<ul style="list-style-type: none">u Normal in well-conditioned heart, such as in an athleteu Increased intracranial pressure; increased vagal tone due to bowel straining, vomiting, intubation, mechanical ventilation; sick sinus syndrome; hypothyroidism; inferior wall MIu May also occur with anticholinesterase, beta blocker, digoxin, and morphine use	<ul style="list-style-type: none">u Regular atrial and ventricular ratesu Rate < 60 beats/minuteu Normal P wave preceding each QRS complex	<ul style="list-style-type: none">u Atropine for low cardiac output, dizziness, weakness, altered level of consciousness, or low blood pressureu Temporary pacemaker if atropine fails; may need permanent pacemaker

Sinoatrial arrest or block
(sinus arrest)

- Acute infection
- Coronary artery disease, degenerative heart disease, acute inferior wall MI
- Vagal stimulation, Valsalva's maneuver, carotid sinus massage
- Digoxin, quinidine, or salicylate toxicity
- Pesticide poisoning
- Pharyngeal irritation caused by endotracheal (ET) intubation
- Sick sinus syndrome

- Atrial and ventricular rhythms normal except for missing complex
- Normal P wave preceding each QRS complex
- Pause not equal to a multiple of the previous sinus rhythm

- Atropine if symptomatic
- Temporary or permanent pacemaker for repeated episodes

Wandering atrial pacemaker

- Rheumatic carditis as a result of inflammation involving the sinoatrial (SA) node
- Digitalis toxicity
- Sick sinus syndrome

- Atrial and ventricular rates vary slightly
- Irregular PR interval
- P waves irregular with changing configuration, indicating they aren't all from SA node or single atrial focus; may appear after the QRS complex
- QRS complexes uniform in shape but irregular in rhythm

- No treatment if asymptomatic
- Treatment of underlying cause if symptomatic

Premature atrial contraction (PAC)

- Coronary or valvular heart disease, atrial ischemia, coronary atherosclerosis, heart failure, acute respiratory failure, chronic obstructive pulmonary disease (COPD), electrolyte imbalance, and hypoxia
- Digitalis toxicity and aminophylline, adrenergics, or caffeine use
- Anxiety

- Premature, abnormal P waves, differing in configuration from normal P waves
- QRS complexes after P waves, except in very early or blocked PACs
- P wave commonly buried in the preceding T wave or identified in the preceding T wave

- No treatment usually
- For frequent PACs or those that cause sustained tachycardia, drugs that prolong atrial refractoriness, such as digoxin, verapamil, or propranolol; after revascularization surgery, propranolol
- Elimination of known causes, such as caffeine, tobacco, and alcohol

Paroxysmal atrial tachycardia (paroxysmal supra-ventricular tachycardia)

- Intrinsic abnormality of atrioventricular (AV) conduction system
- Physical or psychological stress, hypoxia, hypokalemia, cardiomyopathy, congenital heart disease, MI, valvular disease, Wolff-Parkinson-White syndrome, cor pulmonale, hyperthyroidism, systemic hypertension
- Digitalis toxicity; caffeine, marijuana, central nervous system stimulant use

- Atrial and ventricular rates regular
- Heart rate > 160 beats/minute; rarely exceeds 250 beats/minute
- P waves regular but aberrant; difficult to differentiate from preceding T wave
- P wave preceding each QRS complex
- Sudden onset and termination of arrhythmia

- If patient is symptomatic, prepare for immediate cardioversion
- If patient is stable, use vagal stimulation, Valsalva's maneuver, carotid sinus massage
- If patient is stable, adenosine by rapid I.V. bolus injection to rapidly convert arrhythmia
- If patient is stable and rhythm is type of tachycardia, determine QRS complex width:
 - for wide complex width, follow ACLS drug protocol
 - for narrow complex width and normal or elevated blood pressure, follow ACLS drug protocol
 - for narrow complex width and low or unstable blood pressure (and for ineffective response with other drugs), use synchronized cardioversion

Atrial flutter

- Heart failure, tricuspid or mitral valve disease, pulmonary embolism, cor pulmonale, inferior wall MI, and carditis
- Digitalis toxicity

- Atrial rhythm regular; 250 to 400 beats/minute
- Ventricular rates variable, depending on degree of AV block
- Ventricular rhythm regular or irregular, depending on AV conduction
- Sawtooth P-wave configuration possible (F waves)
- QRS complexes uniform in shape but irregular in rate

- If patient is unstable with a ventricular rate > 150 beats/minute), prepare for immediate cardioversion
- If patient is stable, therapy may include diltiazem, beta blockers, calcium channel blockers, digoxin, procainamide, or quinidine

Atrial fibrillation

- Heart failure, COPD, thyrotoxicosis, constrictive pericarditis, ischemic heart disease, sepsis, pulmonary embolus, rheumatic heart disease, hypertension, mitral stenosis, digitalis toxicity (rarely), atrial irritation, and complication of coronary bypass or valve replacement surgery
- Nifedipine and digoxin use

- Atrial rhythm grossly irregular; rate > 400 beats/minute
- Ventricular rhythm grossly irregular
- Ventricular rate normal, fast, or slow
- QRS complexes of uniform configuration and duration
- PR interval indiscernible
- No P waves or erratic, irregular, baseline fibrillary P waves

- If patient is unstable with a ventricular rate > 150 beats/minute, prepare for immediate cardioversion
- If patient is stable, therapy may include diltiazem, beta blockers, verapamil, digoxin, procainamide, or quinidine I.V.

Junctional rhythm

- Inferior wall MI or ischemia, hypoxia, vagal stimulation, or sick sinus syndrome
- Acute rheumatic fever
- Valve surgery
- Digitalis toxicity

- Atrial and ventricular rhythms regular
- Atrial rate 40 to 60 beats/minute
- Ventricular rate usually 40 to 60 beats/minute (60 to 100 beats/minute is accelerated junctional rhythm)
- P waves inverted and preceding, hidden within (absent), or after QRS complex
- PR interval (when present) < 0.12 second
- QRS complex configuration and duration normal, except in aberrant conduction

- Atropine for symptomatic slow rate
- Pacemaker insertion if refractory to drugs
- Discontinuation of digoxin, if appropriate

Premature junctional contractions(junctional premature beats)

- MI or ischemia
- Digitalis toxicity and excessive caffeine or amphetamine use

- Atrial and ventricular rhythms irregular
- P waves inverted; may precede, be hidden within, or follow QRS complex
- PR interval < 0.12 second, if P wave precedes QRS complex
- QRS complex configuration and duration normal

- No treatment usually
- Correction of underlying cause
- Atropine
- Discontinuation of digoxin (if appropriate)

First-degree AV block

- May be seen in a healthy person
- Inferior wall myocardial ischemia or infarction, hypothyroidism, hypokalemia, or hyperkalemia
- Digitalis toxicity; quinidine, procainamide, or propranolol use

- Atrial and ventricular rhythms regular
- PR interval > 0.20 second
- P wave preceding each QRS complex
- QRS complex normal

- Cautious use of digoxin
- Correction of underlying cause
- Atropine may be used if PR interval exceeds 0.26 second or bradycardia develops

Second-degree AV block Mobitz I (Wenckebach)

- Inferior wall MI, cardiac surgery, acute rheumatic fever, and vagal stimulation
- Digitalis toxicity; propranolol, quinidine, or procainamide use

- Atrial rhythm regular
- Ventricular rhythm irregular
- Atrial rate exceeds ventricular rate
- PR interval progressively, but only slightly longer with each cycle until QRS complex disappears (dropped beat); PR interval shorter after dropped beat

- Treatment of underlying cause
- Atropine or temporary pacemaker, for symptomatic bradycardia
- Discontinuation of digoxin, if appropriate

Second-degree AV block Mobitz II

- Severe coronary artery disease, anterior MI, and acute myocarditis
- Digitalis toxicity

- Atrial rate regular
- Ventricular rhythm regular or irregular, with varying degree of block
- P-P interval constant
- QRS complexes periodically absent

- Isoproterenol for symptomatic bradycardia
- Temporary or permanent pacemaker
- Discontinuation of digoxin, if appropriate

Third-degree AV block (complete heart block)

- Inferior or anterior wall MI, congenital abnormality, rheumatic fever, hypoxia, postoperative complications of mitral valve replacement, Lev's disease (fibrosis and calcification that spreads from cardiac structures to the conductive tissue) and Lenègre's disease (conductive tissue fibrosis)
- Digitalis toxicity

- Atrial rate regular
- Ventricular rate slow and regular
- No relationship between P waves and QRS complexes
- No constant PR interval
- QRS interval normal (nodal pacemaker), or wide and bizarre (ventricular pacemaker)

- Atropine for symptomatic bradycardia
- Temporary or permanent pacemaker

Junctional tachycardia

- Myocarditis, cardiomyopathy, inferior wall MI or ischemia, acute rheumatic fever, or valve replacement surgery
- Digitalis toxicity

- Atrial rate > 100 beats/minute; however, P wave may be absent, hidden in QRS complex, or preceding T wave
- Ventricular rate > 100 beats/minute
- P wave inverted
- QRS complex configuration and duration normal
- Onset of rhythm often sudden, occurring in bursts

- Carotid sinus massage, elective cardioversion
- Propranolol, verapamil, or edrophonium
- Discontinuation of digoxin, if appropriate
- Temporary atrial pacemaker to override the rhythm

Premature ventricular contraction(PVC)

- Heart failure; old or acute myocardial ischemia, infarction, or contusion; myocardial irritation by ventricular catheter, such as a pacemaker; hypercapnea; hypokalemia; and hypocalcemia
- Drug toxicity (digoxin, aminophylline, tricyclic antidepressants, and beta-adrenergics [isoproterenol or dopamine])
- Caffeine, tobacco, or alcohol use
- Psychological stress, anxiety, pain, or exercise

- Atrial rate regular
- Ventricular rate irregular
- QRS complex premature, usually followed by a complete compensatory pause
- QRS complex wide and distorted, usually > 0.14 second
- Premature QRS complexes occurring singly, in pairs, or in threes; alternating with normal beats; focus from one or more sites
- Most ominous when clustered, multifocal, with R wave on T pattern

- Treatment of underlying cause
- Lidocaine or procainamide infusions if symptomatic
- Discontinuation of drug causing toxicity
- Potassium chloride I.V. if induced by hypokalemia

Ventricular tachycardia

- Myocardial ischemia, infarction, or aneurysm; coronary artery disease; rheumatic heart disease; mitral valve prolapse; heart failure; cardiomyopathy; ventricular catheters; hypo-kalemia; hypercalcemia; and pulmonary embolism
- Digoxin, procainamide, epinephrine, or quinidine toxicity
- Anxiety

- Ventricular rates 140 to 220 beats/minute, regular or irregular
- QRS complexes wide, bizarre, and independent of P waves
- P waves not discernible
- May start and stop suddenly

- With pulse:
 - if hemodynamically stable with ventricular rate < 150 beats/minute, follow ACLS drug protocol; if drugs are ineffective, initiate synchronized cardioversion
 - if ventricular rate > 150 beats/minute, follow ACLS protocol for immediate synchronized cardioversion followed by antiarrhythmic agents
- Without pulse: initiate CPR and follow ACLS protocol for defibrillation, ET intubation, and drug administration

Ventricular fibrillation 	<ul style="list-style-type: none"> Myocardial ischemia or infarction, untreated ventricular tachycardia, R-on-T phenomenon, hypokalemia, alkalosis, hyperkalemia, hypercalcemia, electric shock, and hypothermia Digoxin, epinephrine, or quinidine toxicity 	<ul style="list-style-type: none"> Ventricular rhythm rapid and chaotic QRS complexes wide and irregular; no visible P waves 	<ul style="list-style-type: none"> Without pulse: initiate CPR and follow ACLS protocol for defibrillation, ET intubation, and drug administration
Ventricular standstill (asystole) 	<ul style="list-style-type: none"> Myocardial ischemia or infarction, aortic valve disease, heart failure, hypoxemia, hypokalemia, severe acidosis, electric shock, ventricular arrhythmias, AV block, pulmonary embolism, heart rupture, cardiac tamponade, hyperkalemia, electromechanical dissociation Cocaine overdose 	<ul style="list-style-type: none"> No atrial or ventricular rate or rhythm No discernible P waves, QRS complexes, or T waves 	<ul style="list-style-type: none"> CPR, following ACLS protocol for ET intubation, drug administration, and possibly transcutaneous pacing

Arrhythmias may respond to treatment of the underlying disorder such as correction of hypoxia. However, arrhythmias associated with heart disease may require continuing and complex treatment.

Nursing diagnoses

Activity intolerance Altered tissue perfusion (cardiopulmonary, renal, cerebral) Anxiety Decreased cardiac output Fatigue Fluid volume deficit Impaired gas exchange Ineffective family coping: Disabling Pain

Key outcomes

- The patient will maintain cardiac output.
- The patient will maintain hemodynamic stability.
- The patient will maintain adequate ventilation.
- The patient will express feelings of comfort and decreased pain.
- The patient will maintain palpable pulses and adequate fluid volume.

Nursing interventions

- Carefully assess the patient's cardiac, electrolyte, and overall clinical status to determine the effect on cardiac output and whether the arrhythmia is life-threatening.
- Assess an unmonitored patient for rhythm disturbances. If the patient's pulse rate is abnormally rapid, slow, or irregular, watch for signs of hypoperfusion, such as hypotension and diminished urine output.
- Document any arrhythmias in a monitored patient, and assess for possible causes and effects.
- When life-threatening arrhythmias develop, quickly assess the patient's level of consciousness and pulse and respiratory rates and initiate cardiopulmonary resuscitation, if indicated.
- Evaluate for altered cardiac output resulting from arrhythmias. Administer medications as ordered, and prepare to assist with medical procedures, if indicated (for example, cardioversion).
- Monitor for predisposing factors, such as fluid and electrolyte imbalance, and signs of drug toxicity, especially with digoxin. If you suspect drug toxicity, report it to the doctor immediately and withhold the next dose.
- To prevent arrhythmias postoperatively, provide adequate oxygen and reduce heart workload, while carefully maintaining metabolic, neurologic, respiratory, and hemodynamic status.
- To avoid temporary pacemaker malfunction, install a fresh battery before each insertion. Carefully secure the external catheter wires and the pacemaker box. Assess the threshold daily. Watch closely for premature contractions, a sign of myocardial irritation.
- After pacemaker insertion, monitor the patient's pulse rate regularly, and watch for signs of pacemaker failure and decreased cardiac output.

Patient teaching

- Explain to the patient the importance of taking all ordered medications at the proper time intervals. Teach him how to take his pulse and recognize an irregular rhythm, and instruct him to report alterations from his baseline to the doctor.
- If the patient has a permanent pacemaker, warn him about environmental and electrical hazards, as indicated by the pacemaker manufacturer. Although hazards may not present a problem, in doubtful situations, a 24-hour ambulatory ECG (Holter monitoring) may be helpful. Tell the patient to report any light-headedness or syncope. Stress the importance of scheduling and keeping appointments for regular checkups.

CARDIAC TAMPONADE

Cardiac tamponade involves a rapid increase in intrapericardial pressure, which impairs diastolic filling of the heart. The increase in pressure usually results from blood or fluid accumulation in the pericardial sac. If fluid accumulates rapidly, as little as 250 ml can create an emergency situation. Slow accumulation and an increase in pressure, as in pericardial effusion associated with cancer, may not produce immediate signs and symptoms because the fibrous wall of the pericardial sac can gradually stretch to accommodate as much as 1 to 2 L of fluid.

Causes

- Cardiac tamponade may be idiopathic (Dressler's syndrome) or may result from:
- effusion (in cancer, bacterial infections, tuberculosis and, rarely, acute rheumatic fever)
 - hemorrhage from trauma (such as gunshot or stab wounds of the chest and perforation by catheter during cardiac or central venous catheterization, or after cardiac surgery)
 - hemorrhage from nontraumatic causes (such as rupture of the heart or great vessels or anticoagulant therapy in a patient with pericarditis)
 - viral, postirradiation, or idiopathic pericarditis
 - acute myocardial infarction
 - chronic renal failure during dialysis
 - drug reaction (such as with procainamide, hydralazine, minoxidil, isoniazid, penicillin, methysergide, and daunorubicin)
 - connective tissue disorders (such as rheumatoid arthritis, systemic lupus erythematosus, rheumatic fever, vasculitis, and scleroderma).

Complications

Pressure resulting from fluid accumulation in the pericardium decreases ventricular filling and cardiac output, resulting in cardiogenic shock and death if untreated.

Assessment findings

The patient's history may show a disorder that can cause cardiac tamponade. He may report acute pain and dyspnea, sitting upright and leaning forward to facilitate breathing and lessen the pain. He may be orthopneic, diaphoretic, anxious, and restless, and appear pale or cyanotic. You may note neck vein distention produced by increased venous pressure, although this may not be present if the patient is hypovolemic.

Palpation of the peripheral pulses may disclose rapid, weak pulses. Palpation of the upper quadrant may reveal hepatomegaly.

Percussion may disclose a widening area of flatness across the anterior chest wall, indicating a large effusion. Hepatomegaly may also be noted.

Auscultation of the blood pressure may demonstrate a decreased arterial blood pressure, pulsus paradoxus (an abnormal inspiratory drop in systemic blood pressure greater than 15 mm Hg), and narrow pulse pressure.

ASSESSMENT TIP Suspect cardiac tamponade in a patient who presents with shocklike symptoms but doesn't have the other obvious signs that are characteristic of hypovolemic, septic, and other types of shock.

Heart sounds may be muffled. A quiet heart with faint sounds usually accompanies only severe tamponade and occurs within minutes of the tamponade, as happens with cardiac rupture or trauma. The lungs are clear.

Diagnostic tests

The following test results are characteristic:

- u Chest X-rays show slightly widened mediastinum and enlargement of the cardiac silhouette.
- u Electrocardiography (ECG) is useful to rule out other cardiac disorders. The QRS amplitude may be reduced, and electrical alternans of the P wave, QRS complex, and T wave may be present. Generalized ST-segment elevation is noted in all leads.
- u Pulmonary artery pressure monitoring detects increased right atrial pressure, right ventricular diastolic pressure, and central venous pressure.
- u Echocardiography records pericardial effusion with signs of right ventricular and atrial compression.

Treatment

The goal of treatment is to relieve intrapericardial pressure and cardiac compression by removing accumulated blood or fluid. Pericardiocentesis (needle aspiration of the pericardial cavity) or surgical creation of an opening dramatically improves systemic arterial pressure and cardiac output with aspiration of as little as 25 ml of fluid. A drain may be inserted into the pericardial sac to drain the effusion. This may be left in until the effusion process stops or the corrective action (pericardial window) is performed.

In the hypotensive patient, trial volume loading with I.V. normal saline solution with albumin, and perhaps an inotropic drug such as dopamine is necessary to maintain cardiac output.

Depending on the cause of tamponade, additional treatment may include:

- u in traumatic injury, blood transfusion or a thoracotomy to drain reaccumulating fluid or to repair bleeding sites
- u in heparin-induced tamponade, the heparin antagonist protamine
- u in warfarin-induced tamponade, vitamin K.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Anxiety u Decreased cardiac output u Fluid volume deficit u Impaired gas exchange u Pain u Risk for infection

Key outcomes

- u The patient will maintain hemodynamic status.
- u The patient will maintain adequate cardiac output.
- u The patient won't develop arrhythmias.
- u The patient will maintain ventilation.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain adequate fluid volume.

Nursing interventions

- u Monitor the patient with cardiac tamponade in the intensive care unit. Check for signs of increasing tamponade, increasing dyspnea, and arrhythmias.

For pericardiocentesis:

- u Reassure the patient to reduce anxiety.
- u Gather a pericardiocentesis tray, an ECG machine, and an emergency cart with a defibrillator at the bedside. Make sure the equipment is turned on and ready to be used. Position the patient at a 45- to 60-degree angle. Connect the precordial ECG lead to the hub of the aspiration needle with an alligator clamp and connecting wire and assist with fluid aspiration. When the needle touches the myocardium, you see ST-segment elevation or premature ventricular contractions.
- u Monitor blood pressure and central venous pressure (CVP) during and after pericardiocentesis. Infuse I.V. solutions, as ordered, to maintain blood pressure. Watch for a decrease in CVP and a concomitant increase in blood pressure, which indicate relief of cardiac compression.
- u Administer oxygen therapy as needed.

ALERT Watch for complications of pericardiocentesis, such as ventricular fibrillation, vagovagal arrest, and coronary artery or cardiac chamber puncture. Closely monitor cardiac rhythm strip changes, blood pressure, pulse rate, level of consciousness, and urine output.

For thoracotomy:

- u Give antibiotics, protamine, or vitamin K as ordered.
- u Postoperatively monitor critical parameters, such as vital signs and arterial blood gas levels, and assess heart and breath sounds. Give pain medication as ordered. Maintain the chest drainage system, and be alert for complications, such as hemorrhage and arrhythmias.

Patient teaching

- u Explain the procedure (pericardiocentesis or thoracotomy) to the patient. Tell him what to expect postoperatively (such as chest tubes, drainage bottles, and administration of oxygen). Teach him how to turn, deep-breathe, and cough. If the patient isn't in an acute situation preoperatively, teach these techniques then.

CARDIOGENIC SHOCK

Cardiogenic shock is a condition of diminished cardiac output that severely impairs tissue perfusion. It's sometimes called pump failure. Cardiogenic shock can occur as a serious complication in nearly 15% of all patients who are hospitalized with acute myocardial infarction (MI). It typically affects patients whose area of infarction involves 40% or more of left ventricular muscle mass; in such patients, mortality may exceed 85%.

Causes and pathophysiology

Cardiogenic shock can result from any condition that causes significant left ventricular dysfunction with reduced cardiac output, such as MI (most common), myocardial ischemia, papillary muscle dysfunction, and end-stage cardiomyopathy.

Other causes include myocarditis and depression of myocardial contractility after cardiac arrest and prolonged cardiac surgery. Mechanical abnormalities of the ventricle, such as acute mitral or aortic insufficiency or an acutely acquired ventricular septal defect or ventricular aneurysm, may also result in cardiogenic shock.

Regardless of the cause, left ventricular dysfunction initiates a series of compensatory mechanisms that attempt to increase cardiac output and, in turn, maintain vital organ function. As cardiac output falls, aortic and carotid baroreceptors activate sympathetic nervous responses. These compensatory responses increase heart rate, left ventricular filling pressure, and peripheral resistance to flow to enhance venous return to the heart. The action initially stabilizes the patient but later causes deterioration with increasing oxygen demands on the already compromised myocardium. These events comprise a vicious cycle of low cardiac output, sympathetic compensation, myocardial ischemia, and even lower cardiac output.

Complications

Death usually ensues because the vital organs can't overcome the deleterious effects of extended hypoperfusion.

Assessment findings

Typically, the patient's history includes a disorder, such as MI or cardiomyopathy, that severely decreases left ventricular function. Patients with underlying cardiac disease may complain of anginal pain because of decreased myocardial perfusion and oxygenation. Urine output is usually less than 20 ml/hour.

Inspection usually reveals pale skin, decreased sensorium, and rapid, shallow respirations. Palpation of peripheral pulses may reveal a rapid, thready pulse. The skin feels cold and clammy.

Auscultation of blood pressure usually discloses a mean arterial pressure of less than 60 mm Hg in adults and a narrowing pulse pressure. In a patient with chronic hypotension, the mean pressure may fall below 50 mm Hg before he exhibits any signs of shock. Auscultation of the heart is used to detect gallop rhythm, faint heart sounds and, possibly (if shock results from rupture of the ventricular septum or papillary muscles), a holosystolic murmur.

Although many of these clinical features also occur in heart failure and other shock syndromes, they are usually more profound in cardiogenic shock. (See [Classifying shock](#).) Patients with pericardial tamponade may have distant heart sounds.

Diagnostic tests

Pulmonary artery pressure monitoring reveals increased pulmonary artery pressure (PAP) and pulmonary artery wedge pressure (PAWP), reflecting an increase in left ventricular end-diastolic pressure (preload) and heightened resistance to left ventricular emptying (afterload) caused by ineffective pumping and increased peripheral vascular resistance. Thermodilution catheterization reveals a reduced cardiac index (less than 1.8 L/minute/ml).

Invasive arterial pressure monitoring shows systolic arterial pressure less than 80 mm Hg caused by impaired ventricular ejection.

Arterial blood gas analysis may show metabolic and respiratory acidosis and hypoxia.

Electrocardiography demonstrates possible evidence of acute MI, ischemia, or ventricular aneurysm.

Serum enzyme measurements display elevated levels of creatine kinase (CK), lactate dehydrogenase (LDH), aspartate aminotransferase, and alanine aminotransferase, which point to MI or ischemia and suggest heart failure or shock. CK and LDH isoenzyme levels may confirm acute MI.

Cardiac catheterization and echocardiography reveal other conditions that can lead to pump dysfunction and failure, such as cardiac tamponade, papillary muscle infarct or rupture, ventricular septal rupture, pulmonary emboli, venous pooling (associated with venodilators and continuous intermittent positive-pressure breathing), and hypovolemia.

Treatment

Treatment aims to enhance cardiovascular status by increasing cardiac output, improving myocardial perfusion, and decreasing cardiac workload with combinations of cardiovascular drugs and mechanical-assist techniques.

Classifying shock	
TYPE	DESCRIPTION
<i>Hypovolemic</i>	Results from a decrease in central vascular volume. Total body fluids may or may not be decreased. Causes include hemorrhage, dehydration, and fluid shifts (caused by trauma, burns, or anaphylaxis).
<i>Cardiogenic</i>	Results from a direct or indirect pump failure with decreasing cardiac output. Total body fluid isn't decreased. Causes include valvular stenosis or insufficiency, myocardial infarction, cardiomyopathy, arrhythmias, cardiac arrest, cardiac tamponade, pericarditis, pulmonary hypertension, and pulmonary emboli.
<i>Distributive</i>	Results from inadequate vascular tone that leads to massive vasodilation. Vascular volume remains normal and heart pumps adequately, but size of vascular space increases. Result is maldistribution of blood within the circulatory system. It includes the following subtypes: ⌞ <i>Septic shock</i> : a form of severe sepsis characterized by hypotension and altered tissue perfusion. Vascular tone is lost and cardiac output may be decreased. ⌞ <i>Neurogenic shock</i> : characterized by massive vasodilation from loss or suppression of sympathetic tone. Causes include head trauma, spinal cord injuries, anesthesia, and stress. ⌞ <i>Anaphylactic shock</i> : characterized by massive vasodilation and increased capillary permeability secondary to a hypersensitivity reaction to an antigen.

I.V. drugs may include dopamine, a vasopressor that increases cardiac output, blood pressure, and renal blood flow; amrinone or dobutamine, inotropic agents that increase myocardial contractility; and norepinephrine, when a more potent vasoconstrictor is necessary. Nitroprusside, a vasodilator, may be used with a vasopressor to further improve cardiac output by decreasing peripheral vascular resistance (afterload) and reducing left ventricular end-diastolic pressure (preload). The patient's blood pressure must be adequate to support nitroprusside therapy and must be monitored closely.

Treatment may also include the intra-aortic balloon pump (IABP), a mechanical-assist device that attempts to improve coronary artery perfusion and decrease cardiac workload. The inflatable balloon pump is inserted through the femoral artery into the descending thoracic aorta. The balloon inflates during diastole to increase coronary artery perfusion pressure and deflates before systole (before the aortic valve opens) to reduce resistance to ejection (afterload) and, therefore, lessen cardiac workload. Improved ventricular ejection, which significantly improves cardiac output, and a subsequent vasodilation in the peripheral vessels lead to lower

preload volume.

When drug therapy and IABP insertion fail, a ventricular assist device may be used.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Anxiety u Decreased cardiac output u Fear u Fluid volume excess u Hopelessness u Impaired gas exchange u Impaired physical mobility

Key outcomes

- u The patient will maintain adequate cardiac output and hemodynamic stability.
- u The patient won't develop complications of fluid volume excess.
- u The patient will maintain adequate ventilation.
- u The patient will resume appropriate rest and activity patterns.
- u The patient will express feelings and develop adequate coping mechanisms.

Nursing interventions

- u In the intensive care unit (ICU), start I.V. infusions with normal saline solution or lactated Ringer's solution, using a large-bore (14G to 18G) catheter, which allows easier administration of later blood transfusions. (*Caution:* Don't start I.V. infusions in the legs of a shock patient who has suffered abdominal trauma because infused fluid may escape through the ruptured vessel into the abdomen.)
- u Monitor and record blood pressure, pulse and respiratory rates, and peripheral pulses every 1 to 5 minutes until the patient is stabilized. Record hemodynamic pressure readings every 15 minutes. Monitor cardiac rhythm continuously. Systolic blood pressure less than 80 mm Hg usually results in inadequate coronary artery blood flow, cardiac ischemia, arrhythmias, and further complications of low cardiac output. When blood pressure drops below 80 mm Hg, increase the oxygen flow rate and notify the doctor immediately.
- u A progressive drop in blood pressure accompanied by a thready pulse generally signals inadequate cardiac output from reduced intravascular volume. Notify the doctor and increase the infusion rate.
- u Using a pulmonary artery catheter, closely monitor PAP, PAWP, and cardiac output. A high PAWP indicates heart failure, increased systemic vascular resistance, decreased cardiac output, and decreased cardiac index and should be reported immediately.
- u Insert an indwelling urinary catheter if necessary to measure hourly urine output. If the output is less than 30 ml/hour in an adult, increase the fluid infusion rate, but watch for signs of fluid overload, such as an increase in PAWP. Notify the doctor if the patient's urine output doesn't improve.
- u Administer an osmotic diuretic, such as mannitol, if ordered, to increase renal blood flow and urine output. Determine how much fluid to give by checking blood pressure, urine output, central venous pressure (CVP), or PAWP. (To increase accuracy, measure CVP at the level of the right atrium, using the same reference point on the chest each time.)
- u Draw an arterial blood sample to measure blood gas levels. Administer oxygen by face mask or airway to ensure adequate oxygenation of tissues. Adjust the oxygen flow rate to a higher or lower level, as blood gas measurements indicate. Many patients need 100% oxygen and some require 5 to 15 cm H₂O of positive end-expiratory or continuous positive airway pressure ventilation.
- u Monitor complete blood count and electrolyte levels.
- u During therapy, assess skin color and temperature, and note any changes. Cold, clammy skin may be a sign of continuing peripheral vascular constriction, indicating progressive shock.

ALERT When a patient is on the IABP, move him as little as possible. Never flex the patient's “ballooned” leg at the hip because this may displace or fracture the catheter. Never place the patient in a sitting position (including for chest X-rays) while the balloon is inflated; the balloon may tear through the aorta and cause immediate death. Assess pedal pulses and skin temperature and color to make sure circulation to the leg is adequate. Check the dressing on the insertion site frequently for bleeding, and change it according to facility protocol. Also check the site for hematoma or signs of infection, and culture any drainage.

- u If the patient becomes hemodynamically stable, gradually reduce the frequency of balloon inflation to wean him from the IABP. During weaning, carefully watch for monitor changes, chest pain, and other signs of recurring cardiac ischemia and shock.
- u To ease emotional stress, plan your care to allow frequent rest periods, and provide for as much privacy as possible. Allow family members to visit and comfort the patient as much as possible.
- u Allow the family to express their anger, anxiety, and fear.

Patient teaching

- u Because the patient and family members may be anxious about the ICU and about the IABP and other tubes and devices, offer explanations and reassurance.
- u Prepare the patient and family members for a probable fatal outcome, and help them find effective coping strategies.

CORONARY ARTERY DISEASE

The foremost effect of coronary artery disease is the loss of oxygen and nutrients to myocardial tissue because of diminished coronary blood flow. Fatty fibrous plaques or calcium-plaque deposits, or combinations of both, narrow the lumens of coronary arteries, reducing the volume of blood that can flow through them.

Coronary artery disease is more prevalent in men, whites, and middle-aged and elderly people than in women or in people of other races and ages.

Causes

Atherosclerosis, the most common cause of coronary artery disease, has been linked to many risk factors. Some risk factors can't be controlled:

- u *Age.* Atherosclerosis usually occurs after age 40.
- u *Sex.* Men are eight times more susceptible than premenopausal women.
- u *Heredity.* A positive family history of coronary artery disease increases the risk.
- u *Race.* White men are more susceptible than nonwhite men, and nonwhite women are more susceptible than white women.

The patient can modify other risk factors, such as the following, with good medical care and appropriate lifestyle changes:

- u *Blood pressure.* Systolic blood pressure that is higher than 160 mm Hg or diastolic blood pressure that is higher than 95 mm Hg increases the risk.
- u *Serum cholesterol levels.* Increased low-density lipoprotein and decreased high-density lipoprotein levels substantially heighten the risk.
- u *Smoking.* Cigarette smokers are twice as likely to have a myocardial infarction and four times as likely to experience sudden death. The risk dramatically drops within 1 year after smoking ceases.
- u *Obesity.* Added weight augments the risk of diabetes mellitus, hypertension, and elevated serum cholesterol levels.
- u *Physical activity.* Regular exercise reduces the risk.
- u *Stress.* Added stress or type A personality increases the risk.
- u *Diabetes mellitus.* This disorder raises the risk, especially in women.
- u *Other modifiable factors.* Increased levels of serum fibrinogen and uric acid; elevated hematocrit; reduced vital capacity; high resting heart rate; thyrotoxicosis; and use of oral contraceptives heighten the risk.

Uncommon causes of reduced coronary artery blood flow include dissecting aneurysms, infectious vasculitis, syphilis, and congenital defects in the coronary vascular system. Coronary artery spasms may also impede blood flow. (See [Understanding coronary artery spasm.](#))

Complications

When a coronary artery goes into spasm or is occluded by plaques, blood flow to the myocardium supplied by that vessel decreases, causing angina pectoris. Failure to remedy the occlusion causes ischemia and, eventually, myocardial tissue infarction.

Assessment findings

The classic symptom of coronary artery disease is angina, the direct result of inadequate flow of oxygen to the myocardium. The patient usually describes it as a burning, squeezing, or crushing tightness in the substernal or precordial chest that may radiate to the left arm, neck, jaw, or shoulder blade. Typically, the patient clenches his fist over his chest or rubs his left arm when describing the pain. Nausea, vomiting, fainting, sweating, and cool extremities may accompany the tightness.

Angina commonly occurs after physical exertion but may also follow emotional excitement, exposure to cold, or a large meal. Angina may also develop during sleep from which symptoms awaken the patient.

The patient's history suggests a pattern to the type and onset of pain. If the pain is predictable and relieved by rest or nitrates, it's called *stable angina*. If it increases in frequency and duration and is more easily induced, it's referred to as *unstable* or *unpredictable angina*. Unstable angina generally indicates extensive or worsening disease and, untreated, may progress to myocardial infarction. An effort-induced pain that occurs with increasing frequency and with decreasing provocation is referred to as *crescendo angina*. If severe non-effort-produced pain occurs at rest without provocation, it's called *variant* or *Prinzmetal's angina*.

Understanding coronary artery spasm

In coronary artery spasm, a spontaneous, sustained contraction of one or more coronary arteries causes ischemia and dysfunction of the heart muscle. This disorder may also cause Prinzmetal's angina and even myocardial infarction in patients with nonoccluded coronary arteries.

Causes

The direct cause of coronary artery spasm is unknown, but possible contributing factors include:

- u altered influx of calcium across the cell membrane
- u intimal hemorrhage into the medial layer of the blood vessel
- u hyperventilation
- u elevated catecholamine levels
- u fatty buildup in the lumen.

Signs and symptoms

The major symptom of coronary artery spasm is angina. Unlike classic angina, this pain commonly occurs spontaneously and may be unrelated to physical exertion or emotional stress; it may, however, follow cocaine use. It's usually more severe than classic angina, lasts longer, and may be cyclic—recurring every day at the same time. Ischemic episodes may cause arrhythmias, altered heart rate, lower blood pressure and, occasionally, fainting caused by decreased cardiac output. Spasm in the left coronary artery may result in mitral valve prolapse, producing a loud systolic murmur and, possibly, pulmonary edema, with dyspnea, crackles, and hemoptysis. Myocardial infarction and sudden death may occur.

Treatment

After diagnosis by coronary angiography and 12-lead electrocardiography, the patient may receive calcium channel blockers (such as verapamil, nifedipine, or diltiazem) to reduce coronary artery spasm and to decrease vascular resistance, and nitrates (such as nitroglycerin or isosorbide dinitrate) to relieve chest pain. During cardiac catheterization, the patient with clean arteries may receive ergotamine to induce the spasm and aid in the diagnosis.

Nursing interventions

When caring for a patient with coronary artery spasm, explain all necessary procedures and teach him how to take his medications safely. For calcium antagonist therapy, monitor the patient's blood pressure, pulse rate, and cardiac rhythm strips to detect arrhythmias.

For nifedipine and verapamil therapy, monitor digoxin levels, and check for signs of digitalis toxicity. Because nifedipine may cause peripheral and periorbital edema, watch for fluid retention.

Because coronary artery spasm is sometimes associated with atherosclerotic disease, advise the patient to stop smoking, avoid overeating, minimize alcohol intake, and maintain a balance between exercise and rest.

Inspection may reveal evidence of atherosclerotic disease, such as xanthelasma and xanthoma. Ophthalmoscopic inspection may show increased light reflexes and arteriovenous nicking, suggesting hypertension, an important risk factor for coronary artery disease.

Palpation can uncover thickened or absent peripheral arteries, signs of cardiac enlargement, and abnormal contraction of the cardiac impulse, such as left ventricular akinesia or dyskinesia.

Auscultation may detect bruits, an S₃, an S₄, or a late systolic murmur (if mitral insufficiency is present).

Diagnostic tests

Diagnostic measures include the following:

- u Electrocardiography (ECG) during angina shows ischemia as demonstrated by T-wave inversion or ST-segment depression and, possibly, arrhythmias such as premature ventricular contractions. ECG results may be normal during pain-free periods. Arrhythmias may occur without infarction, secondary to ischemia. A Holter monitor may be used to obtain continuous graphic tracing of the ECG as the patient performs daily activities.
- u Treadmill or bicycle exercise test may provoke chest pain and ECG signs of myocardial ischemia in response to physical exertion. Monitoring of electrical rhythm may demonstrate T-wave inversion or ST-segment depression in the ischemic areas.
- u Coronary angiography reveals coronary artery stenosis or obstruction, collateral circulation, and the arteries' condition beyond the narrowing.
- u Myocardial perfusion imaging with thallium-201 during treadmill exercise detects ischemic areas of the myocardium, visualized as "cold spots."
- u In pharmacological myocardial perfusion imaging, a patent coronary artery vasodilator, usually dipyridamole, is administered and response is tested. This can be done in combination with stress testing. In normal arteries, coronary blood flow is increased to 3 to 4 times baseline. In arteries with stenosis, the decrease in blood flow is proportional to the percentage of occlusion.
- u Multiple gated acquisition scanning demonstrates cardiac wall motion and reflects injury to cardiac tissue.

Treatment

The goal of treatment in patients with angina is to reduce myocardial oxygen demand or increase the oxygen supply and reduce pain. Activity restrictions may be required to prevent onset of pain. Rather than eliminating activities, performing them more slowly often averts pain. Stress reduction techniques are also essential,

especially if known stressors precipitate pain. (See [Preventing coronary artery disease.](#))

Pharmacologic therapy consists primarily of nitrates, such as nitroglycerin, isosorbide dinitrate, or beta-adrenergic blockers or calcium channel blockers.

Obstructive lesions may necessitate atherectomy or coronary artery bypass graft surgery, using vein grafts. Percutaneous transluminal coronary angioplasty (PTCA) may be performed during cardiac catheterization to compress fatty deposits and relieve occlusion. In patients with calcification, PTCA may reduce the obstruction by fracturing the plaque. (See [Relieving occlusions with angioplasty.](#))

ALERT PTCA carries certain risks but causes fewer complications than surgery. Complications after PTCA can include circulatory insufficiency, death (rarely), myocardial infarction, restenosis of the vessels, retroperitoneal bleeding, sudden coronary occlusions, or vasovagal response and arrhythmias.

PTCA is a viable alternative to grafting in elderly patients or in those who otherwise can't tolerate cardiac surgery. However, patients with a left main coronary artery occlusion, lesions in extremely tortuous vessels, or occlusions older than 3 months aren't candidates for PTCA.

PTCA may be done in combination with coronary stenting, or stents may be placed alone. Stents provide a framework to hold an artery open by securing flaps of tunica media against an artery wall. Intravascular coronary stenting is done to reduce the incidence of restenosis. Prosthetic intravascular cylindrical stents made of stainless steel coil are positioned at the site of the occlusion. To be eligible for this procedure, the patient must be able to tolerate anticoagulant therapy and the vessel to be stented must be at least 3 mm in diameter.

PREVENTION

Preventing coronary artery disease

Because coronary artery disease is so widespread, prevention is important. Dietary restrictions aimed at reducing the intake of calories (in obesity) and of salt, fats, and cholesterol minimize the risk, especially when supplemented with regular exercise. Abstention from smoking and reduction of stress are also essential.

Other preventive actions include control of hypertension (with diuretics or sympathetic beta blockers), control of elevated serum cholesterol or triglyceride levels (with antilipemics such as HMG-reductase inhibitors, such as cerivastatin [Baycol], atorvastatin calcium [Lipitor], pravastatin sodium [Pravachol], or simvastatin [Zocor]), and measures to minimize platelet aggregation and the danger of blood clots (with aspirin, for example).

Laser angioplasty corrects occlusion by vaporizing fatty deposits with the excimer or hot-tip laser device. Percutaneous myocardial revascularization (PMR) is an investigational procedure that uses a laser to create channels in the heart muscle to improve perfusion to the myocardium. A carbon dioxide laser is used to create transmural channels from the epicardial layer to the myocardium, extending into the left ventricle. This technique is also known as transmyocardial revascularization (TMR) and appears to be up to 90% effective in treating severe symptoms.

Rotational ablation (or rotational atherectomy) removes atheromatous plaque with a high-speed, rotating burr covered with diamond crystals. Another method recently approved is an angiojet system septa to remove clots in symptomatic coronary arteries and coronary artery bypass grafts. It's an alternative to thrombolytic therapy and involves a jet stream of saline solution and a catheter to seek out clots. After the clot is removed, the patient can undergo angioplasty.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: More than body requirements
- u Altered role performance
- u Altered sexuality patterns
- u Altered tissue perfusion (cardiopulmonary)
- u Anxiety
- u Decreased cardiac output
- u Denial
- u Impaired gas exchange
- u Knowledge deficit
- u Pain

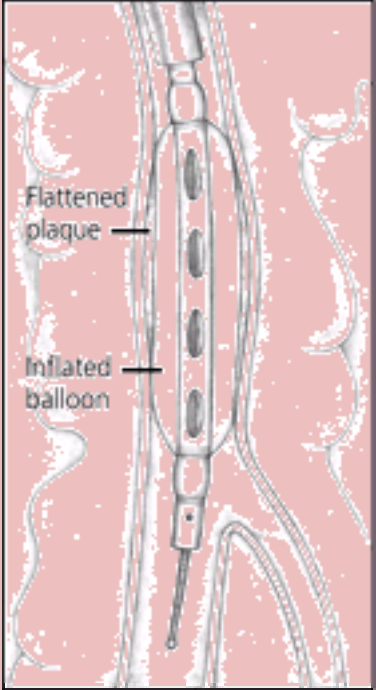

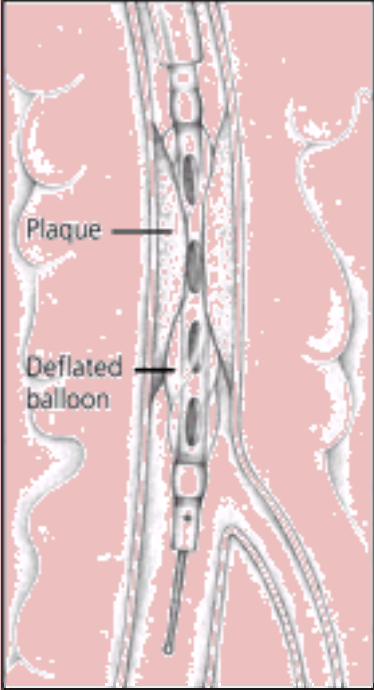

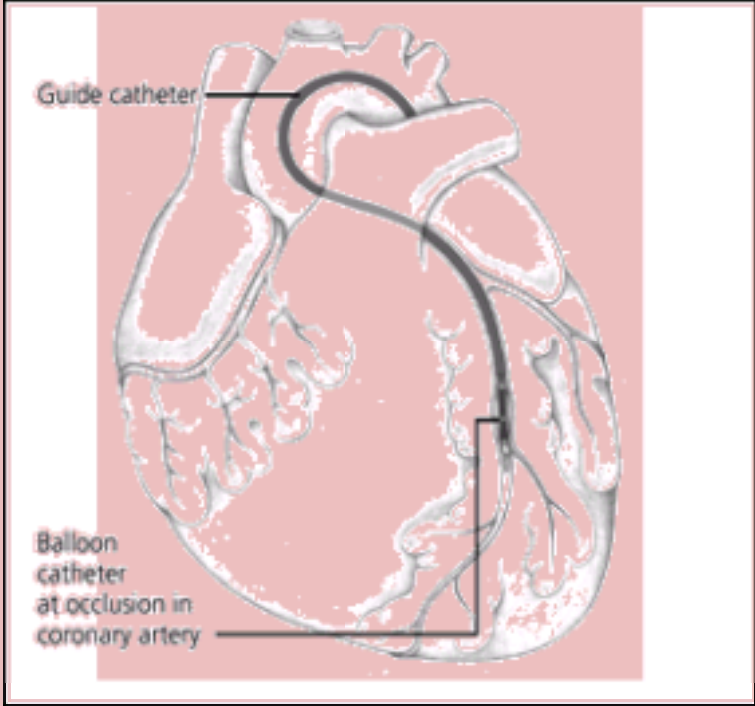

Relieving occlusions with angioplasty

For a patient with an occluded coronary artery, percutaneous transluminal coronary angioplasty can open the artery without opening the chest—an important advantage over bypass surgery.

First, coronary angioplasty must confirm the presence and location of the arterial occlusion. Then, a guide catheter is threaded through the patient's femoral artery into the coronary artery under fluoroscopic guidance.

When angiography shows the guide catheter positioned at the occlusion site, a smaller double-lumen balloon catheter is carefully inserted through the guide catheter and the balloon is directed through the occlusion (below, left). A marked pressure gradient is obvious.

The balloon is alternately inflated and deflated until an angiogram verifies successful arterial dilation (below, right) and that the pressure gradient has decreased.

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain adequate ventilation.
- u The patient will maintain hemodynamic stability.
- u The patient will plan menus appropriate to prescribed diet.

- u The patient will demonstrate understanding of information that has been taught.
- u The patient will express concern about self-concept, esteem, and body image.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u During anginal episodes, monitor blood pressure and heart rate. Take a 12-lead ECG during anginal episodes before administering nitroglycerin or other nitrates. Record duration of pain, amount of medication required to relieve it, and accompanying symptoms.
- u Ask the patient to grade the severity of his pain on a scale of 1 to 10. This allows him to give his individual assessment of pain as well as of the effectiveness of pain-relieving medications.
- u Keep nitroglycerin available for immediate use. Instruct the patient to call immediately whenever he feels chest, arm, or neck pain and before taking nitroglycerin.
- u After catheterization, review the expected course of treatment with the patient and family members. Monitor the catheter site for bleeding. Also check for distal pulses. To counter the diuretic effect of the dye, increase I.V. fluids and make sure the patient drinks plenty of fluids. Assess potassium levels, and add potassium to the I.V. fluid, if necessary.
- u During catheterization, monitor for dye reactions. If symptoms such as falling blood pressure, bradycardia, diaphoresis, and light-headedness appear, increase parenteral fluids as ordered, administer nasal oxygen, place the patient in the Trendelenburg position, and administer I.V. atropine if necessary.
- u After PTCA and intravascular stenting, maintain heparinization, observe for bleeding systemically and at the site, and keep the affected leg immobile. In PMR, the patient must also remain immobile as stents are left in the patient until his clotting time is less than 180 seconds. Precordial blood must be taken every 8 hours for 24 hours for cardiac enzyme levels. Complete blood count and electrolyte levels are monitored.
- u After rotational ablation, monitor the patient for chest pain, hypotension, coronary artery spasm, and bleeding from the catheter site. Provide heparin and antibiotic therapy for 24 to 48 hours as ordered.
- u After bypass surgery, provide care for the I.V. set, pulmonary artery catheter, and endotracheal tube. Monitor blood pressure, intake and output, breath sounds, chest tube drainage, and cardiac rhythm, watching for signs of ischemia and arrhythmias. I.V. epinephrine, nitroprusside, dopamine, albumin, potassium, and blood products may be necessary. The patient may also need temporary epicardial pacing, especially if the surgery included replacement of the aortic valve.

Intra-aortic balloon pump insertion may be necessary until the patient stabilizes. Also observe for and treat chest pain. Perform vigorous chest physiotherapy and guide the patient in pulmonary self-care.

Patient teaching

- u Before cardiac catheterization, explain the procedure to the patient. Make sure he knows why it's necessary, understands the risks, and realizes that it may indicate a need for interventional therapies such as PTCA, bypass surgery, atherectomy, and laser angioplasty.
- u If the patient is scheduled for surgery, explain the procedure, provide a tour of the intensive care unit, introduce him to the staff, and discuss postoperative care.
- u Help the patient determine which activities precipitate episodes of pain. Help him identify and select more effective coping mechanisms to deal with stress. Occupational change may be needed to prevent symptoms, but many patients reject this alternative.
- u Stress the need to follow the prescribed drug regimen.
- u Encourage the patient to maintain the prescribed low-sodium diet and start a low-calorie diet as well.
- u Explain that recurrent angina symptoms after PTCA or rotational ablation may signal reobstruction.
- u Encourage regular, moderate exercise. Refer the patient to a cardiac rehabilitation center or cardiovascular fitness program near his home or workplace. The staff can set up a program of exercise that best meets the patient's needs and limitations. Encourage other family members or a friend to join in the physical activity to encourage the patient's commitment to the exercise program.
- u Reassure the patient that he can resume sexual activity and that modifications can allow for sexual fulfillment without fear of overexertion, pain, or reocclusion.
- u Refer the patient to a program to stop smoking. Acknowledge that this will be difficult but that he should make every attempt to stop smoking immediately and never restart.

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy—also called congestive cardiomyopathy—results from extensively damaged myocardial muscle fibers. It interferes with myocardial metabolism and grossly dilates every heart chamber, giving the heart a globular shape. When hypertrophy coexists with dilated cardiomyopathy, the heart ejects blood less efficiently than normal and a large volume of blood remains in the left ventricle after systole, causing signs of heart failure.

Dilated cardiomyopathy most commonly affects middle-aged men but can occur in any age-group. Because it isn't usually diagnosed until the advanced stages, the prognosis is generally poor. Most patients, especially those over age 55, die within 2 years of symptom onset.

Causes

The cause of most cardiomyopathies is unknown. Dilated cardiomyopathy can result from myocardial destruction by toxic, infectious, or metabolic agents; endocrine and electrolyte disorders; nutritional deficiencies; muscle disorders (such as myasthenia gravis, muscular dystrophy, and myotonic dystrophy); infiltrative disorders (such as hemochromatosis and amyloidosis); and sarcoidosis.

Cardiomyopathy may be associated with alcoholism, viral myocarditis (especially after infection with coxsackievirus B, poliovirus, and influenza virus), and acquired immunodeficiency syndrome.

ADVANCED PRACTICE

<div></div> <div>Assessment findings in cardiomyopathies</div>	
TYPE	ASSESSMENT FINDINGS

<i>Dilated cardiomyopathy</i>	<ul style="list-style-type: none">⌞ Generalized weakness, fatigue⌞ Chest pain, palpitations⌞ Syncope⌞ Tachycardia⌞ Narrow pulse pressure⌞ Pulmonary congestion, pleural effusions⌞ Neck vein distention, peripheral edema⌞ Paroxysmal nocturnal dyspnea, orthopnea, dyspnea on exertion
<i>Hypertrophic cardiomyopathy</i>	<ul style="list-style-type: none">⌞ Angina, palpitations⌞ Syncope⌞ Orthopnea, dyspnea with exertion⌞ Pulmonary congestion⌞ Loud systolic murmur⌞ Life-threatening arrhythmias⌞ Sudden cardiac arrest
<i>Restrictive cardiomyopathy</i>	<ul style="list-style-type: none">⌞ Generalized weakness, fatigue⌞ Bradycardia⌞ Dyspnea⌞ Neck vein distention, peripheral edema⌞ Liver congestion, abdominal ascites

Metabolic cardiomyopathies are related to endocrine and electrolyte disorders and nutritional deficiencies. Dilated cardiomyopathy may develop in patients with hyperthyroidism, pheochromocytoma, beriberi, and kwashiorkor. Cardiomyopathy may also result from rheumatic fever, especially among children with myocarditis.

Cardiomyopathy may develop during the last trimester of pregnancy or within months after delivery. Its cause is unknown, but it occurs most frequently in multiparous women over age 30, particularly those with malnutrition or preeclampsia. In these patients, cardiomegaly and heart failure may reverse with treatment, allowing a subsequent normal pregnancy. If cardiomegaly persists despite treatment, the prognosis is poor.

Dilated cardiomyopathy has been linked to the use of doxorubicin, cyclophosphamide, cocaine, and fluorouracil. Also, familial forms of this disorder may exist, possibly with an X-linked inheritance pattern.

Complications

Dilated cardiomyopathy can lead to intractable heart failure, arrhythmias, and emboli. Ventricular arrhythmias may lead to syncope and sudden death.

Assessment findings

The patient may have a history of a disorder that can cause cardiomyopathy. He often complains of a gradual onset of shortness of breath, orthopnea, dyspnea on exertion, paroxysmal nocturnal dyspnea, fatigue, dry cough at night, palpitations, and vague chest pain.

Inspection may reveal peripheral edema, jugular vein distention, ascites, and peripheral cyanosis.

Palpation of peripheral pulses may disclose tachycardia even at rest and pulsus alternans in late stages. Palpation may also reveal hepatomegaly and splenomegaly.

Percussion may detect hepatomegaly. Dullness is heard over lung areas that are fluid-filled.

Blood pressure auscultation may show a narrow pulse pressure. Cardiac auscultation reveals irregular rhythms, diffuse apical impulses, pansystolic murmur (such as mitral and tricuspid insufficiency caused by cardiomegaly and weak papillary muscles), and S₃ and S₄ gallop rhythms. Lung auscultation may reveal crackles and gurgles.

Dilated cardiomyopathy may need to be differentiated from other types of cardiomyopathy. (See [Assessment findings in cardiomyopathies.](#))

Diagnostic tests

No single test confirms dilated cardiomyopathy. Diagnosis requires elimination of other possible causes of heart failure and arrhythmias.

- ⌞ Electrocardiography (ECG) and angiography rule out ischemic heart disease. The ECG may also show biventricular hypertrophy, sinus tachycardia, atrial enlargement, ST-segment and T-wave abnormalities and, in 20% of patients, atrial fibrillation or left bundle-branch block. QRS complexes are decreased in amplitude.
- ⌞ Chest X-rays demonstrate moderate to marked cardiomegaly usually affecting all heart chambers, along with pulmonary congestion, pulmonary venous hypertension, and pleural effusion. Pericardial effusion may appear as a water-bottle shape.
- ⌞ Echocardiography may identify ventricular thrombi, global hypokinesis, and the degrees of left ventricular dilation and dysfunction.
- ⌞ Cardiac catheterization can show left ventricular dilation and dysfunction, elevated left ventricular and (in some instances) right ventricular filling pressures, and diminished cardiac output.
- ⌞ Gallium scans may identify patients with dilated cardiomyopathy and myocarditis.
- ⌞ Transvenous endomyocardial biopsy may be useful in some patients to determine the underlying disorder, such as amyloidosis or myocarditis.

Treatment

In dilated cardiomyopathy, the goal of treatment is to correct the underlying causes and to improve the heart's pumping ability with digitalis glycosides, diuretics, oxygen, anticoagulants, vasodilators, and a low-sodium diet supplemented by vitamin therapy. Antiarrhythmics may be used to treat arrhythmias. If cardiomyopathy is due to alcoholism, ingestion of alcohol must be stopped. A woman of childbearing age should avoid pregnancy.

Therapy may also include prolonged bed rest and selective use of corticosteroids, particularly when myocardial inflammation is present.

Vasodilators reduce preload and afterload, thereby decreasing congestion and increasing cardiac output. Acute heart failure necessitates vasodilation with nitroprusside I.V. or nitroglycerin I.V. Long-term treatment may include prazosin, hydralazine, isosorbide dinitrate and, if the patient is on prolonged bed rest, anticoagulants. Dopamine, dobutamine, and amrinone may be useful during the acute stage.

When these treatments fail, therapy may require heart transplantation for carefully selected patients.

Cardiomyoplasty may be used for those who aren't candidates for transplants and who are symptomatic at rest. In cardiomyoplasty, the latissimus dorsi muscle is wrapped around the ventricle, assisting the ventricle to effectively pump blood. A cardiomyostimulator delivers bursts of electrical impulses during systole to contract

the muscle.

Nursing diagnoses

u Activity intolerance u Altered family processes u Altered tissue perfusion (cardiopulmonary) u Anxiety u Decreased cardiac output u Fatigue u Fluid volume excess u Hopelessness u Impaired gas exchange u Impaired physical mobility u Ineffective breathing pattern u Knowledge deficit

Key outcomes

- u The patient will maintain adequate cardiac output and hemodynamic stability.
- u The patient will maintain adequate ventilation.
- u The patient won't develop complications of fluid volume excess.
- u The patient will recognize and accept limitations of chronic illness.
- u The patient will resume and maintain as many former roles as possible.
- u The patient will express feelings of increased energy and decreased fatigue.

Nursing interventions

- u Alternate periods of rest with required activities of daily living and treatments. Provide personal care as needed to prevent fatigue.
- u Provide active or passive range-of-motion exercises to prevent muscle atrophy while the patient is on bed rest.
- u Consult with the dietitian to provide a low-sodium diet that the patient can accept.
- u Monitor for signs of progressive failure (decreased arterial pulses, increased neck vein distention) and compromised renal perfusion (oliguria, increased blood urea nitrogen and serum creatinine levels, and electrolyte imbalances). Weigh the patient daily.
- u Administer oxygen as needed.
- u If the patient is receiving vasodilators, check his blood pressure and heart rate frequently. If he becomes hypotensive, stop the infusion and place him supine with legs elevated to increase venous return and ensure cerebral blood flow.
- u If the patient is receiving diuretics, monitor for signs of resolving congestion (decreased crackles and dyspnea) or too vigorous diuresis. Check serum potassium levels for hypokalemia, especially if therapy includes digitalis glycosides.
- u Therapeutic restrictions and an uncertain prognosis usually cause profound anxiety and depression, so offer support and let the patient express his feelings. Be flexible with visiting hours. If confinement to a facility is prolonged, try to obtain permission for the patient to spend occasional weekends at home.
- u Allow the patient and family members to express their fears and concerns. As needed, help them identify effective coping strategies.

CULTURAL TIP Members of many cultures with religious origins and beliefs may request special prayers, rituals, or anointing of the patient for healing purposes and spiritual support. It's important to support these individuals and to inquire as to what rituals they may wish to perform for the patient to help in this process. If a metal object is placed on or near the patient, respect this as part of the spiritual belief of the patient, but be prepared to remove it if necessary (such as if the patient requires defibrillation or transport to undergo tests, such as magnetic resonance imaging or computed tomography scan.)

Patient teaching

- u Before discharge, teach the patient about the illness and its treatment.
- u Emphasize the need to restrict sodium intake, to watch for weight gain, and to take digitalis glycosides as prescribed and watch for toxic effects (such as anorexia, nausea, and vomiting).
- u Encourage family members to learn cardiopulmonary resuscitation because sudden cardiac arrest is possible.

ENDOCARDITIS

Endocarditis is an infection of the endocardium, heart valves, or cardiac prosthesis that results from bacterial or fungal invasion.

In infective endocarditis, fibrin and platelets cluster on valve tissue and engulf circulating bacteria or fungi. This produces vegetation, which, in turn, may cover the valve surfaces, causing deformities and destruction of valvular tissue. It may also extend to the chordae tendineae, causing them to rupture and leading to valvular insufficiency.

Sometimes vegetation forms on the endocardium, usually in areas altered by rheumatic, congenital, or syphilitic heart disease. It also may form on normal surfaces. Vegetative growth on the heart valves, endocardial lining of a heart chamber, or the endothelium of a blood vessel may embolize to the spleen, kidneys, central nervous system, and lungs.

Endocarditis can be classified as native valve endocarditis, endocarditis in I.V. drug users, and prosthetic valve endocarditis. It can be acute or subacute. Untreated, endocarditis is usually fatal. With proper treatment, however, about 70% of patients recover. The prognosis is worst when endocarditis causes severe valvular damage—leading to insufficiency and left-sided heart failure—or when it involves a prosthetic valve.

Causes

Acute infective endocarditis usually results from bacteremia that follows septic thrombophlebitis, open-heart surgery involving prosthetic valves, or skin, bone, and pulmonary infections.

The most common causative organisms are group A nonhemolytic streptococci, staphylococci, and enterococci. However, almost any organism can cause endocarditis, including *Neisseria gonorrhoeae*, *Pseudomonas*, *Salmonella*, *Streptobacillus*, *Serratia marcescens*, bacteroids, *Haemophilus*, *Brucella*, *Mycobacterium*, *N. meningitidis*, *Listeria*, *Legionella*, diphtheroids, enteric gram-negative bacilli, spirochetes, rickettsiae, chlamydiae, and the fungi *Candida* and *Aspergillus*.

Subacute infective endocarditis typically occurs in people with acquired valvular or congenital cardiac lesions. It can also follow dental, genitourinary, gynecologic, and GI procedures. The most common infecting organisms are *Streptococcus viridans*, which normally inhabits the upper respiratory tract, and *Streptococcus faecalis* (enterococcus), which is typically found in GI and perineal flora.

Preexisting conditions can predispose a person to endocarditis (including rheumatic valvular disease), congenital heart disease, mitral valve prolapse, degenerative heart disease, calcific aortic stenosis (in elderly people), asymmetrical septal hypertrophy, Marfan syndrome, syphilitic aortic valve, I.V. drug abuse, and long-term hemodialysis with an arteriovenous shunt or fistula. However, up to 40% of affected patients have no underlying heart disease.

Complications

Typically, the heart compensates for the malfunctioning valves for years until left-sided heart failure, valve stenosis or insufficiency, or myocardial erosion sets in. Also, vegetation on the valves can cause embolic debris to lodge in the small vasculature of the visceral tissue.

Assessment findings

The patient may report a predisposing condition and complain of nonspecific symptoms, such as weakness, fatigue, weight loss, anorexia, arthralgia, night sweats, and an intermittent fever that may recur for weeks.

Inspection may reveal petechiae of the skin (especially common on the upper anterior trunk) and the buccal, pharyngeal, or conjunctival mucosa, and splinter hemorrhages under the nails. Rarely, you may see Osler's nodes (tender, raised, subcutaneous lesions on the fingers or toes), Roth's spots (hemorrhagic areas with white centers on the retina), and Janeway lesions (purplish macules on the palms or soles). Clubbing of the fingers may be present in patients with long-standing

disease.

Auscultation may reveal a murmur in all patients except those with early acute endocarditis and I.V. drug users with tricuspid valve infection. The murmur is usually loud and regurgitant, which is typical of the underlying rheumatic or congenital heart disease. A murmur that changes suddenly or a new murmur that develops in the presence of fever is a classic physical sign of endocarditis.

Percussion and palpation may reveal splenomegaly in long-standing disease. In patients who have developed left-sided heart failure, your assessment may reveal dyspnea, tachycardia, and bibasilar crackles.

In 12% to 35% of patients with subacute endocarditis, embolization from vegetating lesions or diseased valve tissue may produce typical characteristics of splenic, renal, cerebral, or pulmonary infarction, or peripheral vascular occlusion:

- u Splenic infarction causes pain in the upper left quadrant, radiating to the left shoulder, and abdominal rigidity.
- u Renal infarction causes hematuria, pyuria, flank pain, and decreased urine output.
- u Cerebral infarction causes hemiparesis, aphasia, and other neurologic deficits.
- u Pulmonary infarction causes cough, pleuritic pain, pleural friction rub, dyspnea, and hemoptysis. These signs are most common in right-sided endocarditis, which typically occurs among I.V. drug abusers and after cardiac surgery.
- u Peripheral vascular occlusion causes numbness and tingling in an arm, leg, finger, or toe, or signs of impending peripheral gangrene.

Diagnostic tests

Three or more blood cultures during a 24- to 48-hour period identify the causative organism in up to 90% of patients. The remaining 10% may have negative blood cultures, possibly suggesting fungal or difficult-to-diagnose infections such as *Haemophilus parainfluenzae*. Other abnormal but nonspecific laboratory results include:

- u normal or elevated white blood cell count and differential
- u abnormal histiocytes (macrophages)
- u normocytic, normochromic anemia (in subacute infective endocarditis)
- u elevated erythrocyte sedimentation rate and serum creatinine levels
- u positive serum rheumatoid factor in about half of all patients with endocarditis after the disease is present for 6 weeks
- u proteinuria and microscopic hematuria.

Echocardiography may identify valvular damage in up to 80% of patients with native valve disease. An electrocardiogram reading may show atrial fibrillation and other arrhythmias that accompany valvular disease.

Treatment

The goal of treatment is to eradicate all of the infecting organisms from the vegetation. Therapy should start promptly and continue over several weeks. Selection of an anti-infective drug is based on the infecting organism and sensitivity studies. Although blood cultures are negative in 10% to 20% of the subacute cases, the doctor may want to determine the *probable* infecting organism. I.V. antibiotic therapy usually lasts about 4 to 6 weeks.

Supportive treatment includes bed rest, aspirin for fever and aches, and sufficient fluid intake. Severe valvular damage, especially aortic insufficiency or infection of a cardiac prosthesis, may require corrective surgery if refractory heart failure develops or if an infected prosthetic valve must be replaced.

Nursing diagnoses

u Activity intolerance u Altered role performance u Decreased cardiac output u Diversional activity deficit u Impaired gas exchange

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain hemodynamic stability with adequate cardiac output.
- u The patient will exhibit no arrhythmias.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings about diminished capacity to perform usual roles.
- u The patient will express interest in using leisure time meaningfully.

Nursing interventions

- u Stress the importance of bed rest. Assist the patient with bathing, if necessary. Provide a bedside commode because this method puts less stress on the heart than using a bedpan. Offer diversional activities that are physically undemanding.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u Before giving antibiotics, obtain a patient history of allergies. Administer antibiotics on time to maintain consistent drug levels in the blood.
- u Observe for signs of infiltration or inflammation at the venipuncture site, a possible complication of long-term I.V. administration. To reduce the risk of this complication, rotate venous access sites.
- u Assess cardiovascular status frequently, and watch for signs of left-sided heart failure, such as dyspnea, hypotension, tachycardia, tachypnea, crackles, and weight gain. Check for changes in cardiac rhythm or conduction.
- u Administer oxygen and evaluate arterial blood gas values, as needed, to ensure adequate oxygenation.

ALERT Watch for signs of embolization (hematuria, pleuritic chest pain, upper left quadrant pain, or paresis), a common occurrence during the first 3 months of treatment. Tell the patient to watch for and report these signs, which may indicate impending peripheral vascular occlusion or splenic, renal, cerebral, or pulmonary infarction.

- u Monitor the patient's renal status (including blood urea nitrogen levels, creatinine clearance, and urine output) to check for signs of renal emboli and drug toxicity.

Patient teaching

- u Teach the patient about the anti-infectives he'll continue to take. Stress the importance of taking the medication and restricting activities for as long as the doctor orders.
- u Tell the patient to watch closely for fever, anorexia, and other signs of relapse about 2 weeks after treatment stops.
- u Make sure the susceptible patient understands the need for prophylactic antibiotics before, during, and after dental work, childbirth, and genitourinary, GI, or gynecologic procedures.
- u Teach the patient to brush his teeth with a soft toothbrush and rinse his mouth thoroughly. Tell him to avoid flossing his teeth and using irrigation devices.
- u Teach the patient how to recognize symptoms of endocarditis, and tell him to notify the doctor immediately if such symptoms occur.

HEART FAILURE

When the myocardium can't pump effectively enough to meet the body's metabolic needs, heart failure occurs. Pump failure usually occurs in a damaged left ventricle (called left-sided heart failure), but it may happen in the right ventricle (called right-sided heart failure) primarily, or secondary to left-sided heart failure. Usually, though, left-sided and right-sided heart failure develop simultaneously.

Heart failure is classified as *high-output* or *low-output*, *acute* or *chronic*, *left-sided* or *right-sided*, and *forward* or *backward*. (See [Classifying heart failure](#).)

For many patients, the symptoms of heart failure restrict the ability to perform activities of daily living, severely affecting quality of life. Advances in diagnostic and therapeutic techniques have greatly improved the outlook for these patients, but the prognosis still depends on the underlying cause and its response to treatment.

Causes and pathophysiology

Heart failure frequently results from a primary abnormality of the heart muscle (such as an infarction) that impairs ventricular function to the point that the heart can no longer pump sufficient blood. (See [What happens in heart failure](#).) Heart failure can also result from causes not related to myocardial function. These include:

- u mechanical disturbances in ventricular filling during diastole, which result from blood volume that is insufficient for the ventricle to pump. This occurs in mitral stenosis secondary to rheumatic heart disease or constrictive pericarditis and atrial fibrillation.
- u systolic hemodynamic disturbances—such as excessive cardiac workload caused by volume overload or pressure overload—that limit the heart's pumping ability. These disturbances can result from mitral or aortic insufficiency, which causes volume overload, and aortic stenosis or systemic hypertension, which results in increased resistance to ventricular emptying.

In addition, certain conditions can predispose the patient to heart failure, particularly if he has some form of underlying heart disease. These include:

- u arrhythmias—such as tachyarrhythmias, which can reduce ventricular filling time; bradycardia, which can reduce cardiac output; and arrhythmias that disrupt the normal atrial and ventricular filling synchrony
- u pregnancy and thyrotoxicosis because of the increased demand for cardiac output
- u pulmonary embolism because it elevates pulmonary arterial pressures that can cause right-sided heart failure
- u infections because increased metabolic demands further burden the heart
- u anemia because to meet the oxygen needs of the tissues, cardiac output must increase
- u increased physical activity, emotional stress, increased salt or water intake, or failure to comply with the prescribed treatment regimen for the underlying heart disease.

ADVANCED PRACTICE

Classifying heart failure

Heart failure is usually classified by the site of heart failure (left ventricle, right ventricle, or both). Some practitioners may also classify heart failure by level of cardiac output, stage, and direction (high-output or low-output, acute or chronic, or forward or backward). These classifications represent a guide to different clinical aspects of heart failure that may be helpful in practice and treatment.

Left-sided failure

Failure of the left ventricle to pump blood to the vital organs and periphery is usually caused by myocardial infarction (MI). Decreased left ventricular output causes fluid to accumulate in the lungs, which precipitates dyspnea, orthopnea, and paroxysmal nocturnal dyspnea.

Right-sided failure

Resulting from failure of the right ventricle to pump sufficient blood to the lungs, this type usually is caused by disorders that increase pulmonary vascular resistance, such as pulmonary embolism, pulmonic stenosis, and pulmonary hypertension. Right-sided heart failure produces congestive hepatomegaly, ascites, and edema.

High-output failure

Failure with an elevated cardiac output occurs when tissue demands for oxygenated blood exceed the heart's ability to supply it. High-output failure occurs in arteriovenous fistula, hyperthyroidism, anemia, sickle cell anemia, beriberi, Paget's disease of the bone, and thyrotoxicosis.

Low-output failure

Failure with decreased cardiac output is caused by increased pumping ability of the myocardium. Low output failure occurs in coronary artery disease, hypertension, primary myocardial disease, and valvular disease.

Acute failure

Acute heart failure occurs suddenly, such as with an MI or a ruptured cardiac valve. The sudden reduction in cardiac output that occurs results in systemic hypotension without peripheral edema. Acute heart failure may occur in a chronic condition, such as when a patient with chronic heart failure experiences acute heart failure with MI. It may also occur in any condition that stresses a heart that is already diseased.

Chronic failure

This type of heart failure occurs gradually and is sustained for long periods. The arterial blood pressure doesn't drop, but peripheral edema is present. Chronic failure may occur in cardiomyopathy or multivalvular disease, or in a healed, extensive MI.

Forward failure

In forward failure, the heart fails to expel enough blood into the arterial system. Sodium and water retention results from decreased renal perfusion and excessive proximal tubular sodium reabsorption or excessive distal tubular reabsorption, through activation of the renin-angiotensin-aldosterone system.

Backward failure

When backward heart failure occurs, one ventricle fails to empty its contents normally, and end-diastolic ventricular pressures rise. The pressures and volume in the atrium and venous system behind the failing ventricle also increase, and sodium and water retention occurs because of the elevated systemic venous and capillary pressures and the resulting transudation of fluid into the interstitial space.

Complications

Pulmonary congestion can lead to pulmonary edema, a life-threatening condition. Decreased perfusion to major organs, especially the brain and kidneys, can cause these organs to fail. Myocardial infarction can occur because the oxygen demands of the overworked heart can't be met.

Assessment findings

The patient's history reveals a disorder or condition that can precipitate heart failure. The patient commonly complains of shortness of breath, which occurs in early

stages during activity and, in late stages, also at rest. He may report that dyspnea worsens at night when he lies down. He may use two or three pillows to elevate his head to sleep or have to sleep sitting up in a chair. He may relate that his shortness of breath wakes him up shortly after he falls asleep, causing him to sit bolt upright to catch his breath. He may remain dyspneic, coughing, and wheezing even when he sits up. This is referred to as paroxysmal nocturnal dyspnea.

PATHOPHYSIOLOGY

What happens in heart failure

These illustrations show, step-by-step, what happens when myocardial damage leads to heart failure.

Left-sided heart failure

Increased workload and end-diastolic volume enlarge the left ventricle. Because of the lack of oxygen, however, the ventricle enlarges with stretched tissue rather than functional tissue. The patient may experience increased heart rate, pale and cool tingling in the extremities, decreased cardiac output, and arrhythmias.

Diminished left ventricular function allows blood to pool in the ventricle and the atrium and eventually back up into the pulmonary veins and capillaries. At this stage, the patient may experience dyspnea on exertion, confusion, dizziness, postural hypotension, decreased peripheral pulses and pulse pressure, cyanosis, and an S₃ gallop.

As the pulmonary circulation becomes engorged, rising capillary pressure pushes sodium and water into the interstitial space, causing pulmonary edema. Note coughing, subclavian retractions, crackles, tachypnea, elevated pulmonary artery pressure, diminished pulmonary compliance, and increased partial pressure of carbon dioxide.

When the patient lies down, fluid in the extremities moves into systemic circulation. Because the left ventricle can't handle the increased venous return, fluid pools in the pulmonary circulation, worsening pulmonary edema. You may note decreased breath sounds, dullness on percussion, crackles, and orthopnea.

The right ventricle may now become stressed because it's pumping against greater pulmonary vascular resistance and left ventricular pressure. When this occurs, the patient's symptoms worsen.

Right-sided heart failure

The stressed right ventricle hypertrophies with the formation of stretched tissue. Increasing conduction time and deviation of the heart from its normal axis can cause arrhythmias. If the patient doesn't already have left-sided heart failure, he may experience increased heart rate, cool skin, cyanosis, decreased cardiac output, palpitations, and dyspnea.

Blood pools in the right ventricle and right atrium. The backed-up blood causes pressure and congestion in the vena cava and systemic circulation. The patient has elevated central venous pressure, jugular vein distention, and hepatojugular reflux.

Backed-up blood also distends the visceral veins, especially the hepatic vein. As the liver and spleen become engorged, their function is impaired. The patient may develop anorexia, nausea, abdominal pain, palpable liver and spleen, weakness, and dyspnea secondary to abdominal distention.

Increasing capillary pressure forces excess fluid from the capillaries into the interstitial space. This causes tissue edema, especially in the lower extremities and abdomen. The patient may experience weight gain, pitting edema, and nocturia.

The patient may report that his shoes or rings have become too tight, a result of peripheral edema. He may also report increasing fatigue, weakness, insomnia, anorexia, nausea, and a sense of abdominal fullness (particularly in right-sided heart failure).

Inspection may reveal a dyspneic, anxious patient in respiratory distress. In mild cases, dyspnea may occur while the patient is lying down or active; in severe cases, it isn't related to position. The patient may have a cough that produces pink, frothy sputum. You may note cyanosis of the lips and nail beds, pale skin, diaphoresis, dependent peripheral and sacral edema, and jugular vein distention. Ascites may also be present, especially in patients with right-sided heart failure. If heart failure is chronic, the patient may appear cachectic.

When palpating the pulse, you may note that the skin feels cool and clammy. The pulse rate is rapid, and a pulsus alternans may be present. Hepatomegaly and, possibly, splenomegaly also may be present.

Percussion reveals dullness over lung bases that are fluid-filled.

Auscultation of the blood pressure may detect decreased pulse pressure, reflecting reduced stroke volume. Heart auscultation may disclose an S_3 and S_4 . Lung auscultation reveals moist, bibasilar crackles. If pulmonary edema is present, you hear crackles throughout the lung, accompanied by rhonchi and expiratory wheezing.

Diagnostic tests

Electrocardiography reflects heart strain or enlargement, or ischemia. It may also reveal atrial enlargement, tachycardia, and extrasystoles.

Chest X-rays show increased pulmonary vascular markings, interstitial edema, or pleural effusion and cardiomegaly.

Pulmonary artery pressure monitoring typically demonstrates elevated pulmonary artery and pulmonary artery wedge pressures, left ventricular end-diastolic pressure in left-sided heart failure, and elevated right atrial or central venous pressure in right-sided heart failure.

Managing pulmonary edema

Because of heart failure, fluid may accumulate in the extravascular spaces of the lungs. To intervene appropriately, you must accurately assess the severity of the patient's edema.

Initial stage

Signs and symptoms

- Persistent cough, which resembles throat-clearing when it begins
- Slight dyspnea and exercise intolerance
- Restlessness and anxiety
- Crackles at lung bases
- Diastolic gallop and S₃

Special considerations

- Check color and amount of expectoration.
- Start and maintain a keep-vein-open I.V. line.
- Position the patient for comfort, and elevate the head of the bed.
- Auscultate the chest for crackles and S₃.
- Administer medications as ordered; morphine is the drug of choice.
- Administer diuretics and potassium replacement, if necessary.
- Monitor arterial blood gas (ABG) and electrolyte levels.
- Calculate intake and output accurately.
- Monitor apical and radial pulses.
- Help the patient conserve strength.
- Provide emotional support.

Acute stage

Signs and symptoms

- Acute dyspnea
- Rapid, noisy respirations (audible wheeze, crackles) in all lung fields
- More intense cough with frothy blood-tinged sputum
- Cyanosis and cold, clammy skin
- Tachycardia and arrhythmias
- Hypotension
- Restlessness

Special considerations

- Administer supplemental oxygen as needed (preferably by high concentration mask or intermittent positive-pressure breathing apparatus).
- Aspirate the nasopharynx as needed.
- Give inotropic drugs such as digoxin as ordered.
- Give nitrates, morphine, and potent diuretics such as furosemide as ordered.
- Insert an indwelling urinary catheter.
- Monitor and record intake and output.
- Monitor ABG levels.
- Attach cardiac monitor leads, and monitor heart rate and for arrhythmias. Keep resuscitation equipment available. Prepare for intubation and mechanical ventilation in case it's needed.
- Provide emotional support for the patient and family.

Advanced stage

Signs and symptoms

- Decreased level of consciousness
- Ventricular arrhythmias, bradycardia, and shock
- Diminished breath sounds

Special considerations

- Assist with intubation and mechanical ventilation.
- Resuscitate the patient, if necessary.

Treatment

The aim of therapy is to improve pump function by reversing the compensatory mechanisms producing the clinical effects. Heart failure can usually be controlled quickly by treatment consisting of:

- diuresis (with diuretics, such as furosemide, hydrochlorothiazide, ethacrynic acid, bumetanide, spironolactone, or triamterene) to reduce total blood volume and circulatory congestion
- prolonged bed rest
- oxygen administration to increase oxygen delivery to the myocardium and other vital organ tissues
- inotropic drugs, such as digoxin, to strengthen myocardial contractility; sympathomimetics, such as dopamine and dobutamine, in acute situations; or amrinone, to increase contractility and cause arterial vasodilation
- vasodilators to increase cardiac output or angiotensin-converting enzyme inhibitors to decrease afterload
- antiembolism stockings to prevent venostasis and possible thromboembolism formation.

Treatment of acute pulmonary edema requires morphine; nitroglycerin or nitroprusside as a vasodilator to diminish blood return to the heart; dobutamine, dopamine, or amrinone to increase myocardial contractility and cardiac output; diuretics to reduce fluid volume; supplemental oxygen; and high Fowler's position. (See [Managing pulmonary edema.](#))

After recovery, the patient usually must continue taking digitalis glycosides, diuretics, and potassium supplements and must remain under medical supervision. If the patient with valve dysfunction has recurrent acute heart failure, surgical replacement may be necessary.

Nursing diagnoses

- Activity intolerance
- Altered nutrition: Less than body requirements
- Altered tissue perfusion (cardiopulmonary)
- Decreased cardiac output
- Fatigue
- Fluid volume

excess u Ineffective airway clearance u Ineffective breathing pattern u Knowledge deficit

Key outcomes

- u The patient will maintain hemodynamic stability.
- u The patient will maintain adequate cardiac output.
- u The patient will carry out activities of daily living without excess fatigue or decreased energy.
- u The patient won't develop complications of fluid volume excess.
- u The patient will maintain adequate ventilation.
- u The patient will maintain patent airway.

Nursing interventions

- u Place the patient in Fowler's position and give him supplemental oxygen to help him breathe more easily. Organize all activity to provide maximum rest periods.
- u Weigh the patient daily (the best index of fluid retention), and check for peripheral edema. Also, monitor I.V. intake and urine output (especially in the patient receiving diuretics).
- u Assess vital signs (for increased respiratory and heart rates and for narrowing pulse pressure) and mental status. Auscultate for abnormal heart and breath sounds. Report any changes immediately.
- u Frequently monitor blood urea nitrogen and serum creatinine, potassium, sodium, chloride, and magnesium levels.
- u Provide continuous cardiac monitoring during acute and advanced stages to identify and treat arrhythmias promptly.
- u To prevent deep vein thrombosis due to vascular congestion, assist the patient with range-of-motion exercises. Enforce bed rest, and apply antiembolism stockings. Check for calf pain and tenderness.

HOME CARE

Dealing with heart failure

To help a patient with heart failure deal with the disorder at home, use the following interventions:

- u Advise the patient to follow a low-sodium diet, if ordered. Identify low-sodium food substitutes and foods to avoid, and show how to read labels to assess sodium content. To evaluate compliance, analyze the patient's 24-hour dietary intake.
- u Show the patient how to take a pulse by placing a finger on the radial artery and counting for 1 minute. Then have him demonstrate the procedure.
- u Tell the patient to take digoxin at the same time each day, to check the pulse rate and rhythm before taking it, and to call the doctor if the rate is under 60 beats/minute or the rhythm is irregular.
- u Teach the patient to report important signs and symptoms, such as dizziness, blurred vision, shortness of breath, persistent dry cough, palpitations, increased fatigue, paroxysmal nocturnal dyspnea, swollen ankles, and decreased urine output.
- u Advise the patient to weigh himself at least three times per week and to report an increase of 3 to 5 lb (1.4 to 2.3 kg) in 1 week.
- u Instruct the patient taking a potassium-depleting diuretic to eat high-potassium foods, such as bananas and orange juice.
- u Instruct patient to avoid fatigue. Schedule activities to allow for rest periods.

Patient teaching

- u Advise the patient to avoid foods high in sodium content, such as canned or commercially prepared foods and dairy products, to curb fluid overload.
- u Prepare the patient to manage the disorder at home. (See [Dealing with heart failure.](#))

HYPERTENSION

Hypertension is an intermittent or sustained elevation of diastolic or systolic blood pressure. Serial blood pressure measurements greater than 140/90 mm Hg in people under age 50 or greater than 150/95 mm Hg in those over age 50 confirm hypertension.

Aside from characteristic high blood pressure, hypertension is classified according to its cause, severity, and type. The two major types are *essential* (also called primary or idiopathic) *hypertension*, the most common (90% to 95% of cases), and *secondary hypertension*, which results from renal disease or another identifiable cause. *Malignant hypertension* is a severe, fulminant form of hypertension that commonly arises from both types. (See [Malignant hypertension.](#)) Blacks are twice as likely as whites to be affected; if untreated, hypertension carries a high mortality.

WARNING

Malignant hypertension

Malignant hypertension is a medical emergency characterized by marked blood pressure elevation, papilledema, retinal hemorrhages and exudates, and manifestations of hypertensive encephalopathy, such as severe headache, vomiting, visual disturbances, transient paralysis, seizures, stupor, and coma. Cardiac decompensation and acute renal failure may also develop with this disorder.

The average age at diagnosis is 40, and the disorder affects more men than women. Before the availability of effective antihypertensives, most patients died within 2 years. Even with effective treatment, at least half of the patients die within 5 years.

Causes

The cause of malignant hypertension isn't known. Studies show that dilation of cerebral arteries and generalized arteriolar fibrinoid necrosis contribute to the disorder. The cerebral arteries dilate because normal regulation of cerebral blood flow doesn't take place because of markedly high arterial pressure. The resulting excess in cerebral blood flow produces encephalopathy.

Treatment

Emergency treatment aims to quickly reduce blood pressure and identify the underlying cause:

- u Diazoxide given rapidly I.V. can begin to reduce blood pressure in 1 to 3 minutes. Nitroprusside and trimethaphan, given by continuous infusion, may be tried. Other drugs for maintaining long-term control of blood pressure include hydralazine and methyldopa.
- u With suspected pheochromocytoma, drugs that release additional catecholamines—such as methyldopa, reserpine, and guanethidine—are contraindicated.
- u Furosemide and digitalis glycosides may be used to treat associated heart failure.

Essential hypertension usually begins insidiously as a benign disease, slowly progressing to an accelerated or malignant state. If untreated, even mild hypertension can cause significant complications and a high mortality. (See [How hypertension develops.](#)) In many cases, however, treatment with stepped care offers patients an

improved prognosis. (See [Stepped-care approach to antihypertensive therapy.](#))

Causes

The cause of essential hypertension is unknown. Family history, race, stress, obesity, a diet high in sodium or saturated fat, use of tobacco or oral contraceptives, excess alcohol intake, sedentary lifestyle, and aging have all been studied to determine their role in the development of hypertension.

Secondary hypertension may result from renovascular disease; renal parenchymal disease; pheochromocytoma; primary hyperaldosteronism; Cushing's syndrome; diabetes mellitus; dysfunction of the thyroid, pituitary, or parathyroid gland; coarctation of the aorta; pregnancy; and neurologic disorders. Use of oral contraceptives may be the most common cause of secondary hypertension, probably because these drugs activate the renin-angiotensin-aldosterone system. Other medications contributing to secondary hypertension include glucocorticoids, mineralocorticoids, sympathomimetics, cyclosporine, cocaine, and epoetin alfa.

Complications

Hypertension is a major cause of cerebrovascular accident, cardiac disease, and renal failure. Complications occur late in the disease and can attack any organ system. Cardiac complications may include coronary artery disease, angina, myocardial infarction, heart failure, arrhythmias, and sudden death. Neurologic complications include cerebral infarctions and hypertensive encephalopathy. Hypertensive retinopathy can cause blindness. Renovascular hypertension can lead to renal failure.

Assessment findings

In many cases, the hypertensive patient has no symptoms, and the disorder is revealed incidentally during evaluation for another disorder or during a routine blood pressure screening program. When symptoms do occur, they reflect the effect of hypertension on the organ systems.

The patient may report awakening with a headache in the occipital region, which subsides spontaneously after a few hours. This symptom usually is associated with severe hypertension. He may also complain of dizziness, palpitations, fatigue, and impotence.

With vascular involvement, the patient may complain of nosebleeds, bloody urine, weakness, and blurred vision. Complaints of chest pain and dyspnea may indicate cardiac involvement.

PATHOPHYSIOLOGY

How hypertension develops

Increased blood volume, cardiac rate, and stroke volume or arteriolar vasoconstriction that increases peripheral resistance causes blood pressure to rise. Hypertension may also result from the breakdown or inappropriate response of the following intrinsic regulatory mechanisms.

Renin-angiotensin system

Renal hypoperfusion causes the release of renin. Angiotensinogen, a liver enzyme, converts the renin to angiotensin I, which increases preload and afterload. Angiotensin I then converts to angiotensin II in the lungs. A powerful vasoconstrictor, angiotensin II also helps increase preload and afterload by stimulating the adrenal cortex to secrete aldosterone. This serves to increase sodium reabsorption. Next comes hypertonic-stimulated release of antidiuretic hormone from the pituitary gland. This, in turn, increases water absorption, plasma volume, cardiac output, and blood pressure.

Autoregulation

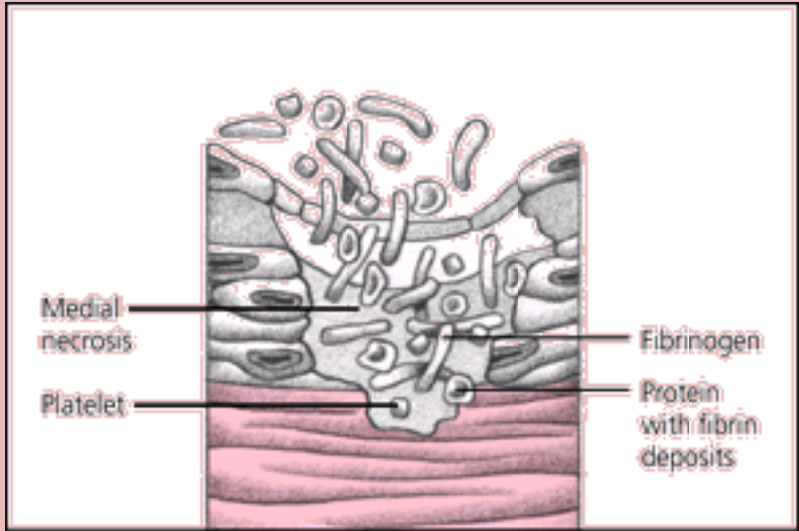

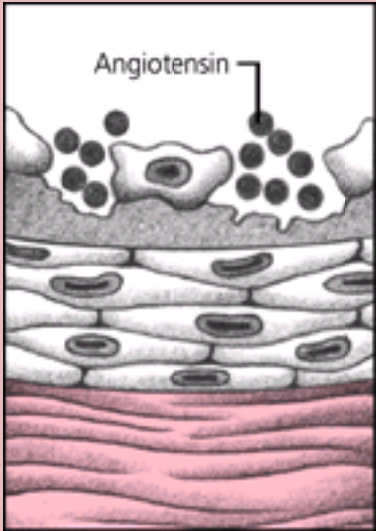

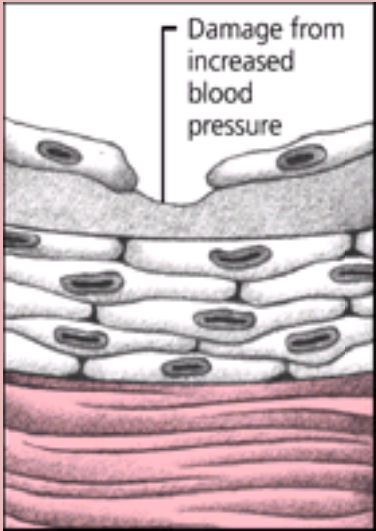

Several intrinsic mechanisms work to change an artery's diameter to maintain tissue and organ perfusion despite fluctuations in systemic blood pressure. Mechanisms include stress relaxation and capillary fluid shift. In stress relaxation, blood vessels gradually dilate when blood pressure rises to reduce peripheral resistance. In capillary fluid shift, plasma moves between vessels and extravascular spaces to maintain intravascular volume.

When blood pressure decreases, baroreceptors in the aortic arch and carotid sinuses decrease their inhibition of the medulla's vasomotor center. This action increases sympathetic stimulation of the heart by norepinephrine. This, in turn, increases cardiac output by strengthening the contractile force, increasing the heart rate, and augmenting peripheral resistance by vasoconstriction. Stress can also stimulate the sympathetic nervous system to increase cardiac output and peripheral vascular resistance.

Blood vessel damage

Sustained hypertension damages blood vessels (as pictured below). Vascular injury begins with alternating areas of dilation and constriction in the arterioles. Increased intra-arterial pressure damages the endothelium (see illustration, below left). Independently, angiotensin induces endothelial wall contraction (see middle illustration below), allowing plasma to leak through interendothelial spaces. Eventually, plasma constituents deposited in the vessel wall cause medial necrosis (see illustration, below right).

VASCULAR DAMAGE

Inspection may reveal peripheral edema in late stages when heart failure is present. Ophthalmoscopic evaluation may reveal hemorrhages, exudates, and papilledema in late stages if hypertensive retinopathy is present.

Palpation of the carotid artery may disclose stenosis or occlusion. Palpation of the abdomen may reveal a pulsating mass, suggesting an abdominal aneurysm.

Enlarged kidneys may point to polycystic disease, a cause of secondary hypertension.

Systolic or diastolic pressure, or both may be elevated. An increase in diastolic blood pressure from a sitting to a standing position suggests essential hypertension, whereas a fall in blood pressure from the sitting to the standing position indicates secondary hypertension.

Stepped-care approach to antihypertensive therapy

The diagram below illustrates the four-step approach to antihypertensive therapy that is recommended by the National Institutes of Health. The progression of therapy is based on the patient's response, which is defined in two ways: the patient has achieved the target blood pressure set by the doctor, or the patient is making considerable progress toward this goal.

```
graph TD
    S1[STEP 1  
Begin lifestyle modifications:  
• weight reduction  
• moderation of alcohol intake  
• regular physical activity  
• reduction of sodium intake  
• smoking cessation] --> D1[If the patient fails to achieve the desired blood pressure or make significant progress]
    D1 --> S2[STEP 2  
Continue lifestyle modifications and begin drug regimen:  
• Initially, use a beta blocker or diuretic drug of choice.  
• If initial drug regimen is ineffective or unacceptable, try an angiotensin-converting enzyme inhibitor, a calcium antagonist, an alpha-1-receptor-adrenergic antagonist, or a mixed alpha- and beta-adrenergic antagonist.]
    S2 --> D2[If the patient fails to achieve the desired blood pressure or make significant progress]
    D2 --> S3[STEP 3  
Increase drug dosage.

Source: U.S. Department of Health and Human Services. National Institutes of Health. *Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*. Washington, D.C. Government Printing Office, 1997.

Auscultation may reveal an abdominal bruit to the right or left of the umbilicus midline or in the flanks if renal artery stenosis is present. Bruits may also be heard over the abdominal aorta and femoral arteries or the carotids.

Diagnostic tests

The following tests may be used to find predisposing factors and help identify the cause of hypertension:

- u Urinalysis may show protein, red blood cells, or white blood cells, suggesting renal disease; or glucose, suggesting diabetes mellitus.
- u Excretory urography may reveal renal atrophy, indicating chronic renal disease; one kidney that is more than 5/8" (1.6 cm) shorter than the other suggests unilateral renal disease.
- u Serum potassium levels less than 3.5 mEq/L may indicate adrenal dysfunction (primary hyperaldosteronism).
- u Blood urea nitrogen levels that are normal or elevated to more than 20 mg/dl and serum creatinine levels that are normal or elevated to more than 1.5 mg/dl suggest renal disease.

Other tests that help to detect cardiovascular damage and other complications include:

- u Electrocardiography may show left ventricular hypertrophy or ischemia, and chest X-rays may demonstrate cardiomegaly.
- u Ophthalmoscopy reveals arteriovenous nicking and, in hypertensive encephalopathy, edema.
- u An oral captopril challenge may be done to test for renovascular hypertension. This functional diagnostic test depends on the abrupt inhibition of circulatory angiotensin II by angiotensin-converting enzyme inhibitors, removing the major support for perfusion through a stenotic kidney. The acutely ischemic kidney immediately releases more renin and undergoes a marked decrease in glomerular filtration rate and renal blood flow.
- u Renal arteriography may show renal artery stenosis.

Treatment

Although essential hypertension has no cure, drugs and modifications in diet and lifestyle can control it. Generally, nondrug treatment such as lifestyle modification, is tried first, especially in early, mild cases. If this is ineffective, treatment progresses in a stepwise manner to include various types of antihypertensives. This stepped-care approach may need modification. For instance, most blacks respond poorly to beta-adrenergic blocking agents; however, for unclear reasons, they respond well to a combination of a diuretic and an angiotensin-converting enzyme inhibitor. Many elderly patients can be treated with diuretics alone.

Treatment for a patient with secondary hypertension includes correcting the underlying cause and controlling hypertensive effects.

Severely elevated blood pressure (hypertensive crisis) may be refractory to medications and may be fatal.

Hypertensive emergencies require parenteral administration of a vasodilator or an adrenergic inhibitor or oral administration of a selected drug (such as nifedipine, captopril, clonidine, or labetalol), to rapidly reduce blood pressure.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary)
- u Fatigue
- u Ineffective individual coping
- u Knowledge deficit
- u Noncompliance
- u Risk for injury

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain hemodynamic stability.
- u The patient won't develop arrhythmias.
- u The patient will express feelings of increased energy.
- u The patient will comply with therapy regimen.

Nursing interventions

- u If a patient is hospitalized with hypertension, find out if he was taking prescribed antihypertensive medication. If he wasn't, ask why. If he can't afford the medication, refer him to the appropriate social service department.
- u When routine blood pressure screening reveals elevated pressure, make sure the sphygmomanometer cuff size is appropriate for the patient's upper arm circumference. Take the pressure in both arms in lying, sitting, and standing positions. Ask the patient if he smoked, drank a beverage containing caffeine, or was emotionally upset before the test. Advise him to return for blood pressure testing at frequent and regular intervals.

u To help identify hypertension and prevent untreated hypertension, participate in public education programs dealing with hypertension and ways to reduce risk factors. Encourage public participation in blood pressure screening programs. Routinely screen all patients, especially those at risk (blacks and people with family histories of hypertension, cerebrovascular accident, or heart attack).

Patient teaching

- u Teach the patient to use a self-monitoring blood pressure cuff and to record the reading at least twice weekly in a journal for review by the doctor at every office appointment. Tell the patient to take his blood pressure at the same hour each time with relatively the same type of activity preceding the measurement.
- u Tell the patient and family to keep a record of drugs used in the past, noting especially which ones are or aren't effective. Suggest recording this information on a card so the patient can show it to his doctor.
- u To encourage compliance with antihypertensive therapy, suggest establishing a daily routine for taking medication. Warn him that uncontrolled hypertension may cause stroke and heart attack. Tell him to report adverse effects of drugs. Advise him to avoid high-sodium antacids and over-the-counter cold and sinus medications containing harmful vasoconstrictors.
- u Help the patient examine and modify his lifestyle. Suggest stress-reduction groups, dietary changes, and an exercise program, particularly aerobic walking, to improve cardiac status and reduce obesity and serum cholesterol levels.
- u Encourage a change in dietary habits. Help the obese patient plan a reducing diet. Tell him to avoid high-sodium foods (such as pickles, potato chips, canned soups, and cold cuts), table salt, and foods high in cholesterol and saturated fat.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HC)—also known as idiopathic hypertrophic subaortic stenosis, hypertrophic obstructive cardiomyopathy, and muscular aortic stenosis—is a primary disease of cardiac muscle. It's characterized by left ventricular hypertrophy and disproportionate, asymmetrical thickening of the intraventricular septum and free wall of the left ventricle. It's also distinguished by a dynamic left ventricular outflow tract pressure gradient related to subaortic narrowing caused by septal hypertrophy in the mitral valve area. The obstruction produced may change between examinations and even from beat to beat.

In HC, cardiac output may be low, normal, or high, depending on whether the stenosis is obstructive or nonobstructive. Eventually, left ventricular dysfunction—resulting from rigidity and decreased compliance—causes pump failure. If cardiac output is normal or high, the stenosis may go undetected for years, but low cardiac output may lead to potentially fatal heart failure.

The course of this disorder varies. Some patients demonstrate progressive deterioration; others remain stable for several years.

Causes

About half of all cases of HC are transmitted as an autosomal dominant trait. Other causes aren't known.

Complications

Pulmonary hypertension and heart failure may occur secondary to left ventricular stiffness. Sudden death is also possible and usually results from ventricular arrhythmias, such as ventricular tachycardia and premature ventricular contractions.

Assessment findings

Generally, clinical features don't appear until the disease is well advanced. Then atrial dilation and, sometimes, atrial fibrillation abruptly reduce blood flow to the left ventricle. Most patients are asymptomatic but have a family history of HC. In some cases, death occurs suddenly, particularly in children and young adults.

Patients who have symptoms complain of orthopnea and dyspnea on exertion. They commonly have anginal pain, fatigue, and syncope even at rest. Inspection of the carotid artery may show a rapidly rising carotid arterial pulse.

Palpation of peripheral arteries reveals a characteristic double impulse (called pulsus biferiens). Palpation of the chest reveals a double or triple apical impulse, which may be displaced laterally. Percussion may reveal bibasilar crackles if heart failure is present.

Auscultation reveals a harsh systolic murmur, heard after S₁ at the apex near the left sternal border. The murmur is intensified by standing and with Valsalva's maneuver. An S₄ may also be audible.

Diagnostic tests

Echocardiography shows left ventricular hypertrophy and a thick, asymmetrical intraventricular septum in obstructive HC, whereas hypertrophy affects various ventricular areas in nonobstructive HC. The septum may have a ground-glass appearance. Poor septal contraction, abnormal motion of the anterior mitral leaflet during systole, and narrowing or occlusion of the left ventricular outflow tract may also be seen in obstructive HC. The left ventricular cavity appears small, with vigorous posterior wall motion but reduced septal excursion.

Cardiac catheterization reveals elevated left ventricular end-diastolic pressure and, possibly, mitral insufficiency. In a rare form of the disease, the left atrium has a slipper-foot shape and the left ventricle, a spade shape.

Electrocardiography usually shows left ventricular hypertrophy; ST-segment and T-wave abnormalities; Q waves in leads II, III, aV_F, and V₄ to V₆ (due to hypertrophy, not infarction); left anterior hemiblock, left axis deviation; and ventricular and atrial arrhythmias.

Chest X-rays may show a mild to moderate increase in heart size, and a thallium scan usually reveals myocardial perfusion defects.

Treatment

The goals of treatment are to relax the ventricle and to relieve outflow tract obstruction. Propranolol, a beta-adrenergic blocking agent, is the drug of choice. It slows the heart rate and increases ventricular filling by relaxing the obstructing muscle, thereby reducing angina, syncope, dyspnea, and arrhythmias. However, propranolol may aggravate symptoms of cardiac decompensation.

Calcium channel blockers may reduce elevated diastolic pressures and severity of outflow tract gradients and increase exercise tolerance. Disopyramide can be used to reduce left ventricular contractility and the outflow gradient.

Atrial fibrillation, a medical emergency with HC, necessitates cardioversion. It also calls for heparin administration before cardioversion and continuing until fibrillation subsides because of the high risk of systemic embolism.

If heart failure occurs, amiodarone may be used, unless an atrioventricular block exists. This drug seems to be effective in reducing ventricular and supraventricular arrhythmias, as well. Vasodilators (such as nitroglycerin), diuretics, and sympathetic stimulators (such as isoproterenol) are contraindicated.

If drug therapy fails, surgery is indicated. Ventricular myotomy (resection of the hypertrophied septum) alone or combined with mitral valve replacement may ease outflow tract obstruction and relieve symptoms. However, ventricular myotomy may cause complications, such as complete heart block and a ventricular septal defect, and is experimental. Heart transplantation may also be considered.

Nursing diagnoses

u Activity intolerance u Decreased cardiac output u Fatigue u Fluid volume excess u Ineffective individual coping u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will maintain adequate cardiac output and hemodynamic stability.
- u The patient won't develop complications of fluid volume excess.
- u The patient will carry out activities of daily living without excess fatigue or decreased energy.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will develop adequate coping mechanisms.
- u The patient will state or demonstrate understanding of what was taught.

Nursing interventions

- u Alternate periods of rest with required activities of daily living and treatments. Provide personal care as needed to prevent fatigue.
- u Provide active or passive range-of-motion exercises to prevent muscle atrophy if the patient is on bed rest.
- u If propranolol is to be discontinued, don't stop the drug abruptly; doing so may cause rebound effects, resulting in myocardial infarction or sudden death. To determine the patient's tolerance for an increased dose of propranolol, take his pulse to check for bradycardia, and have him stand and walk around slowly to check for orthostatic hypotension.
- u Therapeutic restrictions and an uncertain prognosis usually cause profound anxiety and depression, so offer support and let the patient express his feelings. Be flexible with visiting hours. If confinement to a facility is prolonged, try to obtain permission for the patient to spend occasional weekends at home.
- u Allow the patient and family members to express their fears and concerns. As needed, help them identify effective coping strategies.

Patient teaching

- u Remind the patient and family members that propranolol may cause depression. Notify the doctor if symptoms occur.
- u Instruct the patient to take his medication as ordered. Tell him to notify any doctor caring for him that he shouldn't be given nitroglycerin, digitalis glycosides, or diuretics because they can worsen an obstruction.
- u Inform the patient that before dental work or surgery, he needs antibiotic prophylaxis to prevent subacute bacterial endocarditis.

ALERT Warn the patient against strenuous activity, which may precipitate syncope or sudden death. Also advise him to avoid Valsalva's maneuver or sudden position changes; both may worsen an obstruction. Urge his family to learn cardiopulmonary resuscitation.

HYPOVOLEMIC SHOCK

Hypovolemic shock is a potentially life-threatening situation in which reduced intravascular blood volume causes circulatory dysfunction and inadequate tissue perfusion. Tissue anoxia prompts a shift in cellular metabolism from aerobic to anaerobic pathways. This produces an accumulation of lactic acid, resulting in metabolic acidosis.

Without sufficient blood or fluid replacement, hypovolemic shock may lead to irreversible cerebral and renal damage, cardiac arrest and, ultimately, death. (See [How hypovolemic shock progresses](#).) Hypovolemic shock necessitates early recognition of signs and symptoms and prompt, aggressive treatment to improve the prognosis.

Causes

Hypovolemic shock most commonly results from acute blood loss—about one-fifth of total volume. Massive blood loss may result from GI bleeding, internal hemorrhage (such as hemothorax or hemoperitoneum), external hemorrhage (caused by accidental or surgical trauma), or any condition that reduces circulating intravascular plasma volume or other body fluids such as in severe burns.

Other causes of hypovolemic shock include intestinal obstruction, peritonitis, acute pancreatitis, ascites and dehydration from excessive perspiration, severe diarrhea or protracted vomiting, diabetes insipidus, diuresis, and inadequate fluid intake.

Complications

Without immediate treatment, hypovolemic shock can cause adult respiratory distress syndrome, acute tubular necrosis and renal failure, disseminated intravascular coagulation, and multisystem organ dysfunction syndrome.

Assessment findings

The patient's history includes disorders or conditions that reduce blood volume, such as GI hemorrhage, trauma, and severe diarrhea and vomiting. A patient with cardiac disease may complain of anginal pain because of decreased myocardial perfusion and oxygenation.

Inspection may reveal pale skin, decreased sensorium, and rapid, shallow respirations. Urine output is usually less than 20 ml/hour.

Palpation of peripheral pulses may disclose a rapid, thready pulse; the skin feels cold and clammy.

Auscultation of blood pressure usually detects a mean arterial pressure of less than 60 mm Hg in adults and a narrowing pulse pressure. In patients with chronic hypotension, the mean pressure may fall below 50 mm Hg before any signs of shock appear.

Orthostatic vital signs and the tilt test may help determine the presence of hypovolemic shock. (See [Checking for early hypovolemic shock](#).)

Central venous pressure, right atrial pressure, pulmonary artery pressure, pulmonary artery wedge pressure, and cardiac output are all reduced.

Diagnostic tests

- Characteristic laboratory findings include:
- u low hematocrit and decreased hemoglobin levels and red blood cell and platelet counts
 - u elevated serum potassium, sodium, lactate dehydrogenase, creatinine, and blood urea nitrogen levels
 - u increased urine specific gravity (greater than 1.020) and urine osmolality
 - u decreased urine creatinine levels
 - u decreased pH and partial pressure of oxygen in arterial blood and increased partial pressure of carbon dioxide in arterial blood.

In addition, X-rays, gastroscopy, aspiration of gastric contents through a nasogastric tube, and tests for occult blood identify internal bleeding sites. Coagulation studies may detect coagulopathy from disseminated intravascular coagulation.

Treatment

Emergency treatment measures include prompt and adequate blood and fluid replacement to restore intravascular volume and to raise blood pressure and maintain it above 60 mm Hg. Infusion of normal saline solution or lactated Ringer's solution and then possibly plasma proteins (albumin) or other plasma expanders may produce adequate volume expansion until packed cells can be matched. A rapid solution infusion system can provide these crystalloids or colloids at high flow rates.

In severe cases, an intra-aortic balloon pump, ventricular assist device, or pneumatic antishock garment may be helpful.

Treatment may also include oxygen administration, bleeding control by direct application of pressure and related measures, dopamine or another inotropic agent, and possibly surgery to correct the underlying problem. To be effective, dopamine or other inotropic agents must be used with vigorous fluid resuscitation.

Nursing diagnoses

u Altered family processes u Altered thought processes u Altered tissue perfusion (cardiopulmonary, renal, cerebral) u Anxiety u Decreased cardiac output u Fluid volume deficit u Impaired gas exchange u Ineffective family coping: Disabling u Risk for infection u Risk for injury u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain hemodynamic stability.
- u The patient will maintain adequate ventilation.
- u The patient will remain free from signs and symptoms of infection.
- u The patient and family members will express feelings and develop adequate coping mechanisms.
- u The patient will maintain adequate fluid volume.

Nursing interventions

- u Check for a patent airway and adequate circulation. If blood pressure and heart rate are absent, start cardiopulmonary resuscitation.
- u Record the patient's blood pressure, pulse and respiratory rates, and peripheral pulses every 15 minutes until he is stabilized. Monitor cardiac rhythm continuously.
- u When systolic blood pressure drops below 80 mm Hg, increase the oxygen flow rate, and notify the doctor immediately because systolic blood pressure less than 80 mm Hg usually results in inadequate coronary artery blood flow, cardiac ischemia, arrhythmias, and further complications of low cardiac output.
- u Start an I.V. infusion with normal saline solution or lactated Ringer's solution, using a large-bore (14G to 18G) catheter, which allows easier administration of later blood transfusions. (Caution: Don't start an I.V. infusion in the legs of a shock patient who has suffered abdominal trauma because infused fluid may escape through the ruptured vessel into the abdomen.)
- u Also, notify the doctor, and increase the infusion rate if the patient has a progressive drop in blood pressure accompanied by a thready pulse. This generally signals inadequate cardiac output from reduced intravascular volume.
- u Insert an indwelling urinary catheter if necessary to measure hourly urine output. If output is less than 30 ml/hour in adults, increase the fluid infusion rate, but watch for signs of fluid overload such as an increase in pulmonary artery wedge pressure (PAWP). Notify the doctor if urine output doesn't improve.
- u An osmotic diuretic, such as mannitol, may be ordered to increase renal blood flow and urine output. Determine how much fluid to give by checking blood pressure, urine output, central venous pressure (CVP), or PAWP. (To increase accuracy, CVP should be measured at the level of the right atrium, using the same reference point on the chest each time.)
- u Draw an arterial blood sample to measure blood gas levels. Administer oxygen by face mask or endotracheal tube to ensure adequate tissue oxygenation. Adjust the oxygen flow rate to a higher or lower level, as blood gas measurements indicate.
- u Draw venous blood for a complete blood count, electrolyte measurements, type and crossmatching, and coagulation studies.
- u During therapy, assess skin color and temperature, and note any changes. Cold, clammy skin may be a sign of continuing peripheral vascular constriction, indicating progressive shock.
- u Watch for signs of impending coagulopathy (petechiae, bruising, bleeding or oozing from gums or venipuncture sites).
- u Provide emotional support to the patient and family members.

PATHOPHYSIOLOGY

How hypovolemic shock progresses

Vascular fluid volume loss causes the extreme tissue hypoperfusion that characterizes hypovolemic shock. *Internal fluid loss* results from internal hemorrhage (such as GI bleeding) and third-space fluid shifting (such as in diabetic ketoacidosis). *External fluid loss* results from severe bleeding or from severe diarrhea, diuresis, or vomiting.

Inadequate vascular volume leads to decreased venous return and cardiac output. The resulting drop in arterial blood pressure activates the body's compensatory mechanisms in an attempt to increase vascular volume. If compensation is unsuccessful, decompensation and death may rapidly ensue.

Internal or external fluid loss

Decreased intravascular fluid volume

Decreased venous return

Decreased preload (filling pressure)

Decreased stroke volume

Decreased cardiac output

Decreased mean arterial blood pressure

Decreased tissue perfusion

Decreased oxygen and nutrient delivery to cells

Multiple organ dysfunction syndrome

Checking for early hypovolemic shock

Orthostatic vital signs and tilt test results can help assess for the possibility of impending hypovolemic shock.

Orthostatic vital signs

Measure the patient's blood pressure and pulse rate while lying supine, sitting, and standing. Wait at least 1 minute between each position change. A systolic blood pressure decrease of 10 mm Hg or more between positions or a pulse rate increase of 10 beats/minute or more is a sign of volume depletion and impending hypovolemic shock.

Tilt test

With the patient lying supine, raise his legs above heart level. If his blood pressure increases significantly, the test is positive, indicating volume depletion and impending hypovolemic shock.

Patient teaching

- u Explain all procedures and their purpose to ease the patient's anxiety.
- u Explain the risks associated with blood transfusions to the patient and family members.

CULTURAL TIP Members of some groups (such as Jehovah Witnesses) are opposed to blood transfusion and may refuse this type of treatment because of religious reasons. In an emergency, a court order may be obtained to allow such treatment if it's in the patient's best interest.

MITRAL INSUFFICIENCY

Mitral insufficiency—also known as mitral regurgitation—occurs when a damaged mitral valve allows blood from the left ventricle to flow back into the left atrium during systole. As a result, the atrium enlarges to accommodate the backflow. The left ventricle also dilates to accommodate the increased volume of blood from the atrium and to compensate for diminishing cardiac output.

Mitral insufficiency tends to be progressive because left ventricular dilation increases the insufficiency, which further enlarges the left atrium and ventricle, which further increases the insufficiency.

Causes

Damage to the mitral valve can result from rheumatic fever, hypertrophic cardiomyopathy, mitral valve prolapse, myocardial infarction, severe left-sided heart failure, or ruptured chordae tendineae.

In older patients, mitral insufficiency may occur because the mitral annulus has become calcified. The cause is unknown, but it may be linked to a degenerative process. Mitral insufficiency is sometimes associated with congenital anomalies such as transposition of the great arteries.

Complications

Ventricular hypertrophy and increased end-diastolic pressure result in increased pulmonary artery pressure, eventually leading to left- and right-sided heart failure with pulmonary edema and cardiovascular collapse.

Assessment findings

Depending on the severity of the disorder, the patient may be asymptomatic or complain of orthopnea, exertional dyspnea, fatigue, weakness, weight loss, chest pain, and palpitations.

Inspection may reveal jugular vein distention with an abnormally prominent *a* wave. You may also note peripheral edema.

Auscultation may detect a soft *S*₁ that may be buried in the systolic murmur. A grade 3 to 6 or louder holosystolic murmur, most characteristic of mitral insufficiency, is best heard at the apex. You also hear a split *S*₂ and a low-pitched *S*₃. The *S*₃ may be followed by a short, rumbling diastolic murmur. A fourth heart sound may be evident in patients with a recent onset of severe mitral insufficiency and who are in normal sinus rhythm. (See [Identifying the murmur of mitral insufficiency.](#))

Auscultation of the lungs may reveal crackles if the patient has pulmonary edema.

Palpation of the chest may disclose a regular pulse rate with a sharp upstroke. You can probably palpate a systolic thrill at the apex. In patients with marked pulmonary hypertension, you may be able to palpate a right ventricular tap and the shock of the pulmonic valve closing. When the left atrium is markedly enlarged, it may be palpable along the sternal border late during ventricular systole. It resembles a right ventricular lift. Abdominal palpation may reveal hepatomegaly if the patient has right-sided heart failure.

Diagnostic tests

Cardiac catheterization is used to detect mitral insufficiency, with increased left ventricular end-diastolic volume and pressure, increased left atrial and pulmonary artery wedge pressures, and decreased cardiac output.

Chest X-rays demonstrate left atrial and ventricular enlargement, pulmonary vein congestion, and calcification of the mitral leaflets in long-standing mitral insufficiency and stenosis.

Echocardiography reveals abnormal motion of the valve leaflets, left atrial enlargement, and a hyperdynamic left ventricle.

Identifying the murmur of mitral insufficiency

A high-pitched, rumbling pansystolic murmur that radiates from the mitral area to the left axillary line characterizes mitral insufficiency.

Electrocardiography may show left atrial and ventricular hypertrophy, sinus tachycardia, and atrial fibrillation.

Treatment

The nature and severity of associated symptoms determine treatment in valvular heart disease. The patient may need to restrict activities to avoid extreme fatigue and dyspnea.

Heart failure requires digoxin, diuretics, a sodium-restricted diet and, in acute cases, oxygen. Other appropriate measures include anticoagulant therapy to prevent thrombus formation around diseased or replaced valves and prophylactic antibiotics before and after surgery or dental care.

If the patient has severe signs and symptoms that can't be managed medically, he may need open-heart surgery with cardiopulmonary bypass for valve replacement.

Valvuloplasty may be used in elderly patients who have end-stage disease and can't tolerate general anesthesia.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain hemodynamic stability, with cardiac output adequate and no arrhythmias.
- u The patient will maintain adequate ventilation.
- u The patient will remain free from signs and symptoms of infection.
- u The patient won't exhibit complications of fluid volume excess.
- u The patient will maintain joint mobility and range of motion.

Nursing interventions

- u Provide periods of rest between periods of activity to prevent excessive fatigue.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u Keep the patient on a low-sodium diet; consult with the dietitian to ensure that the patient receives as many favorite foods as possible during the restriction.
- u Monitor for left-sided heart failure, pulmonary edema, and adverse reactions to drug therapy. Provide oxygen to prevent tissue hypoxia as needed.
- u If the patient has surgery, monitor postoperatively for hypotension, arrhythmias, and thrombus formation.
- u Monitor the patient's vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.

ALERT Before giving penicillin, ask the patient or his parents (if he's a child) if he's ever had a hypersensitivity reaction to it. Even if he hasn't, warn that such a reaction is possible. Administer antibiotics on time to maintain consistent drug levels in the blood.

Patient teaching

- u Teach the patient about diet restrictions, medications, signs and symptoms that should be reported, and the importance of consistent follow-up care.
- u Explain all tests and treatments.
- u Make sure the patient and family members understand the need to comply with prolonged antibiotic therapy and follow-up care, and the need for additional antibiotics during dental procedures.
- u Tell the parents or patient to stop the drug and call the doctor immediately if the patient develops a rash, fever, chills, or other signs of allergy at any time during penicillin therapy.
- u Instruct the patient and family members to watch for and report early signs of heart failure, such as dyspnea and a hacking, nonproductive cough.

MITRAL STENOSIS

In mitral stenosis, valve leaflets become diffusely thickened by fibrosis and calcification. The mitral commissures fuse, the chordae tendineae fuse and shorten, the valvular cusps become rigid, and the apex of the valve becomes narrowed, obstructing blood flow from the left atrium to the left ventricle.

As a result of these changes, left atrial volume and pressure increase and the atrial chamber dilates. The increased resistance to blood flow causes pulmonary hypertension, right ventricular hypertrophy and, eventually, right-sided heart failure. Also, inadequate filling of the left ventricle reduces cardiac output.

Two-thirds of all patients with mitral stenosis are female.

Causes

Mitral stenosis most commonly results from rheumatic fever. It may also be associated with congenital anomalies.

Complications

Pulmonary hypertension caused by mitral stenosis can rupture pulmonary-bronchial venous connections, causing hemorrhage. Pulmonary hypertension also increases transudation of fluid from pulmonary capillaries, which can cause fibrosis in the alveoli and pulmonary capillaries. This action reduces vital capacity, total lung capacity, maximal breathing capacity, and oxygen uptake per unit of ventilation.

Thrombi may form in the left atrium and, if they embolize, travel to the brain, kidneys, spleen, and extremities, possibly causing infarction. Embolization occurs most commonly in patients with arrhythmias.

Assessment findings

In mild mitral stenosis, the patient may have no symptoms. In moderate to severe mitral stenosis, you may find a history of dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, weakness, fatigue, and palpitations. A dry cough and dysphagia may occur due to an enlarged left atrium or bronchus.

The presence of hemoptysis suggests rupture of pulmonary-bronchial venous connections.

Inspection may reveal peripheral and facial cyanosis, particularly in severe cases. The patient's face may appear pinched and blue, and she may have a malar rash. You may note jugular vein distention and ascites in the patient with severe pulmonary hypertension or associated tricuspid stenosis.

Palpation may reveal peripheral edema, hepatomegaly, and a diastolic thrill at the cardiac apex.

Auscultation may reveal a loud S₁ or opening snap and a diastolic murmur at the apex, along the left sternal border or at the base of the heart. (See [Identifying the](#)

[murmur of mitral stenosis](#).) In patients with pulmonary hypertension, the S₂ is commonly accentuated, and the two components of the S₂ are closely split. A pulmonary systolic ejection click may be heard in patients with severe pulmonary hypertension. Crackles may be heard when the lungs are auscultated.

Because mitral insufficiency is a form of heart disease, the practitioner may need to differentiate it from other forms of valvular heart disease. (See [Forms of valvular heart disease](#).)

Diagnostic tests

Cardiac catheterization shows a diastolic pressure gradient across the valve. It also shows elevated pulmonary artery wedge pressure (greater than 15 mm Hg) and pulmonary artery pressure in the left atrium with severe pulmonary hypertension. It detects elevated right ventricular pressure, decreased cardiac output, and abnormal contraction of the left ventricle. However, this test may not be indicated in patients who have isolated mitral stenosis with mild symptoms.

Chest X-rays show left atrial and ventricular enlargement (in severe mitral stenosis), straightening of the left border of the cardiac silhouette, enlarged pulmonary arteries, dilation of the upper lobe pulmonary veins, and mitral valve calcification.

Echocardiography discloses thickened mitral valve leaflets and left atrial enlargement.

Electrocardiography reveals left atrial enlargement, right ventricular hypertrophy, right axis deviation, and (in 40% to 50% of cases) atrial fibrillation.

Treatment

In valvular heart disease, treatment depends on the nature and severity of associated symptoms. In asymptomatic mitral stenosis in a young patient, penicillin is an important prophylactic.

Identifying the murmur of mitral stenosis

A low, rumbling crescendo-decrescendo murmur in the mitral valve area characterizes mitral stenosis.

If the patient is symptomatic, treatment varies. Heart failure requires bed rest, digoxin, diuretics, a sodium-restricted diet and, in acute cases, oxygen. Small doses of beta-adrenergic blockers may also be used to slow the ventricular rate when digitalis glycosides fail to control atrial fibrillation or flutter. Synchronized cardioversion may be used to correct atrial fibrillation in an unstable patient.

If hemoptysis develops, the patient requires bed rest, salt restriction, and diuretics to decrease pulmonary venous pressure. Embolization mandates anticoagulants along with symptomatic treatments.

A patient with severe, medically uncontrollable symptoms may need open-heart surgery with cardiopulmonary bypass for commissurotomy or valve replacement.

Percutaneous balloon valvuloplasty may be used in young patients who have no calcification or subvalvular deformity, in symptomatic pregnant women, and in elderly patients with end-stage disease who couldn't withstand general anesthesia. This procedure is performed in the cardiac catheterization laboratory.

Nursing diagnoses

u Activity intolerance u Altered role performance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.
- u The patient will maintain hemodynamic stability, cardiac output will remain adequate, and the patient will have no arrhythmias.
- u The patient will express feelings about diminished capacity to perform usual roles.
- u The patient will cope with current medical condition without demonstrating severe signs of anxiety.
- u The patient won't show complications from fluid excess.

ADVANCED PRACTICE

<div><div></div><div>Forms of valvular heart disease</div></div>		
CAUSES AND INCIDENCE	CLINICAL FEATURES	DIAGNOSTIC MEASURES

Mitral stenosis

- Results from rheumatic fever (most common cause)
- Most common in females
- May be associated with other congenital anomalies

- Dyspnea on exertion, paroxysmal nocturnal dyspnea, orthopnea, weakness, fatigue, palpitations
- Peripheral edema, jugular vein distention, ascites, hepatomegaly
- Crackles, atrial fibrillation, signs of systemic emboli
- Auscultation that reveals a loud S₁ or opening snap and a diastolic murmur at the apex

- Cardiac catheterization: diastolic pressure gradient across valve, elevated left atrial and pulmonary artery wedge pressures (PAWP > 15 mm Hg) with severe pulmonary hypertension and pulmonary artery pressures, elevated right-sided heart pressure, decreased cardiac output (CO), abnormal contraction of the left ventricle
- X-ray: left atrial and ventricular enlargement, enlarged pulmonary arteries, mitral valve calcification
- Echocardiography: thickened mitral valve leaflets, left atrial enlargement
- Electrocardiography (ECG): left atrial hypertrophy, atrial fibrillation, right ventricular hypertrophy, right axis deviation

Mitral insufficiency

- Results from rheumatic fever, hypertrophic cardiomyopathy, mitral valve prolapse, myocardial infarction, severe left-sided heart failure, or ruptured chordae tendineae
- Associated with other congenital anomalies such as transposition of the great arteries
- Rare in children without other congenital anomalies

- Orthopnea, dyspnea, fatigue, angina, palpitations
- Peripheral edema, jugular vein distention, hepatomegaly
 - Tachycardia, crackles, pulmonary edema
 - Auscultation that reveals a holosystolic murmur at apex, possible split S₂, and an S₃

- Cardiac catheterization: mitral insufficiency with increased left ventricular end-diastolic volume and pressure, increased atrial pressure and PAWP, decreased CO
- X-ray: left atrial and ventricular enlargement, pulmonary vein congestion
- Echocardiography: abnormal valve leaflet motion, left atrial enlargement
- ECG: possibly left atrial and ventricular hypertrophy, sinus tachycardia, atrial fibrillation

Mitral valve prolapse syndrome

- Cause unknown. Researchers speculate that metabolic or neuroendocrine factors cause constellation of signs and symptoms.
- Most commonly affects young women but may occur in both sexes and in all age-groups

- May produce no signs
- Chest pain, palpitations, headache, fatigue, exercise intolerance, dyspnea, light-headedness, syncope, mood swings, anxiety, panic attacks
- Auscultation that typically reveals a mobile, midsystolic click, with or without a mid-to-late systolic murmur

- Two-dimensional echocardiography: prolapse of mitral valve leaflets into left atrium
- Color-flow Doppler studies: mitral insufficiency
- Resting ECG: ST-segment changes, biphasic or inverted T waves in leads II, III, AV_F
- Exercise ECG: evaluates chest pain and arrhythmias

Aortic insufficiency

- Results from rheumatic fever, syphilis, hypertension, endocarditis, or may be idiopathic
- Associated with Marfan syndrome
- Most common in males
- Associated with ventricular septal defect, even after surgical closure

- Dyspnea, cough, fatigue, palpitations, angina, syncope
- Pulmonary vein congestion, heart failure, pulmonary edema, “pulsating” nail beds (Quincke's sign)
- Rapidly rising and collapsing pulses (pulsus biferiens), cardiac arrhythmias, wide pulse pressure in severe insufficiency
- Auscultation that reveals an S₃ and a diastolic blowing murmur at left sternal border
- Palpation and visualization of apical impulse in chronic disease

- Cardiac catheterization: reduction in arterial diastolic pressures, aortic insufficiency, other valvular abnormalities, increased left ventricular end-diastolic pressure
- X-ray: left ventricular enlargement, pulmonary vein congestion
- Echocardiography: left ventricular enlargement, alterations in mitral valve movement (indirect indication of aortic valve disease), mitral thickening
- ECG: sinus tachycardia, left ventricular hypertrophy, left atrial hypertrophy in severe disease

Aortic stenosis

- Results from congenital aortic bicuspid valve (associated with coarctation of the aorta), congenital stenosis of valve cusps, rheumatic fever, or atherosclerosis in the elderly
- Most common in males

- Dyspnea on exertion, paroxysmal nocturnal dyspnea, fatigue, syncope, angina, palpitations
- Pulmonary vein congestion, heart failure, pulmonary edema
- Diminished carotid pulses, decreased cardiac output, cardiac arrhythmias, possible pulsus alternans
- Auscultation that reveals systolic murmur heard at base or in carotids and, possibly, an S₄

- Cardiac catheterization: pressure gradient across valve (indicating obstruction), increased left ventricular and diastolic pressures
- X-ray: valvular calcification, left ventricular enlargement, pulmonary vein congestion
- Echocardiography: thickened aortic valve and left ventricular wall, possibly coexistent with mitral valve stenosis
- ECG: left ventricular hypertrophy

Pulmonic insufficiency

- May be congenital or may result from pulmonary hypertension
- May rarely result from prolonged use of pressure monitoring catheter in the pulmonary artery

- Dyspnea, weakness, fatigue, chest pain
- Peripheral edema, jugular vein distention, hepatomegaly
- Auscultation that reveals diastolic murmur in pulmonic area

- Cardiac catheterization: pulmonic insufficiency, increased right ventricular pressure, associated cardiac defects
- X-ray: right ventricular and pulmonary arterial enlargement
- ECG: right ventricular or right atrial enlargement

Pulmonic stenosis

- Results from congenital stenosis of valve cusp or rheumatic heart disease (infrequent)
- Associated with other congenital heart defects such as tetralogy of Fallot

- Asymptomatic or symptomatic with dyspnea on exertion, fatigue, chest pain, syncope
- May lead to peripheral edema, jugular vein distention, hepatomegaly
- Auscultation that reveals a systolic murmur at the left sternal border, a split S₂ with a delayed or absent pulmonic component

- Cardiac catheterization: increased right ventricular pressure and decreased pulmonary artery pressure
- ECG: possible right ventricular hypertrophy, right axis deviation, right atrial hypertrophy, atrial fibrillation

(infrequent) ▫ Associated with other congenital heart defects such as tetralogy of Fallot	jugular vein distention, hepatomegaly ▫ Auscultation that reveals a systolic murmur at the left sternal border, a split S ₂ with a delayed or absent pulmonic component	
<i>Tricuspid insufficiency</i> ▫ Results from right-sided heart failure, rheumatic fever and, rarely, trauma and endocarditis ▫ Associated with congenital disorders	▫ Dyspnea, fatigue ▫ May lead to peripheral edema, jugular vein distention, hepatomegaly, ascites ▫ Auscultation that reveals possible S ₃ and systolic murmur at lower left sternal border that increases with inspiration	▫ Right heart catheterization: high atrial pressure, tricuspid insufficiency, decreased or normal cardiac output ▫ X-ray: right atrial dilation, right ventricular enlargement ▫ Echocardiography: systolic prolapse of tricuspid valve, right atrial enlargement ▫ ECG: right atrial or right ventricular hypertrophy, atrial fibrillation
<i>Tricuspid stenosis</i> ▫ Results from rheumatic fever ▫ May be congenital ▫ Associated with mitral or aortic valve disease ▫ Most common in women	▫ May be symptomatic with dyspnea, fatigue, syncope ▫ Possibly peripheral edema, jugular vein distention, hepatomegaly, ascites ▫ Auscultation that reveals diastolic murmur at lower left sternal border that increases with inspiration	▫ Cardiac catheterization: increased pressure gradient across valve, increased right atrial pressure, decreased cardiac output ▫ X-ray: right atrial enlargement ▫ Echocardiography: leaflet abnormality, right atrial enlargement ▫ ECG: right atrial hypertrophy, right or left ventricular hypertrophy, atrial fibrillation

Nursing interventions

- Before giving penicillin, ask the patient if she's ever had a hypersensitivity reaction to it. Even if she never has, warn her that such a reaction is possible.
- If the patient needs bed rest, stress its importance. Assist with bathing, as necessary. Provide a bedside commode because using a commode puts less stress on the heart than using a bedpan. Offer diversional, physically undemanding activities.
- To reduce anxiety, allow the patient to express concerns over her inability to meet responsibilities because of activity restrictions. Give reassurance that activity limitations are temporary.
- Watch closely for signs of heart failure, pulmonary edema, and adverse reactions to drug therapy.
- Place the patient in an upright position to relieve dyspnea if needed. Administer oxygen to prevent tissue hypoxia as needed.
- If the patient has had surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.
- Keep the patient on a low-sodium diet; provide as many favorite foods as possible.

Patient teaching

- Explain all tests and treatments to the patient.
- Advise the patient to plan for periodic rest in her daily routine to prevent undue fatigue.
- Teach the patient about diet restrictions, medications, symptoms that should be reported, and the importance of consistent follow-up care.

MYOCARDIAL INFARCTION

Myocardial infarction (MI) results from reduced blood flow through one of the coronary arteries, which causes myocardial ischemia and necrosis. The infarction site depends on the vessels involved. For instance, occlusion of the circumflex coronary artery causes a lateral wall infarction; occlusion of the left anterior coronary artery causes an anterior wall infarction. True posterior and inferior wall infarctions result from occlusion of the right coronary artery or one of its branches. Right ventricular infarctions can also result from right coronary artery occlusion, can accompany inferior infarctions, and may cause right-sided heart failure. In transmural (Q wave) MI, tissue damage extends through all myocardial layers; in subendocardial (non-Q wave) MI, usually only the innermost layer is damaged. (See [What happens in MI.](#))

Men are more susceptible to MI than premenopausal women, although incidence is rising among women who smoke and take oral contraceptives. The incidence in postmenopausal women resembles that in men.

Causes

- MI results from occlusion of one of the coronary arteries. The occlusion can stem from atherosclerosis, thrombosis, platelet aggregation, or coronary artery stenosis or spasm. Predisposing factors include:
- aging
 - diabetes mellitus
 - elevated serum triglyceride, low-density lipoprotein, and cholesterol levels, and decreased serum high-density lipoprotein levels
 - excessive intake of saturated fats, carbohydrates, or salt
 - hypertension
 - obesity
 - positive family history of coronary artery disease
 - sedentary lifestyle
 - smoking
 - stress or a type A personality (aggressive, competitive attitude, addiction to work, chronic impatience).

In addition, use of drugs, such as amphetamines or cocaine, can cause MI.

Complications

Cardiac complications of acute MI include arrhythmias, cardiogenic shock, heart failure causing pulmonary edema, and pericarditis. Other complications include rupture of the atrial or ventricular septum, ventricular wall, or valves; ventricular aneurysms; mural thrombi causing cerebral or pulmonary emboli; and extensions of the original infarction. Dressler's syndrome (post-MI pericarditis) can occur days to weeks after an MI and cause residual pain, malaise, and fever. (See [Complications of MI.](#))

Typically, elderly patients are more prone to complications and death. Psychological problems can also occur, either from the patient's fear of another MI or from an organic brain disorder caused by tissue hypoxia. Occasionally, a patient may have a personality change.

Assessment findings

Typically, the patient reports the cardinal symptom of MI: persistent, crushing substernal pain that may radiate to the left arm, jaw, neck, and shoulder blades. He commonly describes the pain as heavy, squeezing, or crushing, and it may persist for 12 or more hours. In some patients—particularly elderly patients or those with diabetes—pain may not occur; in others, it may be mild and confused with indigestion.

Patients with coronary artery disease may report increasing anginal frequency, severity, or duration (especially when not precipitated by exertion, a heavy meal, or cold and wind). The patient may also report a feeling of impending doom, fatigue, nausea, vomiting, and shortness of breath. Sudden death, however, may be the first and only indication of MI.

Inspection may reveal an extremely anxious and restless patient with dyspnea and diaphoresis. If right-sided heart failure is present, you may note jugular vein distention. Within the first hour after an anterior MI, about 25% of patients exhibit sympathetic nervous system hyperactivity, such as tachycardia and hypertension. Up to 50% of patients with an inferior MI exhibit parasympathetic nervous system hyperactivity, such as bradycardia and hypotension.

In patients who develop ventricular dysfunction, auscultation may disclose an S₄, an S₃, paradoxical splitting of S₂, and decreased heart sounds. A systolic murmur of mitral insufficiency may be heard with papillary muscle dysfunction secondary to infarction. A pericardial friction rub may also be heard, especially in patients who have a transmural MI or have developed pericarditis.

Fever is unusual at the onset of MI, but a low-grade fever may develop during the next few days.

Diagnostic tests

In MI, diagnostic tests may provide the following results:

- Serial 12-lead electrocardiography (ECG) readings may be normal or inconclusive during the first few hours after an MI. Characteristic abnormalities include serial ST-segment depression in subendocardial MI and ST-segment elevation and Q waves, representing scarring and necrosis, in transmural MI.
- Serum creatine kinase (CK) level is elevated, especially the CK-MB isoenzyme, the cardiac muscle fraction of CK.
- Serum lactate dehydrogenase (LDH) level is elevated. LDH₁ isoenzyme (found in cardiac tissue) is higher than LDH₂ (found in serum). This measurement isn't as reliable as the CK level.
- White blood cell count usually appears elevated on the second day and lasts one week.
- Myoglobin (the hemoprotein found in cardiac and skeletal muscle) is released with muscle damage and may be detected as soon as 2 hours after MI.
- Troponin I, a structural protein found in cardiac muscle, is elevated only in cardiac muscle damage. It's more specific than the CK-MB level. Troponin levels increase within 4 to 6 hours of myocardial injury and may remain elevated for 5 to 11 days.
- Echocardiography shows ventricular wall dyskinesia with a transmural MI and helps evaluate the ejection fraction.
- Scans using I.V. technetium-99m pertechnetate can identify acutely damaged muscle by picking up accumulations of radioactive nucleotide, which appears as a “hot spot” on the film. Myocardial perfusion imaging with thallium-201 reveals a “cold spot” in most patients during the first few hours after a transmural MI.

PATHOPHYSIOLOGY

What happens in MI

When blood supply to the myocardium is interrupted, the following events occur:

1 Injury to the endothelial lining of the coronary arteries causes platelets, white blood cells, fibrin, and lipids to converge at the injured site. Foam cells, or resident macrophages, congregate under the damaged lining and absorb oxidized cholesterol, forming a fatty streak that narrows the arterial lumen.

2 Because the arterial lumen narrows gradually, collateral circulation develops and helps maintain myocardial perfusion distal to the obstruction. During this stage, the patient may have chest pain when myocardial oxygen demand increases.

3 When myocardial demand for oxygen is more than the collateral circulation can supply, myocardial metabolism shifts from aerobic to anaerobic, producing lactic acid (A), which stimulates pain nerve endings. The patient experiences worsening angina that requires rest and medication for relief.

4 Lacking oxygen, the myocardial cells die. This decreases contractility, stroke volume, and blood pressure. The patient experiences tachycardia, hypotension, diminished heart sounds, cyanosis, tachypnea, and poor perfusion to vital organs.

5 Hypoperfusion stimulates baroreceptors, which in turn stimulate the adrenal glands to release epinephrine and norepinephrine. These catecholamines increase heart rate and cause peripheral vasoconstriction, further increasing myocardial oxygen demand. The patient may experience tachyarrhythmias, changes in pulses, decreased level of consciousness, and cold, clammy skin.

5 Hypoperfusion stimulates baroreceptors, which in turn stimulate the adrenal glands to release epinephrine and norepinephrine. These catecholamines increase heart rate and cause peripheral vasoconstriction, further increasing myocardial oxygen demand. The patient may experience tachyarrhythmias, changes in pulses, decreased level of consciousness, and cold, clammy skin.

6 Damaged cell membranes in the infarcted area allow intracellular contents into the vascular circulation. Ventricular arrhythmias then develop with elevated serum levels of potassium (n), creatine kinase (CK) and CK-MB (▲), troponin (I), and lactate dehydrogenase (O).

7 All myocardial cells are capable of spontaneous depolarization and repolarization, so the electrical conduction system may be affected by infarct, injury, and ischemia. The patient may have a fever, leukocytosis, tachycardia, and electrocardiogram signs of tissue ischemia (altered T waves), injured tissue (altered ST segment), and infarcted tissue (deep Q waves).

8 Extensive damage to the left ventricle may impair the ventricle's ability to pump, allowing blood to back up into the left atrium and, eventually into the pulmonary veins and capillaries. When this occurs, the patient may be dyspneic, orthopneic, tachypneic, and cyanotic. Crackles may be heard in the lungs on auscultation. Pulmonary artery pressure and pulmonary artery wedge pressure are increased.

9 As back pressure increases, fluid crosses the alveolar-capillary membrane, impeding diffusion of oxygen (O_2) and carbon dioxide (CO_2). The patient experiences increasing respiratory distress, and arterial blood gases may show decreased partial pressure of oxygen and arterial pH and increased partial pressure of carbon dioxide.

Treatment

The goals of treatment are to relieve chest pain, to stabilize heart rhythm, and to reduce cardiac workload. Treatment includes revascularization to preserve myocardial tissue. Arrhythmias, the most common problem during the first 48 hours after MI, may require antiarrhythmics, possibly a pacemaker and, rarely, cardioversion.

To preserve myocardial tissue, I.V. thrombolytic therapy should be started within 3 hours of the onset of symptoms (unless contraindicated). Thrombolytic therapy includes either streptokinase, alteplase, recombinant tissue plasminogen activator (tPA), reteplase, or urokinase.

Percutaneous transluminal coronary angioplasty (PTCA) may be another option. If PTCA is performed soon after the onset of symptoms, the thrombolytic agent may be administered directly into the coronary artery.

Drug therapy usually includes:

- u aspirin (5 g) to inhibit platelet aggregation (should be initiated within 24 hours after onset of symptoms)
- u lidocaine for ventricular arrhythmias; if lidocaine is ineffective, procainamide, quinidine sulfate, bretylium, or disopyramide may be used
- u atropine I.V. or a temporary pacemaker for heart block or bradycardia
- u nitroglycerin (sublingual, topical, transdermal, or I.V.); calcium channel blockers, such as nifedipine, verapamil, and diltiazem (sublingual, by mouth [P.O.], or I.V.); or isosorbide dinitrate (sublingual, P.O., or I.V.) to relieve pain by redistributing blood to ischemic area of the myocardium, increasing cardiac output, and reducing myocardial workload
- u diltiazem and verapamil, which may prevent reinfarction and ischemia in a non-Q wave MI
- u heparin I.V. (usually follows thrombolytic therapy)
- u morphine I.V., the drug of choice for pain and sedation
- u drugs that increase contractility or blood pressure
- u inotropic drugs, such as dobutamine and amrinone, to treat reduced myocardial contractility
- u beta-adrenergic blockers, such as propranolol and timolol, after acute MI to help prevent reinfarction

u angiotensin-converting inhibitors to improve survival rate in a low ejection fraction (as in large anterior wall MI).

Other therapies may be used, as follows:

- u Oxygen is usually administered (by face mask or nasal cannula) at a modest flow rate for 3 to 6 hours; a lower concentration is necessary if the patient has chronic obstructive pulmonary disease.
- u Bed rest with bedside commode is enforced to decrease cardiac workload.
- u Pulmonary artery catheterization may be performed to detect left- or right-sided heart failure and to monitor response to treatment.
- u Intra-aortic balloon pump may be used for cardiogenic shock.
- u Cardiac catheterization and coronary artery bypass grafting may also be performed.

Complications of MI		
COMPLICATION	ASSESSMENT	TREATMENT
Arrhythmias	<ul style="list-style-type: none">u Electrocardiogram (ECG) shows premature ventricular contractions, ventricular tachycardia, or ventricular fibrillation; in inferior wall MI, bradycardia and junctional rhythms or atrioventricular (AV) block; in anterior wall MI, tachycardia or heart block.	<ul style="list-style-type: none">u Antiarrhythmics, atropine, cardioversion, defibrillation, and pacemaker
Heart failure	<ul style="list-style-type: none">u In left-sided heart failure, chest X-rays show venous congestion and cardiomegaly.u Catheterization shows increases in pulmonary artery systolic and diastolic pressures, pulmonary artery wedge pressure (PAWP), central venous pressure, and systemic vascular resistance (SVR).	<ul style="list-style-type: none">u Diuretics, vasodilators, inotropics, and digitalis glycosides
Cardiogenic shock	<ul style="list-style-type: none">u Catheterization shows decreased cardiac output, increased pulmonary artery systolic and diastolic pressures, decreased cardiac index, increased SVR, and increased PAWP.u Signs are hypotension, tachycardia, decreased level of consciousness, decreased urine output, neck vein distention, S₃ and S₄, and cool, pale skin.	<ul style="list-style-type: none">u I.V. fluids, vasodilators, cardiotonics, digitalis glycosides, intra-aortic balloon pump (IABP), vasopressors, and beta-adrenergic stimulants

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Altered sexuality patterns u Altered tissue perfusion (cardiopulmonary) u Anxiety u Decreased cardiac output u Denial u Fatigue u Fluid volume excess u Ineffective individual coping u Pain

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain hemodynamic stability.
- u The patient won't develop arrhythmias.

- u The patient won't develop complications of fluid volume excess.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will develop adequate coping skills.

Nursing interventions

- u On admission to the intensive care unit (ICU), monitor and record the patient's ECG readings, blood pressure, temperature, and heart and breath sounds.
- u Assess pain and give analgesics as ordered. Record the severity, location, type, and duration of pain. Don't give I.M. injections because absorption from the muscle is unpredictable, CK level may be falsely elevated, and I.V. administration gives more rapid relief of signs and symptoms.
- u Check the patient's blood pressure after giving nitroglycerin, especially the first dose.
- u Frequently monitor ECG rhythm strips to detect rate changes and arrhythmias. Analyze rhythm strips and place a representative strip in the patient's chart if any new arrhythmias are documented, if chest pain occurs, or at least every shift change or according to facility protocol.
- u During episodes of chest pain, obtain ECG readings and blood pressure and pulmonary artery catheter measurements (if applicable) to determine changes.
- u Watch for crackles, cough, tachypnea, and edema, which may indicate impending left-sided heart failure. Carefully monitor daily weight, intake and output, respiratory rate, serum enzyme levels, ECG readings, and blood pressure. Auscultate for adventitious breath sounds periodically (patients on bed rest frequently have atelectatic crackles, which may disappear after coughing) and for S₃ or S₄ gallops.
- u Organize patient care and activities to maximize periods of uninterrupted rest.
- u Ask the dietary department to provide a clear liquid diet until nausea subsides. A low-cholesterol, low-sodium diet, without caffeine-containing beverages, may be ordered.
- u Provide a stool softener to prevent straining during defecation, which causes vagal stimulation and may slow heart rate.
- u Allow the patient to use a bedside commode, and provide as much privacy as possible.
- u Assist with range-of-motion exercises. If the patient is immobilized by a severe MI, turn him often. Antiembolism stockings help prevent venostasis and thrombophlebitis.
- u Provide emotional support, and help reduce stress and anxiety; administer tranquilizers as needed.
- u If the patient has undergone PTCA, sheath care is necessary. Keep the sheath line open with a heparin drip. Observe for generalized and site bleeding. Keep the leg with the sheath insertion site immobile. Maintain strict bed rest. Check peripheral pulses in the affected leg frequently. Provide analgesics for back pain, if needed.
- u After thrombolytic therapy, administer continuous heparin as ordered. Monitor the partial thromboplastin time every 6 hours, and monitor the patient for evidence of bleeding.
- u Monitor ECG rhythm strips for reperfusion arrhythmias and treat them according to facility protocol. If the artery reoccludes, the patient experiences the same symptoms as before. If this occurs, prepare the patient for return to the cardiac catheterization laboratory.

Patient teaching

- u Explain procedures and answer questions for both the patient and family members. Explain the ICU environment and routine. Remember that you may need to repeat explanations after the emergency situation has resolved.
- u To promote compliance with the prescribed medication regimen and other treatment measures, thoroughly explain dosages and therapy. Inform the patient of the drug's adverse reactions, and advise him to watch for and report signs of toxicity (for example, anorexia, nausea, vomiting, mental depression, vertigo, blurred vision, and yellow vision, if the patient is receiving digitalis glycosides).
- u Review dietary restrictions with the patient. If he must follow a low-sodium, low-fat, or low-cholesterol diet, provide a list of foods to avoid. Ask the dietitian to speak to the patient and family members.
- u Encourage the patient to participate in a cardiac rehabilitation exercise program. The doctor and the exercise physiologist should determine the level of exercise and then discuss it with the patient and secure his agreement to a stepped-care program.
- u Counsel the patient to resume sexual activity progressively. He may need to take nitroglycerin before sexual intercourse to prevent chest pain from the increased activity.
- u Advise the patient about appropriate responses to new or recurrent symptoms.
- u Advise the patient to report typical or atypical chest pain. Post-MI syndrome may develop, producing chest pain that must be differentiated from recurrent MI, pulmonary infarction, and heart failure.
- u Stress the need to stop smoking. If necessary, refer the patient to a support group.

MYOCARDITIS

Myocarditis—a focal or diffuse inflammation of the myocardium—is typically uncomplicated and self-limiting. It may be acute or chronic and can occur at any age. In many patients, myocarditis fails to produce specific cardiovascular symptoms or electrocardiogram (ECG) abnormalities. Recovery usually is spontaneous and without residual defects.

Occasionally, myocarditis becomes serious and induces myofibril degeneration, right- and left-sided heart failure with cardiomegaly, and arrhythmias.

Causes

Myocarditis may result from any of the following:

- u viruses — the most common cause in the United States and western Europe — including coxsackievirus A and B and, possibly, poliomyelitis, influenza, rubeola, rubella, human immunodeficiency virus, adenoviruses, and echoviruses
- u bacteria, including diphtheria, tuberculosis, typhoid fever, tetanus, Lyme disease, and staphylococcal, pneumococcal, and gonococcal bacteria
- u hypersensitive immune reactions, such as acute rheumatic fever and postcardiotomy syndrome
- u radiation therapy, especially large doses to the chest during treatment of lung or breast cancer
- u chronic alcoholism
- u parasitic infections, especially toxoplasmosis, and South American trypanosomiasis (Chagas' disease) in infants and immunosuppressed adults
- u helminthic infections such as trichinosis.

The cause of giant cell myocarditis, a rare type of myocarditis, is unknown.

Complications

Occasionally, myocarditis is complicated by left-sided heart failure. Rarely, it leads to cardiomyopathy. Sometimes myocarditis recurs or produces chronic valvulitis (when it results from rheumatic fever), arrhythmias, or thromboembolism.

Assessment findings

The history commonly reveals a recent upper respiratory tract infection with fever, viral pharyngitis, or tonsillitis. The patient may complain of nonspecific symptoms, such as fatigue, dyspnea, palpitations, persistent tachycardia, and persistent fever, all of which reflect the accompanying systemic infection. Occasionally, the patient may complain of a mild, continuous pressure or soreness in the chest. This pain is unlike the recurring, stress-related pain of angina pectoris.

Auscultation usually reveals S₃ and S₄ gallops, a muffled S₁, possibly a murmur of mitral insufficiency (from papillary muscle dysfunction) and, if the patient has pericarditis, a pericardial friction rub. If the patient has left-sided heart failure, you may notice pulmonary congestion, dyspnea, and resting or exertional tachycardia disproportionate to the degree of fever.

Diagnostic tests

Endomyocardial biopsy can be used to confirm a myocarditis diagnosis. The following test results can support the diagnosis:

- u Cardiac enzyme levels, including creatine kinase (CK), CK-MB, serum aspartate aminotransferase, and lactate dehydrogenase, are elevated.

- u White blood cell count and erythrocyte sedimentation rate are elevated.
- u Antibody titers are elevated, such as antistreptolysin-O titer in rheumatic fever.
- u Electrocardiography typically shows diffuse STsegment and T-wave abnormalities as in pericarditis, conduction defects (prolonged PR interval), and other ventricular and supraventricular ectopic arrhythmias.
- u Cultures of stool, throat, pharyngeal washings, or other body fluids may identify the causative bacteria or virus.

Treatment

For most patients, treatment includes anti-infectives for the underlying causative infection, modified bed rest to decrease the heart's workload, and careful management of complications. Left-sided heart failure requires activity restriction to minimize myocardial oxygen consumption, supplemental oxygen therapy, sodium restriction, diuretics to decrease fluid retention, and digitalis compounds to increase myocardial contractility. However, these compounds must be administered carefully because some patients with myocarditis may show a paradoxical sensitivity even to small doses.

Arrhythmias necessitate prompt but cautious administration of antiarrhythmics, such as quinidine or procainamide, to depress myocardial irritability. Thromboembolism requires anticoagulant therapy.

Treatment with corticosteroids or other immunosuppressants is controversial and therefore limited to combating life-threatening complications such as intractable heart failure.

Nursing diagnoses

- u Activity intolerance
- u Altered role performance
- u Anxiety
- u Decreased cardiac output
- u Diversional activity deficit
- u Impaired gas exchange

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain hemodynamic stability and adequate cardiac output and will exhibit no arrhythmias.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings about diminished capacity to perform usual roles.
- u The patient will express interest in using leisure time meaningfully.
- u The patient will cope with current medical condition without demonstrating severe signs of anxiety.

Nursing interventions

- u Stress the importance of bed rest. Assist the patient with bathing, if necessary. Provide a bedside commode because this method puts less stress on the heart than using a bedpan. Offer diversional activities that are physically undemanding.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u Assess cardiovascular status frequently, watching for signs of left-sided heart failure (such as dyspnea, hypotension, and tachycardia). Check for changes in cardiac rhythm or conduction.
- u Administer oxygen and evaluate arterial blood gas levels, as needed, to ensure adequate oxygenation.
- u Observe for signs of digitalis toxicity (such as anorexia, nausea, vomiting, blurred vision, and cardiac arrhythmias) and for complicating factors that may potentiate toxicity, such as electrolyte imbalance and hypoxia.
- u Administer parenteral anti-infectives as ordered.

Patient teaching

- u Teach the patient about anti-infective drugs. Stress the importance of taking the prescribed drug and restricting activities for as long as the doctor orders.
- u If the patient is to take digitalis glycosides at home, teach him to check his pulse for 1 full minute before taking the dose. Direct him to withhold the dose and notify the doctor if his heart rate falls below the predetermined rate (usually 60 beats/minute).
- u During recovery, recommend that the patient resume normal activities slowly and avoid competitive sports.

PERICARDITIS

The pericardium is the fibroserous sac that envelops, supports, and protects the heart. Inflammation of this sac is called pericarditis.

This condition occurs in acute and chronic forms. The acute form can be fibrinous or effusive, with serous, purulent, or hemorrhagic exudate. The chronic form (called constrictive pericarditis) is characterized by dense fibrous pericardial thickening. (See [Understanding pericarditis.](#))

The prognosis depends on the underlying cause but typically is good in acute pericarditis unless constriction occurs.

Causes

Common causes of this disorder include:

- u bacterial, fungal, or viral infection (infectious pericarditis)
- u neoplasms (primary or metastatic from lungs, breasts, or other organs)
- u high-dose radiation to the chest
- u uremia
- u hypersensitivity or autoimmune disease, such as acute rheumatic fever (the most common cause of pericarditis in children), systemic lupus erythematosus, and rheumatoid arthritis
- u drugs, such as hydralazine or procainamide
- u idiopathic factors (most common in acute pericarditis)
- u postcardiac injury, such as myocardial infarction (MI) (which later causes an autoimmune reaction known as Dressler's syndrome in the pericardium). Other types of postcardiac injury include trauma and surgery that leaves the pericardium intact but allows blood to leak into the pericardial cavity.

Less common causes of pericarditis include aortic aneurysm with pericardial leakage and myxedema with cholesterol deposits in the pericardium.

Complications

Pericardial effusion is the major complication of acute pericarditis. If fluid accumulates rapidly, cardiac tamponade may occur, resulting in shock, cardiovascular collapse and, eventually, death.

Assessment findings

The patient's history may include an event or disease that can cause pericarditis, such as chest trauma, MI, or a recent bacterial infection.

The patient with acute pericarditis typically complains of sharp, sudden pain, usually starting over the sternum and radiating to the neck, shoulders, back, and arms. The pain is usually pleuritic, increasing with deep inspiration and decreasing when the patient sits up and leans forward. This decrease occurs because leaning

forward pulls the heart away from the diaphragmatic pleurae of the lungs. The patient may complain of dyspnea.

Pericarditis can mimic the pain of MI. However, the patient may have no pain if he has slowly developing tuberculous pericarditis or postirradiation, neoplastic, or uremic pericarditis.

Auscultation almost always reveals a pericardial friction rub, which is a grating sound heard as the heart moves. You can hear it best during forced expiration, while the patient leans forward or is on his hands and knees in bed. The rub may have up to three components that correspond to atrial systole, ventricular systole, and the rapid-filling phase of ventricular diastole.

Occasionally, the friction rub is heard only briefly or not at all. If acute pericarditis has caused very large pericardial effusions, heart sounds may be distant.

Palpation may reveal a diminished or an absent apical impulse.

Chronic constrictive pericarditis causes the membrane to calcify and become rigid. It also causes a gradual increase in systemic venous pressure and symptoms similar to those of chronic right-sided heart failure (such as fluid retention, ascites, and hepatomegaly).

Tachycardia, an ill-defined substernal chest pain, and a feeling of fullness in the chest may indicate pericardial effusion.

Pallor, clammy skin, hypotension, pulsus paradoxus (drop in systolic blood pressure of 15 mm Hg or greater during slow inspiration), neck vein distention, and dyspnea indicate cardiac tamponade.

PATHOPHYSIOLOGY

Understanding pericarditis

Pericarditis occurs when a pathogen or other substance attacks the pericardium, leading to the following events.

Inflammation

Pericardial tissue damaged by bacteria or other substances releases chemical mediators of inflammation (such as prostaglandins, histamines, bradykinins, and serotonin) into the surrounding tissue, starting the inflammatory process. Friction occurs as the inflamed pericardial layers rub against each other.

Vasodilation and clotting

Histamines and other chemical mediators cause vasodilation and increased vessel permeability. Local blood flow (hyperemia) increases. Vessel walls leak fluids and proteins (including fibrinogen) into tissues, causing extracellular edema. Clots of fibrinogen and tissue fluid form a wall, blocking tissue spaces and lymph vessels in the injured area. This wall prevents the spread of bacteria and toxins to adjoining healthy tissues.

Initial phagocytosis

Macrophages already present in the tissues begin to phagocytize the invading bacteria but usually fail to stop the infection.

Enhanced phagocytosis

Substances released by the injured tissue stimulate neutrophil production in the bone marrow. Neutrophils then travel to the injury site through the bloodstream and join macrophages in destroying pathogens. Meanwhile, additional macrophages and monocytes migrate to the injured area and continue phagocytosis.

Exudation

After several days, the infected area fills with an exudate composed of necrotic tissue and dead and dying bacteria, neutrophils, and macrophages. This exudate, which is thinner than pus, forms until all infection ceases, creating a cavity that remains until tissue destruction stops. The contents of the cavity autolyze and are gradually reabsorbed into healthy tissue.

After several days, the infected area fills with an exudate composed of necrotic tissue and dead and dying bacteria, neutrophils, and macrophages. This exudate, which is thinner than pus, forms until all infection ceases, creating a cavity that remains until tissue destruction stops. The contents of the cavity autolyze and are gradually reabsorbed into healthy tissue.

Fibrosis and scarring

As the end products of the infection slowly disappear, fibrosis and scar tissue may form. Scarring, which can be extensive, can ultimately cause heart failure if it restricts movement.

Diagnostic tests

Laboratory results reflect inflammation and may identify the disorder's cause. They include the following:

- normal or elevated white blood cell count, especially in infectious pericarditis
- elevated erythrocyte sedimentation rate
- slightly elevated serum creatine kinase-MB levels with associated myocarditis
- culture of pericardial fluid obtained by open surgical drainage or pericardiocentesis (which sometimes identifies a causative organism in bacterial or fungal pericarditis).

Other pertinent laboratory data include blood urea nitrogen levels to check for uremia, antistreptolysin-O titers to detect rheumatic fever, and a purified protein derivative skin test to check for tuberculosis.

Electrocardiography shows characteristic changes in acute pericarditis. They include elevated ST segments in the limb leads and most precordial leads. The QRS segments may be diminished when pericardial effusion is present. Rhythm changes may also occur, including atrial ectopic rhythms (such as atrial fibrillation) or sinus arrhythmias.

Echocardiography indicates pericardial effusion when it shows an echo-free space between the ventricular wall and the pericardium.

Treatment

Appropriate treatment aims to relieve symptoms, manage underlying systemic disease, and prevent or treat pericardial effusion and cardiac tamponade.

In idiopathic pericarditis, postmyocardial infarction pericarditis, and postthoracotomy pericarditis, treatment consists of bed rest as long as fever and pain persist and the administration of nonsteroidal drugs, such as aspirin and indomethacin, to relieve pain and reduce inflammation. If symptoms continue, the doctor may prescribe corticosteroids. Although they provide rapid and effective relief, corticosteroids must be used cautiously because the disorder may recur when drug therapy stops.

When infectious pericarditis results from disease of the left pleural space, mediastinal abscesses, or septicemia, the patient requires either antibiotics, surgical drainage, or both. If cardiac tamponade develops, the doctor may perform emergency pericardiocentesis and may inject antibiotics directly into the pericardial sac.

Recurrent pericarditis may require partial pericardectomy, which creates a window that allows fluid to drain into the pleural space. In constrictive pericarditis, total pericardectomy may be necessary to permit the heart to fill and contract adequately. Treatment must also include management of rheumatic fever, uremia, tuberculosis, and other underlying disorders.

Nursing diagnoses

- Altered role performance
- Anxiety
- Decreased cardiac output
- Diversional activity deficit
- Ineffective breathing pattern
- Pain

Key outcomes

- The patient will maintain hemodynamic stability with adequate cardiac output.
- The patient will exhibit no arrhythmias.
- The patient will maintain adequate ventilation.
- The patient will cope with current medical condition without demonstrating serious signs of anxiety specific to the individual.
- The patient will express interest in using leisure time meaningfully.
- The patient will express feelings of comfort and decreased pain.

Nursing interventions

- Stress the importance of bed rest. Assist the patient with bathing, if necessary. Provide a bedside commode because this method puts less stress on the heart than using a bedpan. Offer diversional activities that are physically undemanding.
- Place the patient in an upright position to relieve dyspnea and chest pain.
- Provide analgesics to relieve pain and oxygen to prevent tissue hypoxia.
- Because cardiac tamponade requires immediate treatment, keep a pericardiocentesis set handy whenever you suspect pericardial effusion.
- Assess cardiovascular status frequently, watching for signs of cardiac tamponade.
- To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- Before giving antibiotics, obtain a patient history of allergies. Administer antibiotics on time to maintain consistent drug levels in the blood.
- Observe for signs of infiltration or inflammation at the venipuncture site, a possible complication of long-term I.V. administration. To reduce the risk of this complication, rotate venous access sites.
- Provide appropriate postoperative care, similar to that given after cardiothoracic surgery.

Patient teaching

- Explain all tests and treatments to the patient.
- If surgery is necessary, teach the patient how to perform deep-breathing and coughing exercises before he undergoes the procedure.
- Tell the patient to resume his daily activities slowly and to schedule rest periods into his daily routine, as instructed by the doctor.

PULMONIC INSUFFICIENCY

In pulmonic insufficiency, blood ejected into the pulmonary artery during systole flows back into the right ventricle during diastole, causing fluid overload in the ventricle, ventricular hypertrophy, and eventual right-sided heart failure.

Causes

Pulmonic insufficiency may be congenital or may result from pulmonary hypertension. The most common acquired cause is dilation of the pulmonic valve ring from severe pulmonary hypertension.

Rarely, pulmonic insufficiency may result from prolonged use of a pressure monitoring catheter in the pulmonary artery.

Complications

If the patient has pulmonary hypertension, right-sided heart failure may develop.

Assessment findings

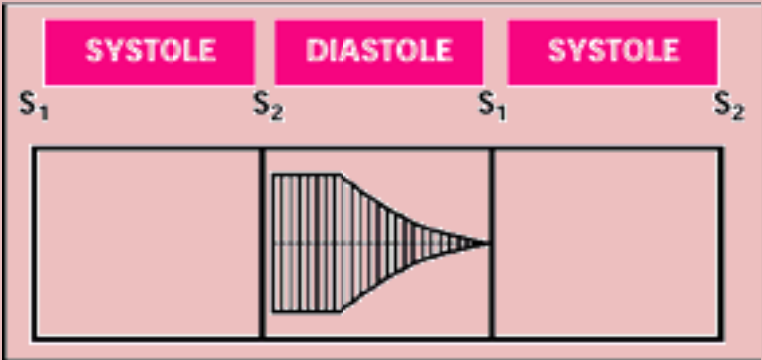

The patient may complain of dyspnea on exertion, fatigue, chest pain, and syncope. Peripheral edema may cause him discomfort.

A patient with severe insufficiency that progresses to right-sided heart failure may appear jaundiced, with severe peripheral edema and ascites. He may also appear malnourished.

Auscultation may reveal a high-pitched, decrescendo, diastolic blowing murmur along the left sternal border (Graham Steell's murmur). This murmur may be difficult to distinguish from the murmur of aortic insufficiency. (See [Identifying the murmur of pulmonic insufficiency.](#))

Identifying the murmur of pulmonic insufficiency

A high-pitched, blowing decrescendo murmur at Erb's point characterizes pulmonic insufficiency.

Palpation may disclose hepatomegaly when the patient has right-sided heart failure.

Diagnostic tests

Cardiac catheterization shows pulmonic insufficiency, increased right ventricular pressure, and associated cardiac defects.

Chest X-rays show right ventricular and pulmonary arterial enlargement.

Echocardiography can be used to visualize the pulmonic valve abnormality.

Electrocardiography findings may be normal in mild cases or reveal right ventricular hypertrophy.

Treatment

In pulmonic insufficiency, treatment is based on the patient's symptoms. A low-sodium diet and diuretics help to reduce hepatic congestion before surgery. Valvulotomy or valve replacement may be required in severe cases.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping u Risk for infection

Key outcomes

- u The patient will perform activities of daily living without fatigue or decreased energy.
- u The patient will maintain hemodynamic stability and adequate cardiac output and won't develop arrhythmias.
- u The patient won't develop complications of excess fluid volume.
- u The patient will maintain adequate ventilation.
- u The patient will maintain joint mobility and range of motion.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Alternate periods of activity and rest to prevent extreme fatigue and dyspnea.
- u Keep the patient's legs elevated while he sits in a chair to improve venous return to the heart.
- u Elevate the head of the bed to improve ventilation.
- u Keep the patient on a low-sodium diet. Consult with a dietitian to ensure that the patient receives foods that he likes while adhering to the diet restrictions.
- u Monitor for signs of heart failure, pulmonary edema, and adverse reactions to drug therapy.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u If the patient has surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor his vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.

Patient teaching

- u Teach the patient about diet restrictions, medications, symptoms that should be reported, and the importance of consistent follow-up care.
- u Tell the patient to elevate his legs whenever he sits.

PULMONIC STENOSIS

In pulmonic stenosis, obstructed right ventricular outflow causes right ventricular hypertrophy as the right ventricle attempts to overcome resistance to the narrow valvular opening.

A congenital defect, pulmonic stenosis is associated with other congenital heart defects such as tetralogy of Fallot. It's rare among elderly people.

Causes

Pulmonic stenosis results from congenital stenosis of the pulmonic valve cusp or (infrequently) from rheumatic heart disease or cancer.

Complications

Right-sided heart failure is the ultimate result of untreated pulmonic stenosis.

Assessment findings

Depending on the severity of the obstruction, the patient with mild stenosis may be asymptomatic. A patient with moderate to severe stenosis may complain of dyspnea on exertion, fatigue, chest pain, and syncope. Accompanying peripheral edema may cause him discomfort.

Inspection may reveal a prominent a wave in the jugular venous pulse. If severe stenosis has progressed to right-sided heart failure, the patient may appear jaundiced, with severe peripheral edema and ascites. He may also appear malnourished.

Auscultation may reveal a fourth heart sound, a thrill at the upper left sternal border, a harsh systolic ejection murmur, and a holosystolic decrescendo murmur of tricuspid insufficiency, particularly if the patient has heart failure. (See [Identifying the murmur of pulmonic stenosis.](#))

Palpation may detect hepatomegaly when the patient has right-sided heart failure, presystolic pulsations of the liver, and a right parasternal lift.

Diagnostic tests

Chest X-rays usually show normal heart size and normal lung vascularity, although the pulmonary arteries may be evident. With severe obstruction and right-sided heart failure, the right atrium and ventricle typically appear enlarged.

Echocardiography can be used to visualize the pulmonic valve abnormality.

Electrocardiography results may be normal in mild cases, or they may show right axis deviation and right ventricular hypertrophy. High-amplitude P waves in leads II and V₁ indicate right atrial enlargement.

Treatment

A low-sodium diet and diuretics help reduce hepatic congestion before surgery. Additionally, cardiac catheter balloon valvuloplasty is usually effective even with moderate to severe obstruction.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping u Risk for infection

Key outcomes

- u The patient will perform activities of daily living without excess fatigue or decreased energy.
- u The patient will maintain adequate cardiac output, hemodynamic stability, and no arrhythmias.
- u The patient won't exhibit complications of excess fluid volume.
- u The patient will maintain adequate ventilation.
- u The patient will maintain joint mobility and range of motion.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Alternate periods of activity and rest to prevent extreme fatigue and dyspnea.
- u Keep the patient's legs elevated while he sits in a chair to improve venous return to the heart.
- u Elevate the head of the bed to improve ventilation.
- u Keep the patient on a low-sodium diet. Consult with a dietitian to ensure that the patient receives foods that he likes while adhering to the diet restrictions.
- u Monitor for signs of heart failure, pulmonary edema, and adverse reactions to drug therapy.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u After cardiac catheterization, apply firm pressure to the catheter insertion site, usually in the groin. Monitor the site for signs of bleeding every 15 minutes for at least 6 hours. If the site bleeds, remove the pressure dressing and manually apply firm pressure to the site.
- u Notify the doctor of any changes in peripheral pulses distal to the insertion site, changes in cardiac rhythm and vital signs, and complaints of chest pain.

Patient teaching

- u Teach the patient about diet restrictions, medications, signs and symptoms that should be reported, and the importance of consistent follow-up care.
- u Teach the patient to elevate the legs when sitting.

Identifying the murmur of pulmonic stenosis

A medium-pitched, harsh crescendo-decrescendo murmur in the area of the pulmonic valve characterizes pulmonic stenosis.

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

A systemic inflammatory disease of childhood, acute rheumatic fever develops after infection of the upper respiratory tract with group A beta-hemolytic streptococci.

Rheumatic fever principally involves the heart, joints, central nervous system, skin, and subcutaneous tissues. It commonly recurs.

The term rheumatic heart disease refers to the cardiac involvement of rheumatic fever—its most destructive effect. Cardiac involvement develops in up to 50% of patients and may affect the endocardium, myocardium, or pericardium during the early acute phase. It may later affect the heart valves, causing chronic valvular disease.

The extent of damage to the heart depends on where the disorder strikes. Myocarditis produces characteristic lesions called Aschoff's bodies in the acute stages as well as cellular swelling and fragmentation of interstitial collagen, leading to formation of a progressively fibrotic nodule and interstitial scars. Endocarditis causes valve leaflet swelling, erosion along the lines of leaflet closure, and blood, platelet, and fibrin deposits, which form beadlike vegetation. It strikes the mitral valve most commonly in females and the aortic valve in males. In both, it affects the tricuspid valves occasionally and the pulmonic valve rarely.

Long-term antibiotic therapy can minimize the recurrence of rheumatic fever, reducing the risks of permanent cardiac damage and valvular deformity.

Although rheumatic fever tends to be familial, this tendency may reflect contributing environmental factors. For example, in lower socioeconomic groups, incidence is highest in children between ages 5 and 15, probably resulting from malnutrition and crowded living conditions. Rheumatic fever strikes most commonly during cool, damp weather in winter and early spring. In the United States, it's most common in the northern states.

Causes

Rheumatic fever appears to be a hypersensitivity reaction in which antibodies produced to combat streptococci react and produce characteristic lesions at specific tissue sites. How and why group A streptococcal infection initiates the process are unknown. Because few people infected with *Streptococcus* ever contract rheumatic fever (about 0.3%), altered host resistance probably is involved in its development or recurrence.

Complications

Rheumatic fever's long-term effects often destroy the mitral and aortic valves. Their malfunction leads to severe pancarditis and occasionally produces pericardial effusion and fatal heart failure. Of the patients who survive this complication, about 20% die within 10 years.

Assessment findings

Nearly all affected patients report having a streptococcal infection a few days to 6 weeks earlier. They usually have a recent history of low-grade fever that spikes to at least 100.4° F (38° C) late in the afternoon, unexplained epistaxis, and abdominal pain.

Most patients complain of migratory joint pain (polyarthritis). Swelling, redness, and signs of effusion usually accompany such pain, which most commonly affects the knees, ankles, elbows, and hips.

If the patient has pericarditis, he may complain of sharp, sudden pain that usually starts over the sternum and radiates to the neck, shoulders, back, and arms. The pain commonly is pleuritic, increases with deep inspiration, and decreases when the patient sits up and leans forward. (This position pulls the heart away from the diaphragmatic pleurae of the lungs.) The pain may mimic that of myocardial infarction.

A patient with heart failure caused by severe rheumatic carditis may complain of dyspnea, right upper quadrant pain, and a hacking, nonproductive cough.

Inspection may reveal skin lesions such as erythema marginatum, a nonpruritic, macular, transient rash. The lesions are red with blanched centers and well-demarcated borders. Lesions typically appear on the trunk and extremities.

Near tendons or the bony prominences of joints, you may notice subcutaneous nodules that are firm, movable, nontender, and about 3 mm to 2 cm in diameter. They occur around the elbows, knuckles, wrists, and knees, and less commonly on the scalp and backs of the hands. These nodules persist for a few days to several weeks and, like erythema marginatum, commonly accompany carditis.

You may notice edema and tachypnea if the patient has left-sided heart failure.

Up to 6 months after the original streptococcal infection, you may notice transient chorea. Mild chorea may produce hyperirritability, a deterioration in handwriting, or inability to concentrate. Severe chorea causes purposeless, nonrepetitive, involuntary muscle spasms and speech disturbances; poor muscle coordination; and weakness. Chorea resolves with rest and causes no residual neurologic damage.

Palpation may reveal a rapid pulse rate, and auscultation may reveal a pericardial friction rub (a grating sound heard as the heart moves) if the patient has pericarditis. You can hear it best during forced expiration, with the patient leaning forward or on his hands and knees.

Murmurs and gallops may also occur. With left-sided heart failure, you may hear bibasilar crackles and a ventricular or an atrial gallop. The most common murmurs include:

- u a systolic murmur of mitral insufficiency (a high-pitched, blowing, holosystolic murmur, loudest at apex, possibly radiating to the anterior axillary line)
- u a midsystolic murmur caused by stiffening and swelling of the mitral leaflet
- u occasionally a diastolic murmur of aortic insufficiency (a low-pitched, rumbling, almost inaudible murmur).

Valvular disease may eventually cause chronic valvular stenosis and insufficiency, including mitral stenosis and insufficiency and aortic insufficiency. In children, mitral insufficiency remains the major sequela of rheumatic heart disease.

Diagnostic tests

No specific laboratory tests determine the presence of rheumatic fever, but the following test results support the diagnosis:

- u White blood cell count and erythrocyte sedimentation rate may be elevated (during the acute phase); blood studies show slight anemia caused by suppressed erythropoiesis during inflammation.
- u C-reactive protein is positive (especially during acute phase).
- u Cardiac enzyme levels may be increased in severe carditis.
- u Antistreptolysin-O titer is elevated in 95% of patients within 2 months of onset.
- u Throat cultures may continue to show the presence of group A streptococci; however, they usually occur in small numbers. Isolating them is difficult.
- u Electrocardiography reveals no diagnostic changes, but 20% of patients show a prolonged PR interval.
- u Chest X-rays show normal heart size (except with myocarditis, heart failure, and pericardial effusion).
- u Echocardiography helps evaluate valvular damage, chamber size, ventricular function, and the presence of a pericardial effusion.
- u Cardiac catheterization is used to evaluate valvular damage and left ventricular function in severe cardiac dysfunction.

Treatment

Effective management eradicates the streptococcal infection, relieves symptoms, and prevents recurrence, thus reducing the chance of permanent cardiac damage.

During the acute phase, treatment includes penicillin or erythromycin (for patients with penicillin hypersensitivity). Salicylates, such as aspirin, relieve fever and minimize joint swelling and pain; if the patient has carditis or if salicylates fail to relieve pain and inflammation, the doctor may prescribe corticosteroids.

Supportive treatment requires strict bed rest for about 5 weeks during the acute phase with active carditis, followed by a progressive increase in physical activity. The increase depends on clinical and laboratory findings and the patient's response to treatment.

After the acute phase subsides, a monthly I.M. injection of penicillin G benzathine or daily doses of oral sulfadiazine or penicillin G may be used to prevent recurrence. Such preventive treatment usually continues for 5 to 10 years.

Heart failure requires continued bed rest and diuretics. Severe mitral or aortic valvular dysfunction that causes persistent heart failure requires corrective surgery, such as commissurotomy (separation of the adherent, thickened leaflets of the mitral valve), valvuloplasty (inflation of a balloon within a valve), or valve replacement (with prosthetic valve). Corrective valvular surgery seldom is necessary before late adolescence.

Nursing diagnoses

u Activity intolerance u Altered role performance u Anxiety u Decreased cardiac output u Diversional activity deficit u Fatigue u Impaired gas exchange u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will carry out activities of daily living without weakness or fatigue.
- u The patient will maintain adequate ventilation.
- u The patient will maintain hemodynamic stability.
- u Cardiac output will remain adequate.
- u The patient will have no arrhythmias.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings about diminished capacity to perform usual roles.
- u The patient will cope with current medical condition without demonstrating severe signs of anxiety.

Nursing interventions

- u Before giving penicillin, ask the patient (or, if the patient is a child, his parents) if he's ever had a hypersensitivity reaction to it. Even if he hasn't, warn him that such a reaction is possible.
- u Administer antibiotics on time to maintain consistent antibiotic blood levels.
- u Stress the importance of bed rest. Assist with bathing, as necessary. Provide a bedside commode because it puts less stress on the heart than using a bedpan. Offer diversional activities that are physically undemanding.
- u Place the patient in an upright position to relieve dyspnea and chest pain, if needed.
- u Provide analgesics to relieve pain and oxygen to prevent tissue hypoxia as needed.
- u To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- u If the patient is unstable because of chorea, clear his environment of objects that could make him fall.
- u After the acute phase, encourage the patient's family and friends to spend as much time as possible with the patient to minimize his boredom. Advise parents to secure a tutor to help their child keep up with schoolwork during the long convalescence.
- u Help the parents overcome any guilt feelings they may have about their child's illness. Failure to seek treatment for streptococcal infection is common because the illness may seem no worse than a cold.
- u Encourage the parents and the child to vent their frustrations during the long, tedious recovery. If the child has severe carditis, help them prepare for permanent changes in the child's lifestyle.

Patient teaching

- u Explain all tests and treatments to the patient.
- u Tell the patient to resume activities of daily living slowly and to schedule rest periods into his routine, as instructed by the doctor.
- u Tell the parents or patient to stop penicillin therapy and call the doctor immediately if the patient develops a rash, fever, chills, or other signs of an allergic reaction.
- u Instruct the patient and family members to watch for and report early signs of left-sided heart failure, such as dyspnea and a hacking, nonproductive cough.
- u Teach the patient and family members about this disease and its treatment. Warn the parents to watch for and immediately report signs of recurrent streptococcal infection: sudden sore throat, diffuse throat redness and oropharyngeal exudate, swollen and tender cervical lymph glands, pain on swallowing, temperature of 101° to 104° F (38.3° to 40° C), headache, and nausea. Urge them to keep the child away from people with respiratory tract infections.
- u Help the patient's family understand the frustrations associated with chorea (such as nervousness, restlessness, poor coordination, weakness, and inattentiveness). Emphasize that these effects are transient.
- u Make sure the patient and family members understand the need to comply with prolonged antibiotic therapy and follow-up care. Arrange for a visiting nurse to oversee home care, if necessary.
- u Explain that antibiotics must be given prophylactically before any dental work or other invasive procedure.

SEPTIC SHOCK

Low systemic vascular resistance and an elevated cardiac output characterize septic shock. The disorder is thought to occur in response to infections that release microbes or one of the immune mediators.

Septic shock is usually a complication of another disorder or invasive procedure and has a mortality as high as 25%.

Causes and pathophysiology

Any pathogenic organism can cause septic shock. Gram-negative bacteria, such as *Escherichia coli*, *Klebsiella pneumoniae*, *Serratia*, *Enterobacter*, and *Pseudomonas*, rank as the most common causes and account for up to 70% of all cases. Opportunistic fungi cause about 3% of cases. Rare causative organisms include mycobacteria and some viruses and protozoa.

Many organisms that are normal flora on the skin and in the intestines are beneficial and pose no threat. However, when they spread throughout the body by way of the bloodstream (gaining entry through any alteration in the body's normal defenses or through artificial devices that penetrate the body, such as I.V., intra-arterial, and urinary catheters, and knife or bullet wounds), they can progress to an overwhelming infection unless body defenses destroy them.

Initially, the body's defenses activate chemical mediators in response to the invading organisms. The release of these mediators results in low systemic vascular resistance and increased cardiac output. Blood flow is unevenly distributed in the microcirculation and plasma leaking from capillaries causes functional hypovolemia. Eventually, cardiac output decreases, and poor tissue perfusion and hypotension cause multisystem organ dysfunction syndrome and death.

Septic shock can occur in any person with impaired immunity, but neonates and elderly people are at greatest risk. About two-thirds of septic shock cases occur in hospitalized patients, most of whom have underlying diseases. Those at high risk include patients with burns; chronic cardiac, hepatic, or renal disorders; diabetes mellitus; immunosuppression; malnutrition; stress; and excessive antibiotic use. Also at risk are patients who have had invasive diagnostic or therapeutic procedures, surgery, or traumatic wounds.

Complications

In septic shock, complications include disseminated intravascular coagulation, renal failure, heart failure, GI ulcers, and abnormal liver function.

Assessment findings

The patient's history may include a disorder or treatment that can cause immunosuppression. Or, it may include a history of invasive tests or treatments, surgery, or trauma. At onset, the patient may have fever and chills, although 20% of patients may be hypothermic.

The patient's signs and symptoms reflect either the *hyperdynamic* or *warm phase* of septic shock (such as increased cardiac output, peripheral vasodilation, and decreased systemic vascular resistance) or the *hypodynamic* or *cold phase* (such as decreased cardiac output, peripheral vasoconstriction, increased systemic vascular resistance, and inadequate tissue perfusion).

In the hyperdynamic phase, the patient's skin may appear pink and flushed. His altered level of consciousness is reflected in agitation, anxiety, irritability, and shortened attention span. Respirations are rapid and shallow. Urine output is below normal.

Palpation of peripheral pulses may detect a rapid, full, bounding pulse. The skin may feel warm and dry. Blood pressure may be normal or slightly elevated.

In the hypodynamic phase, the patient's skin may appear pale and, possibly, cyanotic. Peripheral areas may be mottled. His level of consciousness may be decreased; obtundation and coma may be present. Respirations may be rapid and shallow, and urine output may be less than 25 ml/hour or absent.

Palpation of peripheral pulses may reveal a rapid pulse that is weak, thready, or absent. It may also be irregular if arrhythmias are present. The skin may feel cold and clammy.

Auscultation of blood pressure may reveal hypotension, usually with a systolic pressure below 90 mm Hg or 50 to 80 mm Hg below the patient's previous level. Auscultation of the lungs may reveal crackles or rhonchi if pulmonary congestion is present.

If central pressures are being monitored, the pulmonary artery wedge pressure is reduced or normal, and cardiac output is moderately to severely increased or normal. Rarely, cardiac output is decreased.

Diagnostic tests

The following are characteristic laboratory findings:

- u Blood cultures are positive for the offending organism.
- u Complete blood count shows the presence or absence of anemia and leukopenia, severe or absent neutropenia, and usually the presence of thrombocytopenia.
- u Blood urea nitrogen and creatinine levels are increased and creatinine clearance is decreased.
- u Prothrombin time and partial thromboplastin time are abnormal.
- u Electrocardiogram shows ST depression, inverted T waves, and arrhythmias resembling myocardial infarction.
- u Serum lactate dehydrogenase levels are elevated with metabolic acidosis.
- u Urine studies show increased specific gravity (more than 1.020) and osmolality and decreased sodium level.
- u Arterial blood gas analysis demonstrates elevated blood pH and partial pressure of arterial oxygen (P_{aO_2}) and decreased partial pressure of arterial carbon dioxide (P_{aCO_2}) with respiratory alkalosis in early stages. As shock progresses, metabolic acidosis develops with hypoxemia indicated by decreased P_{aCO_2} as well as decreasing P_{aO_2} , HCO_3^- , and pH levels.

Treatment

Location and treatment of the underlying sepsis is essential to treating septic shock. If any I.V., intra-arterial, or urinary drainage catheters are in place, they should be removed. Aggressive antimicrobial therapy appropriate for the causative organism must be initiated immediately. Culture and sensitivity tests help determine the most effective antimicrobial drug.

In patients who are immunosuppressed because of drug therapy, drugs should be discontinued or reduced. Granulocyte transfusions may be used in patients with severe neutropenia.

Oxygen therapy should be initiated to maintain arterial oxygen saturation greater than 95%. Mechanical ventilation may be required if respiratory failure occurs.

Colloid or crystalloid infusions are given to increase intravascular volume and raise blood pressure. After sufficient fluid volume has been replaced, diuretics such as furosemide can be given to maintain urine output above 20 ml/hour. If fluid resuscitation fails to increase blood pressure, a vasopressor such as dopamine can be started. Blood transfusion may be needed if anemia is present.

Nursing diagnoses

- u Altered family processes
- u Altered tissue perfusion (cardiopulmonary, renal)
- u Anxiety
- u Decreased cardiac output
- u Fluid volume deficit
- u Impaired gas exchange
- u Ineffective family coping: Disabling
- u Risk for infection
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain hemodynamic stability.
- u The patient will maintain adequate ventilation.
- u The patient will remain free from signs and symptoms of infection.
- u The patient and family members will express feelings and develop adequate coping mechanisms.
- u The patient will maintain adequate fluid volume.

Nursing interventions

- u Remove any I.V., intra-arterial, or urinary drainage catheters and send to the laboratory to culture for the presence of the causative organism. New catheters can be reinserted in the intensive care unit.
- u Start an I.V. infusion with normal saline solution or lactated Ringer's solution, using a large-bore (14G to 18G) catheter, which allows easier administration of later blood transfusions. (*Caution:* Don't start I.V. infusions in the legs of a shock patient who has suffered abdominal trauma because infused fluid may escape through the ruptured vessel into the abdomen.)
- u Record the patient's blood pressure, pulse and respiratory rates, and peripheral pulses every 1 to 5 minutes until he is stabilized. Record hemodynamic pressure readings every 15 minutes. Monitor cardiac rhythm continuously. Systolic blood pressure less than 80 mm Hg usually results in inadequate coronary artery blood flow, cardiac ischemia, arrhythmias, and further complications of low cardiac output. When blood pressure drops below 80 mm Hg, increase the oxygen flow rate and notify the doctor immediately.
- u A progressive drop in blood pressure accompanied by a thready pulse generally signals inadequate cardiac output from reduced intravascular volume. Notify the doctor and increase the infusion rate.
- u Administer appropriate antimicrobial drugs I.V. to achieve effective blood levels rapidly.
- u Measure hourly urine output. If output is less than 30 ml/hour in adults, increase the fluid infusion rate; however, watch for signs of fluid overload such as an increase in pulmonary artery wedge pressure. Notify the doctor if urine output doesn't improve. A diuretic may be ordered to increase renal blood flow and urine

- output.
- u Draw an arterial blood sample to measure blood gas levels. Administer oxygen by face mask or airway to ensure adequate tissue oxygenation. Adjust the oxygen flow rate to a higher or lower level, as blood gas measurements indicate.
 - u Provide emotional support to the patient and family members.
 - u Document the occurrence of a nosocomial infection and report it to the infection-control nurse. Investigating all hospital-acquired infections can help identify their sources and prevent future infections.

Patient teaching

- u Explain all procedures and their purpose to ease the patient's anxiety.
- u Explain the risks associated with blood transfusions to the patient and family members, and answer their questions as completely as possible.

TRICUSPID INSUFFICIENCY

In tricuspid insufficiency, also known as tricuspid regurgitation, an incompetent tricuspid valve allows blood to flow back into the right atrium during systole, decreasing blood flow to the lungs and left side of the heart. Cardiac output also decreases.

Causes

Tricuspid insufficiency results from marked dilation of the right ventricle and tricuspid valve ring. It most commonly occurs in the late stages of heart failure because of rheumatic or congenital heart disease.

Less commonly, it results from congenitally deformed tricuspid valves, atrioventricular canal defects, or Ebstein's malformation of the tricuspid valve. Other causes include infarction of the right ventricular papillary muscles, tricuspid valve prolapse, carcinoid heart disease, endomyocardial fibrosis, infective endocarditis, and trauma.

Complications

Fluid overload in the right side of the heart can lead to right-sided heart failure.

Assessment findings

The patient may have a history of a disorder that can cause tricuspid insufficiency.

The patient may complain of dyspnea, fatigue, weakness, and syncope. Peripheral edema may cause him discomfort.

Inspection may reveal jugular vein distention with prominent v waves in a patient with normal sinus rhythm. In severe tricuspid insufficiency that has progressed to right-sided heart failure, the patient may appear jaundiced, with severe peripheral edema and ascites.

Auscultation may disclose a blowing holosystolic murmur at the lower left sternal border that increases with inspiration and decreases with expiration and Valsalva's maneuver. (See [Identifying the murmur of tricuspid insufficiency.](#))

Palpation may reveal hepatomegaly when the patient has right-sided heart failure, systolic pulsations of the liver, and a positive hepatojugular reflex. You also may feel a prominent right ventricular pulsation along the left parasternal region.

Diagnostic tests

Cardiac catheterization demonstrates markedly decreased cardiac output. The right atrial pressure pulse may exhibit no x descent during early systole, but instead a prominent c-v wave with a rapid y descent. The mean right atrial and right ventricular end-diastolic pressures typically are elevated.

Chest X-rays show right atrial and ventricular enlargement.

Echocardiography reveals right ventricular dilation and prolapse or flailing of the tricuspid leaflets.

Electrocardiography discloses right atrial hypertrophy, right or left ventricular hypertrophy, atrial fibrillation, and incomplete right bundle-branch block.

Treatment

A sodium-restricted diet and diuretics help reduce hepatic congestion before surgery. When rheumatic fever has deformed the tricuspid valve and resulted in severe insufficiency, the patient usually needs open-heart surgery for tricuspid annuloplasty or tricuspid valve replacement.

Nursing diagnoses

- u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping u Risk for infection

Key outcomes

- u The patient will perform activities of daily living without excess tiredness or fatigue.
- u The patient will maintain adequate cardiac output and hemodynamic stability.
- u The patient won't exhibit arrhythmias.
- u The patient won't exhibit complications of excess fluid volume.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain joint mobility and range of motion.

Identifying the murmur of tricuspid insufficiency

A high-pitched, blowing holosystolic murmur in the tricuspid area characterizes tricuspid insufficiency.

Nursing interventions

- Alternate periods of activity and rest to prevent extreme fatigue and dyspnea.
- Keep the patient's legs elevated while he's sitting to improve venous return to his heart.
- Elevate the head of his bed to improve ventilation.
- Maintain a low-sodium diet. Consult with a dietitian to ensure that the patient receives foods that he likes while adhering to the diet restrictions.
- Monitor for signs of heart failure, pulmonary edema, and adverse reactions to drug therapy.
- To reduce anxiety, allow the patient to express his concerns about the effects of activity restrictions on his responsibilities and routines. Reassure him that the restrictions are temporary.
- If the patient has surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor his vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.

Patient teaching

- Teach the patient about diet restrictions, medications, signs and symptoms that should be reported, and the importance of consistent follow-up care.
- Tell the patient to elevate his legs whenever he's sitting.

Identifying the murmur of tricuspid stenosis

A low, rumbling crescendo-decrescendo murmur in the tricuspid area characterizes tricuspid stenosis.

TRICUSPID STENOSIS

This relatively uncommon disorder obstructs blood flow from the right atrium to the right ventricle, which causes the right atrium to dilate and hypertrophy. Eventually, this leads to right-sided heart failure and increases pressure in the vena cava.

Tricuspid stenosis seldom occurs alone and is most commonly associated with mitral stenosis. It's most common in women.

Causes

Although this disorder is caused most commonly by rheumatic fever, it also may be congenital.

Complications

Patients with untreated tricuspid stenosis may develop right-sided heart failure.

Assessment findings

The patient with tricuspid stenosis may complain of dyspnea, fatigue, weakness, and syncope. Peripheral edema may cause her discomfort.

Inspection may reveal jugular vein distention with giant *a* waves in a patient who has normal sinus rhythm. The patient with severe tricuspid stenosis that has progressed to right-sided heart failure may appear jaundiced, with severe peripheral edema and ascites. She also may appear malnourished.

Auscultation may reveal a diastolic murmur at the lower left sternal border and over the xiphoid process. It's most prominent during presystole in sinus rhythm. The murmur increases with inspiration and decreases with expiration and during Valsalva's maneuver. (See [Identifying the murmur of tricuspid stenosis.](#))

Palpation may discover hepatomegaly when the patient has right-sided heart failure.

Diagnostic tests

Cardiac catheterization shows an increased pressure gradient across the valve, increased right atrial pressure, and decreased cardiac output.

Chest X-rays demonstrate right atrial and superior vena cava enlargement.

Echocardiography indicates thick tricuspid valve and right atrial enlargement.

Electrocardiography reveals right atrial hypertrophy, right or left ventricular hypertrophy, and atrial fibrillation. Tall, peaked P waves appear in lead II and prominent, upright P waves appear in lead V₁.

Treatment

In tricuspid stenosis, treatment is based on the patient's symptoms. A sodium-restricted diet and diuretics can help to reduce hepatic congestion before surgery.

A patient with moderate to severe stenosis probably requires open-heart surgery for valvulotomy or valve replacement. Valvuloplasty may be performed on elderly patients with end-stage disease in the cardiac catheterization laboratory.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary) u Decreased cardiac output u Fatigue u Fear u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Ineffective individual coping

Key outcomes

- u The patient will carry out activities of daily living without excess fatigue.
- u The patient will maintain adequate cardiac output, exhibit no arrhythmias, and attain hemodynamic status.
- u The patient won't exhibit complications of fluid volume excess.
- u The patient will maintain adequate ventilation.
- u The patient will maintain joint mobility and range of motion.
- u The patient will manifest no signs or symptoms of fever.

Nursing interventions

- u Alternate periods of activity and rest to prevent extreme fatigue and dyspnea.
- u When the patient sits in a chair, elevate her legs to improve venous return to the heart.
- u Elevate the head of the bed to improve ventilation.
- u Keep the patient on a low-sodium diet. Consult with a dietitian to ensure that the patient receives foods that she likes while adhering to the diet restrictions.
- u Monitor for signs of heart failure, pulmonary edema, and adverse reactions to the drug therapy.
- u Allow the patient to express her fears and concerns about the disorder, its impact on her life, and any impending surgery. Reassure her as needed.
- u If the patient has surgery, watch for hypotension, arrhythmias, and thrombus formation. Monitor her vital signs, arterial blood gas levels, intake and output, daily weights, blood chemistry studies, chest X-rays, and pulmonary artery catheter readings.

Patient teaching

- u Teach the patient about diet restrictions, medications, signs and symptoms that should be reported, and the importance of consistent follow-up care.
- u Urge the patient to elevate her legs whenever she sits.

VENTRICULAR ANEURYSM

Ventricular aneurysm is a potentially life-threatening condition that involves an outpouching—almost always of the left ventricle—that produces ventricular wall dysfunction in about 20% of patients after myocardial infarction (MI). It may develop within days to weeks after MI or may be delayed for years. Resection improves the prognosis in patients with ventricular failure or ventricular arrhythmias.

Causes and pathophysiology

MI causes ventricular aneurysm. When MI destroys a large muscular section of the left ventricle, necrosis reduces the ventricular wall to a thin sheath of fibrous tissue. Under intracardiac pressure, this thin layer stretches and forms a separate noncontractile sac (aneurysm). Abnormal muscle wall movement accompanies ventricular aneurysm. (See [Understanding ventricular aneurysm.](#))

During systolic ejection, the abnormal muscle wall movements associated with the aneurysm cause the remaining normally functioning myocardial fibers to increase the force of contraction to maintain stroke volume and cardiac output. At the same time, a portion of the stroke volume is lost to passive distention of the noncontractile sac.

Complications

Ventricular aneurysms enlarge but seldom rupture. However, an untreated ventricular aneurysm can lead to ventricular arrhythmias, cerebral embolization, or heart failure and is potentially fatal.

Assessment findings

The patient may have a history of a previous MI. However, sometimes MI is silent, and the patient may be unaware of having had one. He may complain of palpitations and anginal pain.

If the patient has developed heart failure as a result of the aneurysm, he may complain of dyspnea, fatigue, and edema.

Inspection of the chest may reveal a visible or palpable systolic precordial bulge. Distended neck veins may appear if heart failure is present.

Palpation of peripheral pulses may reveal an irregular rhythm caused by arrhythmias (such as premature ventricular contractions). A pulsus alternans may be felt. Palpation of the chest usually detects a double, diffuse, or displaced apical impulse.

Auscultation of the heart may detect an irregular rhythm and a gallop rhythm. Crackles and rhonchi may be present in the lung if heart failure is present.

Diagnostic tests

- The following tests may determine the presence of a ventricular aneurysm:
- u Two-dimensional echocardiography demonstrates abnormal motion in the left ventricular wall.
 - u Left ventriculography reveals left ventricular enlargement, with an area of akinesia or dyskinesia (during cineangiocardiology) and diminished cardiac function.
 - u Electrocardiography may show persistent ST-segment and T-wave elevations at rest. ST-segment elevation over the aneurysm creates an elevated rounded appearance. Chest X-rays may disclose an abnormal bulge distorting the heart's contour if the aneurysm is large; X-rays may be normal if the aneurysm is small.
 - u Noninvasive nuclear cardiology scan may indicate the site of infarction and suggest the area of aneurysm.

Treatment

Depending on the size of the aneurysm and the presence of complications, treatment may require only routine medical examination to follow the patient's condition, or aggressive measures for intractable ventricular arrhythmias, heart failure, and emboli.

When myocardial infarction destroys a large, muscular section of the left ventricle, necrosis reduces the ventricular wall to a thin layer of fibrous tissue. The thin wall stretches under intracardiac pressure and forms a ventricular aneurysm. Ventricular aneurysms usually occur on the anterior or apical surface of the heart.

Ventricular aneurysms balloon outward with each systole (dyskinesia). Blood is diverted to the distended muscle wall of the aneurysm, which doesn't contract (akinesia). Mural thrombus is present about 50% of the time—thromboembolism rarely is. Calcification of the thrombus is common.

To maintain stroke volume and cardiac output, the remaining normally functioning myocardial fibers increase contractile force. If they can't, overall ventricular function is impaired and complications, such as heart failure and ventricular arrhythmias, may develop.

Emergency treatment of ventricular arrhythmia includes I.V. antiarrhythmics, cardioversion, and defibrillation. Preventive treatment continues with oral antiarrhythmics, such as procainamide, quinidine, or disopyramide.

Emergency treatment for heart failure with pulmonary edema includes oxygen, digoxin I.V., furosemide I.V., potassium replacement, morphine sulfate I.V. and, when necessary, nitroprusside I.V. and endotracheal (ET) intubation. Maintenance therapy may include oral nitrates, prazosin, and hydralazine.

Systemic embolization requires anticoagulation therapy or embolectomy. Refractory ventricular tachycardia, heart failure, recurrent arterial embolization, and persistent angina with coronary artery occlusion may require surgery. The most effective surgery is aneurysmectomy with myocardial revascularization.

Nursing diagnoses

- u Activity intolerance
- u Altered tissue perfusion (cardiopulmonary)
- u Anxiety
- u Decreased cardiac output
- u Fatigue
- u Fear
- u Fluid volume excess
- u Impaired gas exchange
- u Ineffective breathing pattern
- u Risk for infection

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain hemodynamic stability.
- u The patient won't develop complication of fluid volume excess.
- u The patient will express feelings of increased energy and decreased fatigue.
- u The patient will express feelings of decreased anxiety.

Nursing interventions

- u In a patient with heart failure, closely monitor vital signs, heart sounds, intake and output, fluid and electrolyte balance, and blood urea nitrogen and serum creatinine levels.
- u Be alert for sudden changes in sensorium that indicate cerebral embolization and for any signs that suggest renal failure or MI.
- u Arrhythmias require elective cardioversion. If the patient is conscious, give diazepam I.V., as ordered, before cardioversion.
- u If the patient is receiving antiarrhythmics, check appropriate laboratory tests. For instance, if the patient takes procainamide, check antinuclear antibodies because the drug may induce signs and symptoms that mimic lupus erythematosus.
- u Provide psychological support for the patient and family members to reduce anxiety.
- u If the patient is scheduled to undergo resection, explain expected postoperative care in the intensive care unit (such as an ET tube, a ventilator, hemodynamic monitoring, and chest tubes).
- u After surgery, monitor vital signs, intake and output, heart sounds, and pulmonary artery catheter. Watch for signs of infection, such as fever and drainage.

Patient teaching

- u Teach the patient how to check for pulse irregularity and rate changes. Encourage him to follow his prescribed medication regimen — even during the night—and to watch for adverse reactions.
- u Because arrhythmias can cause sudden death, refer the family to a community-based cardiopulmonary resuscitation training program.

Vascular disorders

Vascular disorders can affect the arteries, the veins, or both types of vessels. Arterial disorders include aneurysms, which result from a weakening of the arterial wall; arterial occlusive disease, which commonly results from atherosclerotic narrowing of the artery's lumen; and Raynaud's disease, which may be linked to immunologic dysfunction. Thrombophlebitis, a venous disorder, results from inflammation or occlusion of the affected vessel.

ABDOMINAL ANEURYSM

An abdominal aneurysm is an abnormal dilation in the arterial wall that generally occurs in the aorta between the renal arteries and the iliac branches. Nearly 98% of all abdominal aneurysms are located in the infrarenal aorta. These aneurysms can be fusiform (spindle-shaped) or saccular (pouchlike) and develop slowly.

First, a focal weakness in the muscular layer of the aorta (tunica media), due to degenerative changes, allows the inner layer (tunica intima) and outer layer (tunica adventitia) to stretch outward. Blood pressure within the aorta progressively weakens the vessel walls and enlarges the aneurysm.

Abdominal aneurysms are seven times more common in hypertensive men than in women and are most common in whites ages 50 to 80.

Causes

About 95% of abdominal aneurysms result from arteriosclerosis or atherosclerosis; the rest, from cystic medial necrosis, trauma, syphilis, and other infections.

Complications

More than 50% of all people with untreated abdominal aneurysms die of hemorrhage and shock from aneurysmal rupture within 2 years of diagnosis; more than 85%, within 5 years.

Assessment findings

Most patients with abdominal aneurysms are asymptomatic until the aneurysm enlarges and compresses surrounding tissue. A large aneurysm may produce signs and symptoms that mimic renal calculi, lumbar disk disease, and duodenal compression.

The patient may complain of gnawing, generalized, steady abdominal pain or low back pain that is unaffected by movement. He may have a sensation of gastric or abdominal fullness caused by pressure on the GI structures.

ALERT Sudden onset of severe abdominal pain or lumbar pain that radiates to the flank and groin from pressure on lumbar nerves may signify enlargement and imminent rupture. If the aneurysm ruptures into the peritoneal cavity, severe and persistent abdominal and back pain, mimicking renal or ureteral colic, occurs. If it ruptures into the duodenum, GI bleeding occurs with massive hematemesis and melena.

The patient may have a history of a syncopal episode that occurs when an aneurysm ruptures, causing hypovolemia and a subsequent drop in blood pressure. Once a clot forms and the bleeding stops, he may again be asymptomatic or have abdominal pain because of bleeding into the peritoneum.

Inspection of the patient with an intact abdominal aneurysm usually reveals no significant findings. However, if the patient isn't obese, you may notice a pulsating mass in the periumbilical area. If the aneurysm has ruptured, you may notice signs of hypovolemic shock, such as skin mottling, decreased level of consciousness (LOC), diaphoresis, and oliguria. The abdomen may appear distended and an ecchymosis or hematoma may be present in the abdominal, flank, or groin area.

Paraplegia may occur if aneurysm rupture reduces blood flow to the spine. Auscultation of the abdomen may reveal a systolic bruit over the aorta caused by turbulent blood flow in the widened arterial segment. Hypotension occurs with aneurysm rupture.

Palpation of the abdomen may disclose some tenderness over the affected area. A pulsatile mass may be felt; however, avoid deep palpation to locate the mass because this may cause the aneurysm to rupture. Palpation of the peripheral pulses may reveal absent pulses distal to a ruptured aneurysm.

Diagnostic tests

Because an abdominal aneurysm seldom produces symptoms, it's typically detected accidentally on an X-ray or during a routine physical examination.

Several tests can confirm suspected abdominal aneurysm:

- Abdominal ultrasonography or echocardiography can determine the size, shape, and location of the aneurysm.
- Anteroposterior and lateral X-rays of the abdomen can be used to detect aortic calcification, which outlines the mass, at least 75% of the time.
- Computed tomography scan can be used to visualize the aneurysm's effect on nearby organs, particularly the position of the renal arteries in relation to the aneurysm.
- Aortography shows the condition of vessels proximal and distal to the aneurysm and the extent of the aneurysm, but aneurysm diameter may be underestimated because it shows only the flow channel and not the surrounding clot.

Treatment

Usually, abdominal aneurysm requires resection of the aneurysm and Dacron graft replacement of the aortic section. If the aneurysm is small and produces no symptoms, surgery may be delayed; however, small aneurysms can rupture. Beta-adrenergic blockers may be administered to decrease the rate of growth of the aneurysm. Regular physical examination and ultrasound checks monitor progression of the aneurysm. Large aneurysms or those that produce symptoms risk rupture and require immediate repair. In symptomatic patients, surgery is advised when the aneurysm is 2" to 2 ³/₈" (5 to 6 cm) in diameter. In symptomatic patients, repair is indicated regardless of size. In patients with poor perfusion distal to the aneurysm, external grafting may be done.

In acute dissection, emergency treatment before surgery includes resuscitation with fluid and blood replacement, I.V. propranolol to reduce myocardial contractility, I.V. nitroprusside to reduce and maintain blood pressure to 100 to 120 mm Hg systolic, and analgesics to relieve pain. An arterial line and indwelling urinary catheter are inserted to monitor the patient's condition.

Nursing diagnoses

▫ Altered tissue perfusion (cardiopulmonary, renal) ▫ Anxiety ▫ Decreased cardiac output ▫ Fluid volume deficit ▫ Impaired gas exchange ▫ Impaired physical mobility ▫ Impaired skin integrity ▫ Knowledge deficit ▫ Pain

Key outcomes

- The patient will maintain adequate cardiac output.
- The patient will maintain hemodynamic stability.
- Pulses will remain palpable distal to the aneurysm site.
- The patient will maintain adequate ventilation.
- The patient will maintain adequate urine output (output will be equivalent to intake).
- The patient will express feelings of increasing comfort and decreased pain.

Nursing interventions

In a nonacute situation:

- Allow the patient to express his fears and concerns. Help him identify effective coping strategies as he attempts to deal with his diagnosis.
- Offer the patient and family members psychological support. Answer all questions honestly, and provide reassurance.
- Before elective surgery, weigh the patient, insert an indwelling urinary catheter and an I.V. line, and assist with insertion of the arterial line and pulmonary artery catheter to monitor hemodynamic balance.
- Give prophylactic antibiotics as ordered.

In an acute situation:

- Monitor the patient's vital signs on his admission to the intensive care unit (ICU).
- Insert an I.V. line with at least a 14G needle to facilitate blood replacement.
- As ordered, obtain blood samples for kidney function tests (such as blood urea nitrogen, creatinine, and electrolyte levels), a complete blood count with differential, blood typing and crossmatching, and arterial blood gas (ABG) levels.
- Monitor the patient's cardiac rhythm strip. Insert an arterial line to allow for continuous blood pressure monitoring. Assist with insertion of a pulmonary artery line to monitor for hemodynamic balance.
- Administer ordered medications, such as antihypertensives and beta blockers to control aneurysm progression and analgesics to relieve pain.
- Be alert for signs of rupture, which may be immediately fatal. Watch closely for any signs of acute blood loss (such as decreasing blood pressure, increasing pulse and respiratory rates, restlessness, decreased sensorium, and cool, clammy skin).
- If rupture does occur, get the patient to surgery immediately. Medical antishock trousers may be used while transporting him to surgery.

After surgery:

- u With the patient in the ICU, closely monitor vital signs, intake and hourly output, neurologic status (such as LOC, pupil size, and sensation in arms and legs), and ABG levels.
- u Assess fluid status and replace fluids as needed to ensure adequate hydration.
- u Watch for signs of bleeding (such as increased pulse and respiratory rates, and hypotension), which may occur retroperitoneally from the graft site.
- u Check abdominal dressings for excessive bleeding or drainage. Assess the wound site for evidence of infection. Be alert for temperature elevations and other signs of infection. Use aseptic technique to change dressings.
- u After nasogastric (NG) intubation for intestinal decompression, irrigate the tube frequently to ensure patency. Record the amount and type of drainage.
- u Large amounts of blood may be needed during the resuscitative period to replace blood loss. Thus, renal failure due to ischemia is a major postoperative complication, possibly requiring hemodialysis.

ALERT Assess for return of severe back pain, which can indicate that the graft is tearing.

- u Mechanical ventilation is required after surgery. Assess the depth, rate, and character of respirations and breath sounds at least every hour. Have the patient cough, or suction the endotracheal (ET) tube as needed to maintain a clear airway. If the patient can breathe unassisted and has good breath sounds and adequate ABG levels, tidal volume, and vital capacity 24 hours after surgery, he will be extubated and will require oxygen by mask. Weigh the patient daily to evaluate fluid balance.
- u Provide frequent turning, and help the patient walk as soon as he's able (generally the second day after surgery).

Patient teaching

- u Provide psychological support for the patient and family members. Help ease their fears about the ICU, the threat of impending rupture, and surgery by providing appropriate explanations and answering all questions.
- u Explain the surgical procedure and the expected postoperative care in the ICU for patients undergoing complex abdominal surgery (I.V. lines, ET and NG intubation, and mechanical ventilation).
- u Instruct the patient to take all medications as prescribed and to carry a list of medications at all times, in case of an emergency.
- u Tell the patient not to push, pull, or lift heavy objects until medically cleared by the doctor.

ARTERIAL OCCLUSIVE DISEASE

Arterial occlusive disease is an obstruction or narrowing of the lumen of the aorta and its major branches, which interrupts blood flow, usually to the legs and feet. Arterial occlusive disease may affect the carotid, vertebral, innominate, subclavian, mesenteric, and celiac arteries.

PATHOPHYSIOLOGY

What causes acute arterial occlusion?

The most common cause of acute arterial occlusion is obstruction of a major artery by a clot. The occlusive mechanism may be endogenous, resulting from emboli formation, thrombosis, or plaques, or exogenous, resulting from trauma or fracture.

Embolism

Often the obstruction results from an embolus originating in the heart. Emboli typically lodge in the arms and legs, where blood vessels narrow or branch. In the arms, emboli usually lodge in the brachial artery but may occlude the subclavian or axillary arteries. Common leg sites include the iliac, femoral, and popliteal arteries. Emboli originating in the heart can cause neurologic damage if they enter the cerebral circulation.

Thrombosis

In a patient with atherosclerosis and marked arterial narrowing, thrombosis may cause acute intrinsic arterial occlusion. This complication typically arises in areas with severely stenotic vessels, especially in a patient who also has heart failure, hypovolemia, polycythemia, or traumatic injury.

Plaques

Atheromatous debris (plaques) from proximal arterial lesions also may intermittently obstruct small vessels (usually in the hands or feet). These plaques also may develop in the brachiocephalic vessels and travel to the cerebral circulation, where they may lead to transient cerebral ischemia or infarction.

Exogenous causes

Acute arterial occlusion may stem from insertion of an indwelling arterial catheter or intra-arterial drug abuse.

In addition, extrinsic arterial occlusion can result from direct blunt or penetrating trauma to the artery.

Arterial occlusive disease is more common in males than in females. The prognosis depends on the location of the occlusion, the development of collateral circulation to counteract reduced blood flow and, in acute disease, the time elapsed between the development of the occlusion and its removal.

Causes

Arterial occlusive disease is a common complication of atherosclerosis. (See [What causes acute arterial occlusion?](#))

Predisposing factors include smoking; aging; conditions such as hypertension, hyperlipidemia, and diabetes mellitus; and family history of vascular disorders, myocardial infarction, or cerebrovascular accident.

Complications

Occlusions may be acute or chronic and can cause severe ischemia, skin ulceration, and gangrene.

Assessment findings

Varied assessment findings depend on the vessel involved. (See [Signs and symptoms of arterial occlusive disease.](#))

Acute arterial occlusion occurs suddenly, in many instances without warning. However, peripheral occlusion can often be recognized by the five Ps:

- u *Pain* the most common symptom, occurs suddenly and is localized to the affected arm or leg.
- u *Pallor* results from vasoconstriction distal to the occlusion.
- u *Pulselessness* occurs distal to the occlusion.

⌞ *Paralysis* and *paresthesia* occur in the affected arm or leg from disturbed nerve endings or skeletal muscles.

A sixth P, known as *poikilothermy*, refers to temperature changes that occur distal to the occlusion, making the skin feel cool.

Diagnostic tests

Arteriography demonstrates the type, location, and degree of obstruction and the establishment of collateral circulation. It's particularly useful in chronic disease or for evaluating candidates for reconstructive surgery.

Ultrasonography and plethysmography are noninvasive tests that, in acute disease, show decreased blood flow distal to the occlusion.

Doppler ultrasonography typically reveals a relatively low-pitched sound and a monophasic waveform.

Segmental limb pressures and pulse volume measurements help evaluate the location and extent of the occlusion.

Ophthalmodynamometry helps determine the degree of obstruction in the internal carotid artery by comparing ophthalmic artery pressure with brachial artery pressure on the affected side. More than a 20% difference between pressures suggests arterial insufficiency.

Signs and symptoms of arterial occlusive disease	
A patient with arterial occlusive disease may have a wide variety of signs and symptoms depending on which portion of the vasculature is affected by the disorder.	
SITE OF OCCLUSION	SIGNS AND SYMPTOMS
Internal and external carotid arteries	Transient ischemic attacks (TIAs) due to reduced cerebral circulation produce unilateral sensory or motor dysfunction (transient monocular blindness, hemiparesis), possible aphasia or dysarthria, confusion, decreased mentation, and headache (these recurrent clinical features usually last for 5 to 10 minutes but may persist for up to 24 hours and may herald a cerebrovascular accident; absent or decreased pulsation with an auscultatory bruit over the affected vessels)
Vertebral and basilar arteries	TIAs of brain stem and cerebellum, producing binocular visual disturbances, vertigo, dys-arthria, and “drop attacks” (falling down without loss of consciousness) (less common than carotid TIA)
Innominate (brachiocephalic) artery	Signs and symptoms of vertebrobasilar occlusion, indications of ischemia (claudication) of right arm, possible bruit over right side of neck
Subclavian artery	Subclavian steal syndrome characterized by backflow of blood from the brain through the vertebral artery on the same side as the occlusion, into the subclavian artery distal to the occlusion, clinical effects of vertebrobasilar occlusion and exercise-induced arm claudication, possible gangrene (usually limited to the digits)
Mesenteric artery	Bowel ischemia, infarct necrosis, and gangrene; sudden, acute abdominal pain; nausea and vomiting; diarrhea; leukocytosis; shock due to massive intraluminal and plasma loss
Aortic bifurcation (saddle block occlusion, a medical emergency associated with cardiac embolization)	Sensory and motor deficits (muscle weakness, numbness, paresthesia, paralysis), signs of ischemia (sudden pain; cold, pale legs with decreased or absent peripheral pulses) in both legs.
Iliac artery (Leriche's syndrome)	Intermittent claudication of lower back, buttocks, and thighs, relieved by rest; absent or reduced femoral or distal pulses; shiny, scaly skin, subcutaneous tissue loss, and no body hair on affected limb; nail deformities; increased capillary refill time; blanching of feet on elevation; possible bruit over femoral arteries; impotence in males
Femoral and popliteal arteries (associated with aneurysm formation)	Intermittent claudication of the calves on exertion; ischemic pain in feet; pretrophic pain (heralds necrosis and ulceration); leg pallor and coolness; shiny, scaly skin, subcutaneous tissue loss, and no body hair on affected limb; nail deformities; increased capillary refill time; blanching of feet on elevation; gangrene; no palpable pulses distal to occlusion (auscultation over affected area may reveal a bruit)

Electroencephalography and a computed tomography scan may be necessary to rule out brain lesions.

Treatment

In mild chronic disease, treatment usually consists of supportive measures: elimination of smoking, hypertension control, walking exercise, and foot and leg care. In carotid artery occlusion, antiplatelet therapy may begin with dipyridamole and aspirin. For those patients with intermittent claudication caused by chronic arterial occlusive disease, pentoxifylline may improve blood flow through the capillaries. This drug is particularly useful for poor surgical candidates.

Thrombolytics, such as urokinase, streptokinase, and alteplase, can dissolve clots and relieve the obstruction caused by a thrombus.

Acute arterial occlusive disease usually requires surgery, such as:

- ⌞ *Embolectomy*. A balloon-tipped catheter is used to remove thrombotic material from the artery. Embolectomy is used mainly for mesenteric, femoral, or popliteal artery occlusion.
- ⌞ *Thromboendarterectomy*. This involves the opening of the artery and removal of the obstructing thrombus and the medial layer of the arterial wall. Plaque deposits remain intact. Thromboendarterectomy is usually performed after angiography and is commonly used in conjunction with autogenous vein or Dacron bypass surgery (femoropopliteal or aortofemoral).
- ⌞ *Atherectomy*. Plaque is excised using a drill or slicing mechanism.

- u *Balloon angioplasty*. The obstruction is compressed using balloon inflation.
- u *Laser angioplasty*. Excision and a hot-tip laser are used to vaporize the destruction.
- u *Stents*. A mesh of wires that stretch and mold to the arterial walls are inserted to prevent reocclusion.
- u *Combined therapy*. Any of the above treatments may be used concomitantly.
- u *Percutaneous transluminal coronary angioplasty (PTCA)*. Using fluoroscopy and a special balloon catheter, the stenosis or occluded artery is dilated to a predetermined diameter without overdistending it.
- u *Laser surgery*. An excimer or a hot-tip laser obliterates the clot and plaque by vaporizing it.
- u *Patch grafting*. This involves removal of the thrombosed arterial segment and replacement with an autogenous vein or Dacron graft.
- u *Bypass graft*. Blood flow is diverted through an anastomosed autogenous or woven Dacron graft to bypass the thrombosed arterial segment.
- u *Lumbar sympathectomy*. Depending on the condition of the sympathetic nervous system, this procedure may be an adjunct to reconstructive surgery.

Amputation may be necessary if arterial reconstructive surgery fails or if gangrene, uncontrollable infection, or intractable pain develops.

Other therapy includes heparin to prevent emboli (for embolic occlusion) and bowel resection after restoration of blood flow (for mesenteric artery occlusion).

Nursing diagnoses

- u Activity intolerance
- u Altered tissue perfusion (peripheral)
- u Diversional activity deficit
- u Impaired physical mobility
- u Impaired skin integrity
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will report increased comfort and relief of pain.
- u The patient will maintain palpable pulses and collateral circulation.
- u The patient will maintain skin integrity.
- u The patient will maintain joint mobility and range of motion.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will develop meaningful use of spare time with activity.

Nursing interventions

For chronic arterial occlusive disease:

- u Prevent trauma to the affected extremity. Use minimal pressure mattresses, heel protectors, a foot cradle, or a footboard to reduce pressure that could lead to skin breakdown. Keep the arm or leg warm but never use heating pads. If the patient is wearing socks, remove them frequently to check the skin.
- u Avoid using restrictive clothing, such as antiembolism stockings.
- u Administer analgesics, as ordered, to relieve pain.
- u Allow the patient to express fears and concerns, and help him identify and use effective coping strategies.

For preoperative care during an acute episode:

- u Assess the patient's circulatory status by checking for the most distal pulses and by inspecting his skin color and temperature.
- u Administer analgesics for pain as needed.
- u Administer heparin or thrombolytics by continuous I.V. drip as ordered. Use an infusion monitor or pump to ensure the proper flow rate.
- u Wrap the patient's affected foot in soft cotton batting, and reposition it frequently to prevent pressure on any one area. Strictly avoid elevating or applying heat to the affected leg.
- u Watch for signs of fluid and electrolyte imbalance, and monitor intake and output for signs of renal failure (such as urine output of less than 30 ml/hour).
- u If the patient has carotid, innominate, vertebral, or subclavian artery occlusion, monitor him for signs of cerebrovascular accident, such as numbness in an arm or a leg and intermittent blindness.

For postoperative care:

- u Monitor the patient's vital signs. Continuously assess his circulatory function by assessing skin color and temperature and by checking for distal pulses. In charting, compare earlier assessments and observations. Watch closely for signs of hemorrhage (such as tachycardia and hypotension), and check dressings for excessive bleeding.
- u In carotid, innominate, vertebral, or subclavian artery occlusion, assess the patient's neurologic status frequently for changes in level of consciousness, pupil size, and muscle strength.
- u In mesenteric artery occlusion, connect a nasogastric tube to low intermittent suction. Monitor intake and output (low urine output may indicate damage to renal arteries during surgery). Check bowel sounds for the return of peristalsis. Increasing abdominal distention and tenderness may indicate extension of bowel ischemia with resulting gangrene, necessitating further excision, or it may indicate peritonitis.
- u In saddle block occlusion, check distal pulses for adequate circulation. Watch for signs of renal failure and mesenteric artery occlusion (severe abdominal pain), and for cardiac arrhythmias, which may precipitate embolus formation.
- u If PTCA was performed, sheath (catheter) care must be done. The line must be kept open with a heparin infusion; monitor the insertion site for bleeding. Keep the catheterized leg immobile, and keep the patient on strict bed rest. Monitor and record pulses in the catheterized leg. Provide analgesics for back pain associated with catheter placement.
- u In iliac artery occlusion, monitor urine output for signs of renal failure from decreased perfusion to the kidneys as a result of surgery. Provide meticulous catheter care.
- u In both femoral and popliteal artery occlusion, assist with early ambulation, and don't allow the patient to sit for an extended period.
- u When caring for a patient who has undergone amputation, check the stump carefully for drainage. If drainage occurs, note and record its color and amount, and the time. Elevate the stump, as ordered, and administer adequate analgesics. Because phantom limb pain is common, explain this phenomenon to the patient.

Patient teaching

- u When preparing the patient for discharge, instruct him to watch for signs of recurrence (such as pain, pallor, numbness, paralysis, or absence of pulse) that can result from graft occlusion or occlusion at another site. Caution against wearing constrictive clothing, crossing her legs, or wearing garters. Tell her to avoid "bumping" injuries to affected limbs.
- u Warn the patient to avoid all tobacco products.
- u Tell the patient to avoid temperature extremes. If he must go outside in the cold, remind him to dress warmly and take special care to keep his feet warm.
- u Instruct the patient to wash his feet daily and inspect them for signs of injury or infection. Remind him to report any abnormalities to the doctor.
- u Advise the patient to wear sturdy, properly fitting shoes. Refer him to a podiatrist for any foot problems.
- u Teach the patient about preventive measures, such as smoking-cessation programs, regular exercise, weight control, reduction of dietary fat intake, and avoidance of pressure and constriction to extremities. These measures may reduce the risk of arterial occlusive disease, especially in patients with histories of cardiovascular disease.

BUERGER'S DISEASE

Buerger's disease is an inflammatory, nonatheromatous occlusive condition that causes segmental lesions and subsequent thrombus formation in the small and medium-sized arteries (and sometimes the veins), resulting in decreased blood flow to the legs and feet. It's also called thromboangiitis obliterans.

This disease affects the legs more commonly than the arms. Cerebral, visceral, and coronary vessels may also be affected. Incidence is highest among men of Asian and Jewish ancestry, ages 20 to 40, who smoke heavily.

Causes and pathophysiology

Although the cause of Buerger's disease is unknown, a definite link exists to smoking and an increased incidence of human leukocyte antigen (HLA)-B5 and HLA-A9, suggesting a hypersensitivity reaction to nicotine.

In the initial stages of the disease, polymorphonuclear leukocytes infiltrate the walls of the small and medium-sized arteries and veins. The internal elastic lamina is preserved, and a thrombus may develop in the vascular lumen. As the disease progresses, mononuclear cells, fibroblasts, and giant cells replace the neutrophils. In later stages, perivascular fibrosis and recanalization occur.

Complications

Impaired tissue perfusion can cause ulcerations and poor wound healing, possibly leading to amputation if gangrene and systemic infection occur.

Assessment findings

The patient with Buerger's disease typically complains of painful, intermittent claudication of the instep, which is aggravated by exercise and relieved by rest.

During exposure to low temperature, the feet initially become cold and numb and appear cyanotic; later, they redden, become hot, and tingle. Occasionally, Buerger's disease also affects the hands, possibly resulting in severe digital ischemia, trophic nail changes, painful fingertip ulcerations, and gangrene.

Palpation of peripheral pulses reveals normal brachial and popliteal pulses but absent or diminished radial, ulnar, or tibial pulses.

Late in the disease, the patient may experience migratory superficial vein thrombophlebitis, peripheral ulceration, muscle atrophy, and gangrene.

Diagnostic tests

Doppler ultrasonography may show diminished circulation in the peripheral vessels. Plethysmography helps to detect decreased circulation in the peripheral vessels.

Arteriography helps locate lesions and rules out atherosclerosis. Smooth tapering segmental lesions in the distal vessels and collateral vessels at the site of vascular occlusion are characteristic findings.

Biopsy of the affected vessel can confirm the diagnosis.

Treatment

Abstention from smoking tobacco is essential. An exercise program that uses gravity to fill and drain the blood vessels may also help in mild to moderate disease. Severe disease may require a lumbar sympathectomy or arterial bypass to increase blood supply to the skin. Parenteral or oral antibiotics may be used to treat secondary infections. Amputation may be necessary for nonhealing ulcers, intractable pain, or gangrene.

Nursing diagnoses

⌞ Activity intolerance ⌞ Altered role performance ⌞ Altered tissue perfusion (peripheral) ⌞ Anxiety ⌞ Impaired tissue integrity ⌞ Ineffective individual coping ⌞ Ineffective thermoregulation ⌞ Knowledge deficit ⌞ Pain ⌞ Risk for infection

Key outcomes

- ⌞ The patient will express feelings of comfort and decreased pain.
- ⌞ The patient will remain free from signs and symptoms of infection.
- ⌞ The patient will maintain adequate temperature.
- ⌞ The patient will develop adequate coping mechanisms.
- ⌞ The patient will maintain tissue integrity.
- ⌞ The patient will carry out previous roles within the limitations of the disease process.

Nursing interventions

- ⌞ If the patient has ulcers and gangrene, enforce bed rest, and use a padded footboard or bed cradle to prevent pressure from bed linens. Protect the feet with soft padding. Wash them gently with a mild soap and tepid water, rinse thoroughly, and pat dry with a soft towel.
- ⌞ Administer antibiotics, as ordered, and document the condition of ulceration daily.
- ⌞ Provide emotional support. If necessary, refer the patient for psychological counseling to help him cope with restrictions imposed by this chronic disease.
- ⌞ If the patient has undergone amputation, assess rehabilitative needs, especially regarding changes in body image. Refer him to a physical therapist, an occupational therapist, and the social service department, as needed.

Patient teaching

- ⌞ Strongly urge the patient to quit smoking to enhance the effectiveness of treatment. If necessary, refer him to a self-help group or a psychologist.
- ⌞ Warn the patient to avoid precipitating factors, such as stress, exposure to extreme temperatures, and trauma.
- ⌞ Teach proper foot care, especially the importance of wearing well-fitting shoes and cotton or wool socks. Show the patient how to inspect his feet daily for cuts, abrasions, and signs of skin breakdown, such as redness and soreness. Remind him to seek medical attention immediately after any trauma.

FEMORAL AND POPLITEAL ANEURYSMS

Because femoral and popliteal aneurysms occur in the two major peripheral arteries, they're also known as peripheral arterial aneurysms. They may be fusiform (spindle-shaped) or saccular (pouchlike). Fusiform types are three times more common. They may be singular or multiple segmental lesions, in many instances affecting both legs, and may accompany other arterial aneurysms located in the abdominal aorta or iliac arteries.

This condition is most common in men over age 50. Elective surgery before complications arise greatly improves the prognosis.

Causes

Femoral and popliteal aneurysms usually result from progressive atherosclerotic changes in the arterial walls (medial layer). Rarely, they result from congenital weakness in the arterial wall. They may also result from trauma (blunt or penetrating), bacterial infection, or peripheral vascular reconstructive surgery (which causes “suture line” aneurysms, also called false aneurysms, whereby a blood clot forms a second lumen).

Complications

If thrombosis, emboli, or gangrene occurs, poor tissue perfusion to areas distal to the aneurysm may require amputation.

Assessment findings

The patient may complain of pain in the popliteal space when a popliteal aneurysm is large enough to compress the medial popliteal nerve. Inspection may reveal edema and venous distention if the vein is compressed.

Femoral and popliteal aneurysms can produce signs and symptoms of severe ischemia in the leg or foot resulting from acute thrombosis within the aneurysmal sac, embolization of mural thrombus fragments and, rarely, rupture.

In acute aneurysmal thrombosis, the patient may complain of severe pain. Inspection may reveal distal petechial hemorrhages from aneurysmal emboli. The affected leg or foot may show loss of color. Palpation of the affected leg or foot may indicate coldness and a loss of pulse. Gangrene may develop.

Bilateral palpation that reveals a pulsating mass above or below the inguinal ligament in femoral aneurysm and behind the knee in popliteal aneurysm usually confirms the diagnosis. When thrombosis has occurred, palpation detects a firm, nonpulsating mass.

Diagnostic tests

Arteriography or ultrasonography may help resolve doubtful situations. Arteriography may also detect associated aneurysms, especially those in the abdominal aorta and the iliac arteries. Ultrasonography may also help determine the size of the femoral or popliteal artery.

Treatment

Femoral and popliteal aneurysms require surgical bypass and reconstruction of the artery, usually with an autogenous saphenous vein graft replacement. Arterial occlusion that causes severe ischemia and gangrene may require leg amputation.

Nursing diagnoses

u Activity intolerance u Altered tissue perfusion (cardiopulmonary, peripheral) u Defensive coping u Denial u Diversional activity deficit u Impaired physical mobility u Impaired skin integrity u Pain u Risk for infection

Key outcomes

u The patient will maintain pulses and adequate circulation distal to damaged aneurysm site.
u The patient will express feelings of increased comfort and decreased pain.
u Skin integrity will remain intact.
u The patient will remain free from signs and symptoms of infection.
u The patient will carry out activities of daily living without excess fatigue or exhaustion.

Nursing interventions

Before arterial surgery:
u Assess and record the patient's circulatory status, noting location and quality of peripheral pulses in the affected leg.
u Administer prophylactic antibiotics or anticoagulants as ordered.

After arterial surgery:
u Monitor carefully for early signs of thrombosis or graft occlusion (such as loss of pulse, decreased skin temperature and sensation, and severe pain) and infection (fever).
u Palpate distal pulses at least every hour for the first 24 hours and then as often as ordered. Correlate these findings with the preoperative circulatory assessment. Mark the sites on the patient's skin where pulses are palpable to facilitate repeated checks.
u Help the patient walk soon after surgery to prevent venous stasis and, possibly, thrombus formation.

Patient teaching

u Discuss expected postoperative procedures, review the explanation of the surgery, and answer the patient's questions.
u Tell the patient to immediately report any recurrence of symptoms because the saphenous vein graft replacement can fail or another aneurysm may develop.
u Explain to the patient with popliteal artery resection that swelling may persist for some time. If antiembolism stockings are ordered, make sure they fit properly, and teach the patient how to apply them. Warn against wearing constrictive apparel.
u If the patient is receiving anticoagulants, suggest measures to prevent accidental bleeding, such as using an electric razor. Tell the patient to report any signs of bleeding immediately (for example, bleeding gums, tarry stools, and easy bruising). Explain the importance of follow-up blood studies to monitor anticoagulant therapy. Warn the patient to avoid trauma, tobacco, and aspirin.

RAYNAUD'S DISEASE

Raynaud's disease—also known as vasospastic arterial disease—is one of several primary arteriospastic disorders. These disorders are characterized by episodic vasospasm in the small peripheral arteries and arterioles precipitated by exposure to cold or stress.

Raynaud's disease occurs bilaterally and usually affects the hands or, less commonly, the feet and, rarely, the earlobes and the tip of the nose. The disease is five times more common in females than in males, particularly between late adolescence and age 40. The disorder is benign, requiring no specific treatment and with no serious sequelae.

Raynaud's phenomenon, however, is a condition commonly associated with several connective tissue disorders, such as scleroderma, systemic lupus erythematosus, and polymyositis. The concurrent disorders have a progressive course, leading to ischemia, gangrene, and amputation. (For other disorders and conditions associated with Raynaud's phenomenon, see [Causes of Raynaud's phenomenon](#).)

Causes

Although the cause is unknown, several conditions account for the reduced digital blood flow: intrinsic vascular wall hyperactivity to cold, ineffective basal heat production, increased vasomotor tone from sympathetic stimulation, stress, and an antigen-antibody immune response (the most probable theory because abnormal immunologic test results accompany Raynaud's phenomenon).

Complications

Severe, persistent vasoconstriction can lead to ischemia, gangrene, and amputation. Although extremely uncommon, full-thickness tissue necrosis and gangrene necessitate amputation of one or more phalanges.

Assessment findings

The patient with Raynaud's disease may complain of skin color changes induced by cold or stress.

The response to cold and stress is typically triphasic. Initially, the skin of affected areas appears markedly pale from severe vasoconstriction. During this phase, the

patient may complain of numbness and tingling.

In the second phase, the skin appears cyanotic, resulting from dilation of cutaneous arterioles and venules.

Because vasoconstriction is diminished, reactive hyperemia results, so the skin in the third phase appears red and feels warm. During this phase, the patient may complain of a throbbing, burning, painful sensation.

Between attacks, the affected areas usually appear normal, although they may feel cool and perspire excessively. In long-standing disease, you may notice trophic changes, such as sclerodactyly and ulcerations.

Diagnostic tests

Diagnosis is based primarily on presenting symptoms. Before Raynaud's phenomenon can be diagnosed, secondary disease processes, such as chronic arterial occlusive disease and connective tissue disease, must be ruled out.

Arteriography and digital photoplethysmography may also help diagnose the presence of Raynaud's phenomenon.

Treatment

Initially, treatment consists of avoidance of cold, mechanical, or chemical injury; cessation of smoking; and reassurance that symptoms are benign. Because adverse reactions to drugs, especially vasodilators, may be more bothersome than the disease itself, drug therapy is reserved for unusually severe signs and symptoms. Such therapy may include phenoxybenzamine, nifedipine, reserpine, or guanethidine combined with prazosin. Biofeedback therapy may be useful if signs and symptoms are caused by stress.

CULTURAL TIP Members of some cultures routinely practice various stress reduction techniques. Ask about your patient's preferred method for reducing stress. For example, many find meditation and yoga helpful, especially with ongoing practice.

Sympathectomy may be helpful when conservative treatment fails to prevent ischemic ulcers (occurring in less than 25% of patients).

Nursing diagnoses

⌞ Altered role performance ⌞ Altered tissue perfusion (peripheral) ⌞ Impaired skin integrity ⌞ Impaired tissue integrity ⌞ Ineffective individual coping ⌞ Ineffective thermoregulation ⌞ Knowledge deficit ⌞ Pain

Key outcomes

- ⌞ The patient will express feelings of increased comfort and decreased pain.
- ⌞ The patient will maintain collateral circulation.
- ⌞ The patient will maintain skin integrity.
- ⌞ The patient will assume as many previous roles (prior to disease onset) as possible.
- ⌞ The patient will demonstrate effective coping skills.
- ⌞ The patient will maintain adequate temperature.

Nursing interventions

- ⌞ If signs and symptoms are caused by stress, help the patient identify stress-producing areas of her life, and help her identify and use effective coping strategies. If appropriate, refer her to a biofeedback program to help control signs and symptoms related to stress.
- ⌞ Provide psychological support and reassurance to allay the patient's fear of amputation and disfigurement.
- ⌞ Evaluate the patient's occupation and its effect on symptom occurrence. If needed, refer the patient to occupational rehabilitation to prevent progression to untreatable complications.

Patient teaching

- ⌞ Warn against exposure to the cold. Tell the patient to wear mittens or gloves in cold weather or when handling cold items or defrosting the freezer.
- ⌞ Advise the patient to avoid stress and to stop smoking. Refer her to a stop-smoking program, if needed.
- ⌞ Instruct the patient to inspect her skin frequently and to seek immediate care for signs of skin breakdown or infection.
- ⌞ Teach the patient about prescribed drugs, their proper use, and their adverse effects. Tell her to report any adverse effects to the doctor.

Causes of Raynaud's phenomenon

In primary or idiopathic Raynaud's phenomenon, more than 50% of patients have Raynaud's disease. Raynaud's phenomenon may also occur secondary to the following diseases and conditions as well as with the use of certain drugs.

Collagen vascular disease

- u Dermatomyositis
- u Polymyositis
- u Rheumatoid arthritis
- u Scleroderma
- u Systemic lupus erythematosus

Arterial occlusive disease

- u Acute arterial occlusion
- u Atherosclerosis of the extremities
- u Thoracic outlet syndrome
- u Thromboangiitis obliterans

Neurologic disorders

- u Carpal tunnel syndrome
- u Cerebrovascular accident
- u Invertebral disk disease
- u Poliomyelitis
- u Spinal cord tumors
- u Syringomyelia

Blood dyscrasias

- u Cold agglutinins
- u Cryofibrinogenemia
- u Myeloproliferative disorders
- u Waldenström's disease

Trauma

- u Cold injury
- u Electric shock
- u Hammering
- u Keyboarding
- u Piano playing
- u Vibration injury

Drugs

- u Beta-adrenergic blocking agents
- u Bleomycin
- u Cisplatin
- u Ergot derivatives such as ergotamine
- u Methysergide
- u Vinblastine

Other

- u Pulmonary hypertension

THORACIC AORTIC ANEURYSM

Thoracic aortic aneurysm is a potentially life-threatening disorder characterized by abnormal widening of the ascending, transverse, or descending part of the aorta. The aneurysm may be saccular, an outpouching of the arterial wall, with a narrow neck, involving only a portion of the vessel circumference; or fusiform, a spindle-shaped enlargement, encompassing the entire aortic circumference.

Dissection of the aneurysm is the circumferential or transverse tear of the aortic wall intima, usually within the medial layer. It occurs in about 60% of patients, is usually an emergency, and has a poor prognosis. (See [Classifying aortic dissector.](#))

The ascending thoracic aorta is the most common site for the aneurysm, which occurs predominantly in men under age 60 who have coexisting hypertension. Descending thoracic aortic aneurysms are most common in younger patients who have had chest trauma.

Causes

Commonly, ascending thoracic aortic aneurysm results from atherosclerosis, which weakens the aortic wall and gradually distends the lumen in this area. It's also closely associated with cigarette smoking and hypertension.

Descending thoracic aortic aneurysm usually occurs after blunt chest trauma that shears the aorta transversely (acceleration-deceleration injury), such as in a motor vehicle accident, or a penetrating chest injury such as a knife wound. It also may be caused by hypertension.

Mycotic aneurysm develops from staphylococcal, streptococcal, or salmonella infections, usually at an atherosclerotic plaque.

Cystic medial necrosis caused by degeneration of the collagen and elastic fibers in the media of the aorta causes aneurysms during pregnancy and in patients with hypertension and Marfan syndrome. However, it can also be the cause without any underlying condition.

Other causes include congenital disorders, such as coarctation of the aorta, syphilis infection, and rheumatic vasculitis.

Complications

Some aneurysms progress to serious and, eventually, lethal complications, such as rupture of untreated thoracic dissecting aneurysm into the pericardium, with resulting cardiac tamponade.

Assessment findings

Thoracic aortic aneurysms fail to produce signs and symptoms until they expand and begin to dissect. Pain and other symptoms result from compression of the surrounding structures or from dissection of the aneurysm. (See [Clinical characteristics of thoracic dissection.](#))

The patient may complain of hoarseness, dyspnea, throat pain, dysphagia, and a dry cough when a transverse aneurysm compresses the surrounding structures. Dissection of the aneurysm causes sudden pain and possibly syncope.

In *dissecting ascending aneurysm*, the patient may complain of pain with a boring, tearing, or ripping sensation in the thorax or the right anterior chest. It may extend to the neck, shoulders, lower back, and abdomen but seldom radiates to the jaw and arms. The pain is most intense at its onset and is commonly misdiagnosed as a transmural myocardial infarction (MI).

In *dissecting descending aneurysm*, the pain is sharp, tearing, and located between the shoulder blades, and in many cases radiates to the chest.

In *dissecting transverse aneurysm*, the pain is sharp, boring, and tearing and radiates to the shoulders.

In a patient with a thoracic aortic aneurysm, you may find pallor, diaphoresis, dyspnea, cyanosis, leg weakness or transient paralysis, and an abrupt onset of intermittent neurologic deficits. Palpation of peripheral pulses in dissecting ascending aneurysm may disclose abrupt loss of radial and femoral pulses and right and left carotid pulses. In dissecting descending aneurysm, carotid and radial pulses may be present and equal bilaterally.

Percussion of the chest may reveal an increasing area of flatness over the heart, suggesting cardiac tamponade and hemopericardium. Auscultation of the heart in dissecting ascending aneurysm may disclose a murmur of aortic insufficiency, a diastolic murmur, and (if hemopericardium is present) a pericardial friction rub. The blood pressure may be normal or significantly elevated, with a large difference in systolic blood pressure between the right and left arms.

In dissecting descending aneurysm, systolic blood pressure is equal bilaterally, and you hear no murmur of aortic insufficiency or pericardial friction rub. You may detect bilateral crackles and rhonchi if pulmonary edema is present.

Diagnostic tests

In an asymptomatic patient, the diagnosis commonly occurs accidentally, through posteroanterior and oblique chest X-rays showing widening of the aorta and mediastinum.

Classifying aortic dissection

These drawings illustrate the DeBakey classification of aortic dissections (shaded areas) according to location. Dissections can also be classified by their location in relation to the aortic valve. Thus, types I and II are proximal; type III, distal.

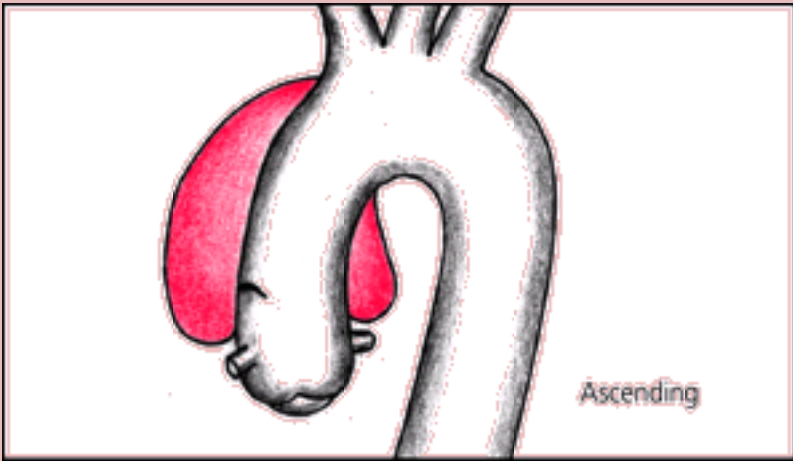

Type I

Type I, the most common and lethal type of dissection, intimal tearing occurs in the ascending aorta, and the dissection extends into the descending aorta.

Type II

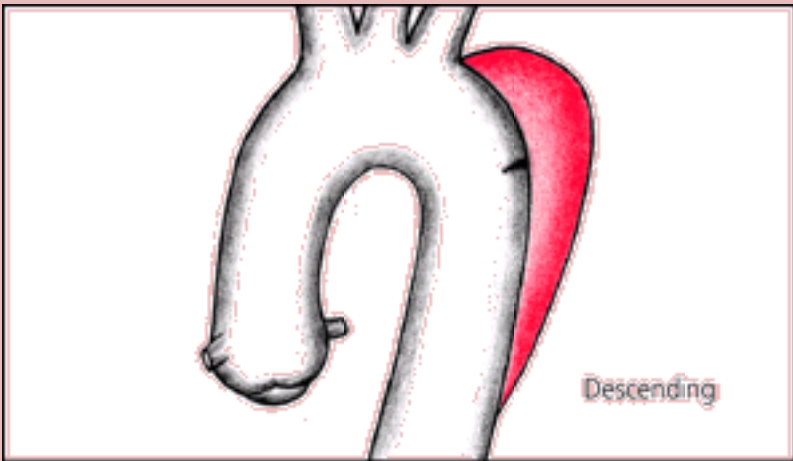

In type II, which appears most commonly with Marfan syndrome, dissection is limited to the ascending aorta.

Type III

Type III dissection includes two formations. In the first, type IIIa, the intimal tear is located in the descending aorta with distal propagation of the dissection that is confined to the thorax. The second, type IIIb, has the same origin site, but may extend beyond the diaphragm.

Type IIIa

Type IIIb

- Several tests can help confirm the aneurysm:
- u Aortography, the most definitive test, shows the lumen of the aneurysm, its size, and its location.
 - u Magnetic resonance imaging and computed tomography scanning help confirm and locate the presence of aortic dissection.
 - u Electrocardiography helps rule out the presence of MI as the cause of the symptoms, and echocardiography may help identify dissecting aneurysm of the aortic root.
 - u Transesophageal echocardiography can be used to measure the aneurysm in both the ascending and the descending aorta.
 - u Hemoglobin levels may be normal or decreased, resulting from blood loss from a leaking aneurysm.

Treatment

For long-term treatment, beta-adrenergic blockers and other agents can control hypertension and cardiac output. In an emergency, antihypertensives such as nitroprusside, negative inotropic agents such as labetalol, oxygen for respiratory distress, narcotics for pain, I.V. fluids; and whole blood transfusions, if needed, may be used.

ADVANCED PRACTICE

Clinical characteristics of thoracic dissection

ASCENDING AORTA

DESCENDING AORTA

TRANSVERSE AORTA

Character of pain

Severe, boring, ripping, extending to neck, shoulders, lower back, and abdomen (rarely to jaw and arms); more severe on right side	Sudden onset; sharp, tearing, usually between the shoulder blades; may radiate to the chest; most diagnostic feature	Sudden onset; sharp, boring, tearing; radiates to shoulders
--	--	---

Others symptoms and effects

If dissection involves carotid arteries, abrupt onset of neurologic deficit (usually intermittent); bradycardia, aortic insufficiency, and hemopericardium detected by pericardial friction rub; unequal intensity of right and left carotid pulses and radial pulses; difference in blood pressure, especially systolic, between right and left arms	Aortic insufficiency without murmur, hemopericardium, or pleural friction rub; carotid and radial pulses and blood pressure in both arms typically equal	Hoarseness, dyspnea, pain, dysphagia, and dry cough due to compression of surrounding structures
---	--	--

Diagnostic features

Chest X-ray

Best diagnostic tool; shows widening of mediastinum, enlargement of ascending aorta	Widening of mediastinum; descending aorta larger than ascending section False lumen; narrowing of lumen of aorta in descending section	Widening of mediastinum; descending aorta larger than ascending section; widened transverse arch False lumen; narrowing of lumen of aorta in transverse arch
---	---	---

Aortography

False lumen; narrowing of lumen of aorta in ascending section

Treatment

Surgical repair needed; this is a medical emergency that requires immediate aggressive treatment to reduce blood pressure (usually with nitroprusside or trimethaphan)	Surgical repair required but less urgent than for the ascending dissection; to control hypertension, nitroprusside and propranolol may be used if bradycardia and heart failure are absent	Immediate surgical repair (mortality as high as 50%), control of hypertension
--	--	---

In dissecting ascending aortic aneurysm—an extreme emergency— surgical resection of the aneurysm can restore normal blood flow through a Dacron or Teflon graft replacement. With aortic valve insufficiency, surgery consists of replacing the aortic valve.

Postoperative measures include careful monitoring and continuous assessment in the intensive care unit, antibiotics, insertion of endotracheal and chest tubes, ECG monitoring and, in many instances, pulmonary artery catheterization and monitoring.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary, renal) u Anxiety u Decreased cardiac output u Hopelessness u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will maintain adequate cardiac output and hemodynamic stability.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings of hope.
- u The patient will maintain adequate fluid volume.

Nursing interventions

- u In a nonemergency situation when a patient is diagnosed with a thoracic aneurysm, allow him to express his fears and concerns. Help him identify and use effective coping strategies.
- u Offer the patient and family psychological support. Answer all questions honestly, and provide reassurance.
- u In an acute situation, monitor blood pressure, pulmonary artery wedge pressure (PAWP), and central venous pressure. Assess pain, breathing, and carotid, radial, and femoral pulses.
- u Give analgesics to relieve pain as ordered.
- u Make sure laboratory tests include a complete blood count with differential, electrolyte measurements, typing and crossmatching for whole blood, arterial blood gas analyses, and urinalysis.
- u Insert an indwelling urinary catheter to monitor hourly outputs. Administer dextrose 5% in water or lactated Ringer's solution, and antibiotics as ordered. Carefully monitor nitroprusside I.V.; use a separate I.V. line for infusion. Adjust the dose by slowly increasing the infusion rate. Meanwhile, check blood pressure every 5 minutes until it stabilizes. With suspected bleeding from an aneurysm, give whole blood transfusions as ordered.

After repair of thoracic aneurysm:

- u Carefully assess the patient's level of consciousness. Monitor vital signs, pulmonary artery and central venous pressures, PAWP, pulse rate, urine output, and pain.
- u Check respiratory function. Carefully observe and record type and amount of chest tube drainage, and frequently assess heart and lung sounds.
- u Monitor I.V. therapy and intake and output to determine the adequacy of renal function.
- u Administer analgesics as ordered, especially before the patient performs breathing exercises or is moved.
- u After stabilization of vital signs, encourage and assist the patient in turning, coughing, and deep breathing. If necessary, provide intermittent positive-pressure breathing to promote lung expansion. Help the patient walk as soon as he's able.
- u Watch for signs of infection, especially fever, and excessive drainage on the dressing. Monitor for signs that resemble those of the initial dissecting aneurysm, suggesting a tear at the graft site.
- u Assist with range-of-motion exercises of legs to prevent thromboemboli from venostasis during prolonged bed rest.

Patient teaching

- u Explain any diagnostic tests. If surgery is scheduled, explain the procedure and expected postoperative care (I.V. lines, endotracheal and drainage tubes, cardiac monitoring, and ventilation).
- u Before discharge, ensure compliance with antihypertensive therapy by explaining the need for such drugs and the expected adverse effects. Teach the patient how to monitor his blood pressure. Refer him to community agencies for continued support and assistance as needed.
- u Direct the patient to call the doctor immediately if he has any sharp pain in the chest or back of the neck.

THROMBOPHLEBITIS

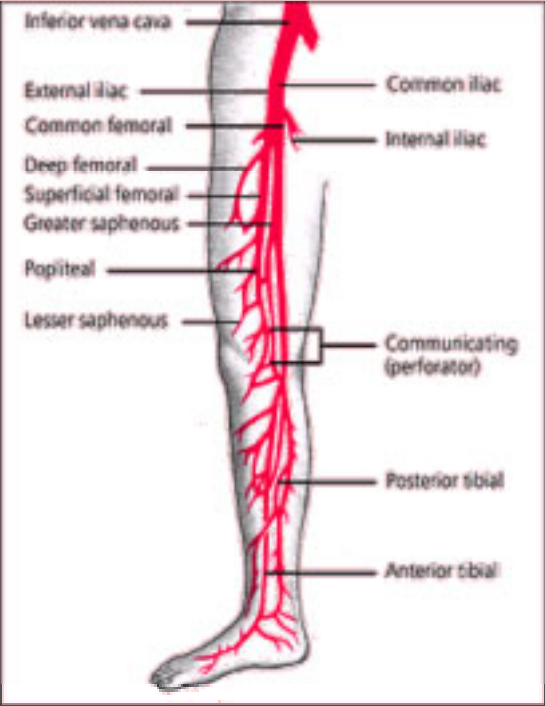

Thrombophlebitis is an acute condition characterized by inflammation and thrombus formation. It may occur in deep or superficial veins. Thrombophlebitis typically occurs at the valve cusps because venous stasis encourages accumulation and adherence of platelet and fibrin. It usually begins with localized inflammation alone (phlebitis), but such inflammation rapidly provokes thrombus formation. Rarely, venous thrombosis develops without associated inflammation of the vein (phlebothrombosis).

Deep vein thrombophlebitis affects small veins, such as the lesser saphenous vein, or large veins, such as the vena cava and the iliac, femoral, and popliteal veins. It's more serious than superficial vein thrombophlebitis because it affects the veins deep in the leg musculature that carry 90% of the venous outflow from the leg. (See [Major venous pathways of the leg.](#))

The incidence of deep vein thrombophlebitis involving the subclavian vein is increasing with the increased use of subclavian vein catheters. Some hospitalized patients are more at risk than others; however, the risk of developing deep vein thrombophlebitis increases dramatically after age 40.

Major venous pathways of the leg

Thrombophlebitis can occur in any leg vein. It most commonly occurs at valve sites.

Superficial vein thrombophlebitis is usually self-limiting and, because the superficial veins have fewer valves than the deep veins, is less likely to cause complications.

Causes

Deep vein thrombophlebitis may be idiopathic, but it usually results from endothelial damage, accelerated blood clotting and reduced blood flow, such as in predisposing factors of prolonged bed rest, trauma, surgery, childbirth, and use of oral contraceptives such as estrogens. It's also more likely to occur in the presence

- of certain diseases, treatments, injuries, or other factors, such as the following:
- u hypercoagulable states—cigarette smoking; circulating lupus anticoagulant; deficiencies of antithrombin III, protein C, or protein S; disseminated intravascular coagulation; estrogen use; dysfibrinogenemia; myeloproliferative diseases; and systemic infection
 - u intimal damage—infection, infusion of irritating I.V. solutions, trauma, or venipuncture
 - u neoplasms—of the lung, ovary, pancreas, stomach, testicles, or urinary tract
 - u surgery—abdominal, genitourinary, orthopedic, or thoracic
 - u fracture—of the spine, pelvis, femur, or tibia
 - u venous stasis—acute myocardial infarction, heart failure, dehydration, immobility, incompetent vein valves, postoperative convalescence, or cerebrovascular accident
 - u venulitis—Behçet's disease, homocystinuria, or thromboangiitis obliterans
 - u other—pregnancy or previous deep vein thrombosis.

Superficial thrombophlebitis commonly begins with localized inflammation alone (phlebitis), but such inflammation rapidly provokes thrombus formation. Rarely, venous thrombosis develops without association of the vein (phlebothrombosis). Causes include trauma, infection, I.V. drug abuse, and chemical irritation due to the extensive use of the I.V. route for medications and diagnostic tests.

Complications

The major complications of thrombophlebitis are pulmonary embolism and chronic venous insufficiency (See [Dealing with chronic venous insufficiency.](#))

Assessment findings

In both deep vein and superficial vein thrombophlebitis, clinical features vary with the site of inflammation and length of the affected vein. Up to 50% of patients with deep vein thrombophlebitis may be asymptomatic, but others may complain of some tenderness, aching, or severe pain in the affected leg or arm, fever, chills, and malaise. Complete your physical examination carefully because much of the patient's subsequent care depends on your findings.

Inspection may reveal redness, swelling, and cyanosis of the affected leg or arm. Some patients with deep vein thrombophlebitis of a leg vein may have a positive Homans' sign (pain on dorsiflexion of the foot), but this is considered an unreliable sign. A positive cuff sign (elicited by inflating a blood pressure cuff until pain occurs) may be present in deep vein thrombophlebitis of either the arm or leg.

When palpated, the affected leg or arm may feel warm.

Patients with superficial vein thrombophlebitis may also be asymptomatic, or they may complain of pain localized to the thrombus site. Inspection may disclose redness and swelling at the site and surrounding area. When palpated, the area feels warm, and a tender, hard cord extends over the affected vein's length.

Extensive vein involvement may cause lymphadenitis.

Physical examination aids the differential diagnosis, especially in superficial thrombophlebitis. The initial findings are redness and warmth over the affected area, palpable veins, and pain during palpation or compression.

Diagnostic tests

- Diagnosis must rule out arterial occlusive disease, lymphangitis, cellulitis, and myositis. Diagnosis of superficial vein thrombophlebitis is based on physical findings, whereas diagnosis of deep vein thrombophlebitis is based on the following characteristic test findings:
- u Doppler ultrasonography identifies reduced blood flow to a specific area and any obstruction to venous flow, particularly in iliofemoral deep vein thrombophlebitis.
 - u Plethysmography shows decreased circulation distal to the affected area; it's more sensitive than ultrasonography in detecting deep vein thrombophlebitis.
 - u Phlebography usually confirms the diagnosis and shows filling defects and diverted blood flow.

Treatment

In deep vein thrombophlebitis, treatment includes bed rest, with elevation of the affected arm or leg; application of warm, moist compresses to the affected area; and analgesics. After the acute episode subsides, the patient may begin to ambulate while wearing antiembolism stockings (applied before he gets out of bed).

Treatment may include anticoagulants (initially, heparin; later, warfarin) to prolong clotting time. However, the full anticoagulant dose must be discontinued during any surgery to avoid the risk of hemorrhage. After some types of surgery, especially major abdominal or pelvic operations, prophylactic doses of anticoagulants may reduce the risk of deep vein thrombophlebitis.

For lysis of acute, extensive deep vein thrombophlebitis, treatment should include streptokinase or urokinase, if the risk of bleeding doesn't outweigh the potential benefits of thrombolytic treatment.

Rarely, deep vein thrombophlebitis may cause complete venous occlusion, which necessitates venous interruption through simple ligation to vein plication, or clipping. Embolectomy may be done if clots are being shed to the pulmonary and systemic vasculature and other treatment is unsuccessful. Caval interruption with transvenous placement of an umbrella filter can trap emboli, preventing them from traveling to the pulmonary vasculature.

ADVANCED PRACTICE

Dealing with chronic venous insufficiency

Chronic venous insufficiency results from the valvular destruction of deep vein thrombophlebitis, usually in the iliac and femoral veins and occasionally in the saphenous veins. It's commonly accompanied by incompetence of the communicating veins of the ankle, causing increased venous pressure and fluid migration into the interstitial tissue.

Signs and symptoms

Chronic venous insufficiency causes chronic swelling of the affected leg from edema, leading to tissue fibrosis and induration, skin discoloration from extravasation of blood in subcutaneous tissue, and stasis ulcers around the ankle.

Treatment

Appropriate treatment for small stasis ulcers consists of bed rest, elevation of the legs, warm soaks, and antimicrobial therapy for infection.

Treatment to counteract increased venous pressure, the result of reflux from the deep venous system to superficial veins, may include compression dressings or a zinc gelatin boot (Unna's boot). This therapy begins after massive swelling subsides.

Large stasis ulcers unresponsive to conservative treatment may require excision and skin grafting. Care includes daily inspection to assess healing and measures similar to those for varicose veins.

Therapy for severe superficial vein thrombophlebitis may include an anti-inflammatory drug such as indomethacin along with antiembolism stockings, warm compresses, and elevating the patient's leg.

Nursing diagnoses

- u Activity intolerance
- u Altered tissue perfusion (peripheral, cardiopulmonary)
- u Impaired skin integrity
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient will maintain collateral circulation.
- u The patient will express feelings of comfort and decreased pain.
- u Skin color and temperature will remain unchanged.
- u The patient will maintain tissue perfusion and cellular oxygenation.
- u The patient will reduce metabolic demands.
- u The patient will remain free from signs and symptoms of infection.

PREVENTION

Preventing thrombophlebitis

The prevention of thrombophlebitis involves identifying those with increased risk factors and educating these individuals about prevention. Patients who are pregnant, taking birth control pills, or on estrogen replacement should be educated about the risk. Patients undergoing abdominal, orthopedic, or pelvic surgery, or those who are immobile for prolonged periods are at higher risk and should receive prophylactic therapies.

Nursing interventions

- u Enforce bed rest as ordered, and elevate the patient's affected arm or leg. If you plan to use pillows for elevating the leg, place them so they support its entire length to avoid compressing the popliteal space.
- u Apply warm compresses or a covered aquamatic K pad to increase circulation to the affected area and to relieve pain and inflammation. Give analgesics to relieve pain as ordered.
- u Mark, measure, and record the circumference of the affected arm or leg daily, and compare this measurement with that of the other arm or leg. To ensure accuracy and consistency of serial measurements, mark the skin over the area, and measure at the same spot daily.
- u Administer heparin I.V., as ordered, with an infusion monitor or pump to control the flow rate, if necessary.
- u Measure partial thromboplastin time regularly for the patient on heparin therapy. Measure prothrombin time for the patient on warfarin (therapeutic anticoagulation values for both are 1½ to 2 times control values).
- u Watch for signs and symptoms of bleeding, such as tarry stools, coffee-ground vomitus, and ecchymoses. Watch for oozing of blood at I.V. sites, and assess gums for excessive bleeding.
- u Be alert for signs of pulmonary emboli (such as crackles, dyspnea, hemoptysis, sudden changes in mental status, restlessness, and hypotension).
- u To prevent thrombophlebitis in high-risk patients, perform range-of-motion exercises while the patient is on bed rest, use intermittent pneumatic calf massage during lengthy surgical or diagnostic procedures, apply antiembolism stockings postoperatively, and encourage early ambulation.
- u Before discharge, emphasize the importance of follow-up blood studies to monitor anticoagulant therapy.
- u If the patient is being discharged on heparin therapy, teach him or his family how to give subcutaneous injections. If he requires further assistance, arrange for a home health care nurse.
- u Tell the patient to avoid prolonged sitting or standing to help prevent a recurrence.
- u Teach the patient how to properly apply and use antiembolism stockings. Tell him to report any complications such as cold, blue toes. (See [Preventing thrombophlebitis.](#))
- u To prevent bleeding, encourage the patient to use an electric razor and to avoid medications that contain aspirin.

VARICOSE VEINS

Varicose veins are dilated, tortuous veins, engorged with blood, which result from improper venous valve function. They can be either primary or secondary. Primary varicose veins originate in the superficial veins—the saphenous veins and their branches; secondary varicose veins occur in the deep and perforating veins. (See [How varicose veins develop.](#))

Primary varicose veins tend to run in families, affect both legs, and are twice as common in women as in men. Usually, secondary varicose veins only occur in one leg. Both types are more common in middle adulthood.

Causes

Primary varicose veins can result from congenital weakness of the valves or venous wall; from conditions that produce prolonged venous stasis, such as pregnancy or wearing tight clothing; or from occupations that necessitate standing for an extended period. Secondary varicose veins result from disorders of the venous system, such as deep vein thrombophlebitis, trauma, and occlusion.

Complications

Long-standing varicose veins produce venous insufficiency and venous stasis ulcers, particularly around the ankles.

Assessment findings

The patient with varicose veins may be asymptomatic or complain of mild to severe leg symptoms, including a feeling of heaviness that worsens in the evening and in warm weather; cramps at night; diffuse, dull aching after prolonged standing or walking; aching during menses; and fatigue. Exercise may relieve symptoms because venous return improves.

Inspection of the affected leg reveals dilated, purplish, ropelike veins, particularly in the calf. Deep vein incompetence causes orthostatic edema and stasis of the calves and ankles. Palpation may reveal nodules along affected veins and valve incompetence, which can be checked by the manual compression test and Trendelenburg's test.

To do the *manual compression test*, palpate the dilated vein with the fingertips of one hand. With the other hand, firmly compress the vein at a point at least 8" (20 cm) higher. Feel for an impulse transmitted to your lower hand. With competent saphenous valves, you don't detect any impulse. A palpable impulse indicates incompetent valves in a vein segment between your hands.

To do *Trendelenburg's test* (retrograde filling test), mark the distended veins with a pen while the patient stands. Then have him lie on the examination table and elevate his leg for 1 minute to drain the veins. Next, have him stand while you measure venous filling time. Competent valves take at least 30 seconds to fill. If the veins fill in less than 30 seconds, have the patient lie on the examination table again and elevate his leg for 1 minute. Then apply a tourniquet around his upper thigh. Next, have him stand. If leg veins still fill in less than 30 seconds, suspect an incompetent perforating vein and deep vein valves (functioning valves block retrograde

flow).

Now remove the tourniquet. If the veins fill again in less than 30 seconds, suspect incompetent superficial vein valves that allow backward blood flow.

To pinpoint incompetent valve location, repeat this procedure by applying the tourniquet just below the knee and then around the upper calf.

If the condition of the veins is chronic, the patient may show the complication of venous stasis ulcers. These ulcers need to be differentiated from arterial and diabetic ulcerations. (See [Differential features of lower extremity ulcers.](#))

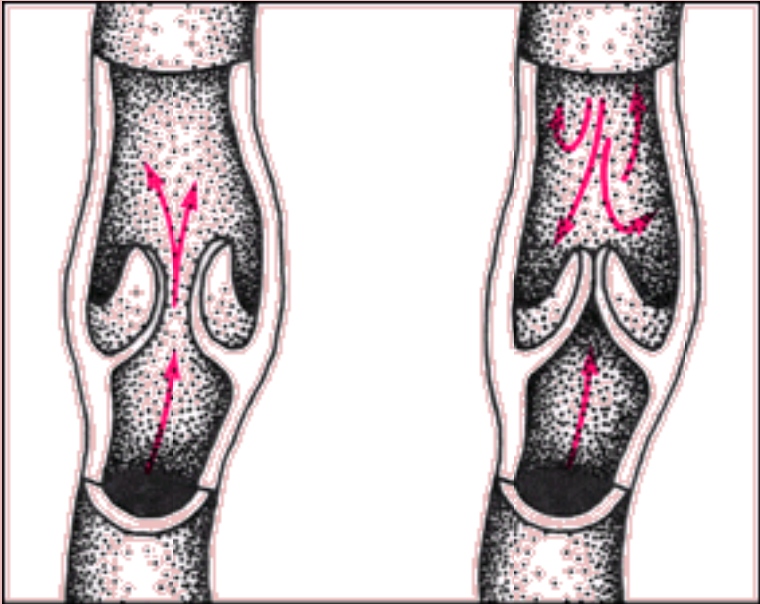

PATHOPHYSIOLOGY

How varicose veins develop

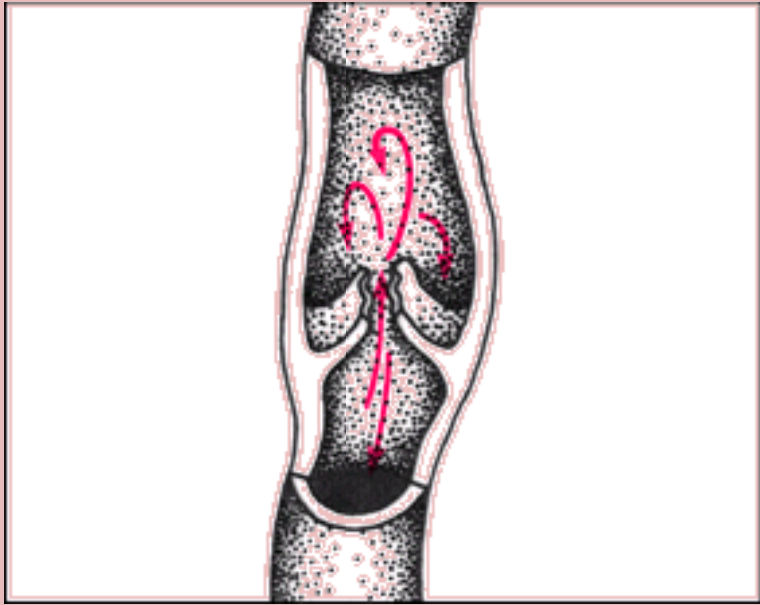

Varicose veins result when incompetent venous valves allow blood backflow and pooling. Normally, venous valves open and close smoothly and completely. This helps the blood along as it returns from the periphery to the heart.

NORMAL VENOUS VALVES (OPEN LEFT, CLOSED RIGHT)

In varicose veins, injury to the valves, defective valvular structure or function, or venous occlusion leads to improper valve closure, resulting in venous blood backflow. As pressure builds, valves become incompetent, causing still more backflow. Progressive blood pooling produces the characteristic leg-vein dilation and leads to disturbed tissue oxygen and nutrient exchange.

INCOMPETENT VENOUS VALVE

Diagnostic tests

Photoplethysmography, a noninvasive test, characterizes venous blood flow by noting changes in the skin's circulation.

Doppler ultrasonography quickly and accurately detects the presence or absence of venous backflow in deep or superficial veins.

Venous outflow and reflux plethysmography can be used to detect deep venous occlusion.

Ascending and descending venography can demonstrate venous occlusion and patterns of collateral flow. It's an invasive test and not routinely used.

Treatment

In mild varicose veins, treatment involves wearing elastic stockings, avoiding tight clothing and prolonged standing, exercising, and elevating the legs. Treatment of moderate varicose veins consists of wearing antiembolism stockings or elastic bandages. Severe varicose veins may require custom-fitted, surgical-weight stockings with graduated pressure (highest at the ankle, lowest at the top). An exercise program such as walking promotes muscle contraction and forces blood through the veins, thereby minimizing venous pooling.

Severe varicose veins may require stripping and ligation or, in patients who are poor surgical risks, injection of a sclerosing agent into small segments of affected veins.

Nursing diagnoses

- Activity intolerance
- Altered body image
- Altered tissue perfusion (peripheral)
- Fatigue
- Impaired skin integrity
- Impaired tissue integrity
- Knowledge deficit
- Pain
- Risk for infection
- Risk for injury

Key outcomes

- The patient will maintain adequate distal and collateral circulation.
- The patient's skin integrity will remain intact.
- The patient will express increased comfort and relief of pain.
- The patient will state feelings of increased energy.
- The patient will carry out activities of daily living without excess fatigue or discomfort.

Nursing interventions

- After stripping and ligation or after injection of a sclerosing agent, administer analgesics as ordered to relieve pain.
- Frequently check circulation in toes (color and temperature), and observe elastic bandages for bleeding. When ordered, rewrap bandages at least once a shift, wrapping from toe to thigh, with the leg elevated. (See [Preventing varicose veins](#).)

ALERT Watch for signs and symptoms of complications, such as sensory loss in the leg (which could indicate saphenous nerve damage), calf pain (which could indicate thrombophlebitis), and fever (a sign of infection).

Patient teaching

- To promote comfort and minimize worsening of varicose veins, tell the patient to avoid wearing constrictive clothing.
- Tell the patient to elevate his legs above heart level when possible and to avoid prolonged standing or sitting.
- Teach the patient to put on the elastic, antiembolism, or compression stockings before getting out of bed in the morning. If he can't do that, tell him to lie with his legs raised for 1 minute and then to put on the stockings.
- Teach the patient to avoid injury to the lower legs, ankles, and feet and to observe for altered skin integrity of those areas. Have him report any problems to the doctor as soon as possible. Impaired tissue perfusion reduces the leg's healing ability and predisposes it to infection and further tissue damage.

PREVENTION

Preventing varicose veins

Prevention involves identifying patients with increased risk factors, such as those in professions that require prolonged standing or time on the feet (nurses, surgeons, letter carriers, beauticians, teachers, and waiters). Other risk factors include obesity, heavy lifting, and pregnancy. People with these risk factors should be educated to rest with legs elevated periodically at work, wear supportive stockings, drink 2 to 3 L of fluid per day, and avoid crossing legs.

INTRODUCTION

The respiratory system provides vital gas exchange by distributing air to the alveoli. Here, pulmonary capillary blood takes on oxygen (O₂) and gives off carbon dioxide (CO₂). Other gases, such as carbon monoxide, diffuse from pulmonary capillary blood to the alveoli, where they're excreted by the lungs.

Various specialized structures in the respiratory system prepare air for the body to use. The nose, for example, contains vestibular hairs that filter impurities from the air and an extensive vascular network to warm it. The nose also contains a layer of goblet cells and a moist mucosal surface. From this surface, water vapor enters the airstream to saturate the inspired air as it's warmed in the upper airways. Ciliated mucosae in the posterior nose and the nasopharynx (and in major portions of the tracheobronchial tree) propel particles to the oropharynx, where the particles are swallowed.

External respiration

The external component of respiration—ventilation, or breathing—delivers inspired air (or gas) to the lower respiratory tract and alveoli. Expansion and contraction of the respiratory muscles move air into and out of the lungs. Ventilation begins with the contraction of the inspiratory muscles: The diaphragm, the major muscle of respiration, descends, while external intercostal muscles move the rib cage upward and outward. The accessory muscles of inspiration (which include the scalene and sternocleidomastoid muscles) raise the clavicles, upper ribs, and sternum. The accessory muscles aren't used in normal inspiration but are used in certain disease states.

An adult lung contains about 300 million alveoli, with many capillaries supplying each alveolus. To reach the capillary lumen, O₂ must cross the alveolocapillary membrane, which consists of an alveolar epithelial cell, a narrow interstitial space, the capillary basement membrane, and the capillary endothelial cell membrane. The tension created by O₂ entering the respiratory tract is about 160 mm Hg. In the alveoli, this inspired air mixes with CO₂ and water vapor, lowering pressure to about 100 mm Hg. Because the partial pressure of O₂ in alveolar blood (PaO₂) exceeds that in the mixed venous blood entering the pulmonary capillaries (about 40 mm Hg), O₂ diffuses across the alveolocapillary membrane into the blood.

Internal respiration and gas transport

Circulating blood delivers O₂ to the body's cells for metabolism and transports metabolic wastes and CO₂ from the tissues back to the lungs. When oxygenated arterial blood reaches tissue capillaries, O₂ diffuses from the blood into the cells again because of an oxygen tension gradient. The amount of O₂ available is determined by the level of hemoglobin (the principal carrier of O₂), regional blood flow, arterial oxygen tension, and carboxyhemoglobin tension.

Internal, or cellular, respiration occurs during cellular metabolism, which can occur with O₂ (aerobic) or without O₂ (anaerobic). The most efficient method of providing fuels (compounds such as adenosine triphosphate [ATP]) for cellular reactions is aerobic metabolism, which produces CO₂ and water besides ATP. Anaerobic metabolism is less efficient because a cell produces only a limited amount of ATP and releases both lactic acid and CO₂ as metabolic byproducts.

Because circulation is continuous, CO₂ doesn't normally accumulate in tissues. CO₂ produced during cellular respiration diffuses from tissues to regional capillaries and is transported by systemic venous circulation. When CO₂ reaches the alveolar capillaries, it diffuses into the alveoli, where the partial pressure of CO₂ (PacO₂) is lower. During exhalation, CO₂ exits the alveoli.

Mechanisms of control

The central nervous system (CNS) controls respiration from the respiratory control center in the lateral medulla oblongata of the brain stem. Impulses travel along the phrenic nerves to the diaphragm and then along the intercostal nerves to the intercostal muscles, where the impulses control the rate and depth of respiration. The inspiratory and expiratory centers, located in the posterior medulla, establish the involuntary rhythm of the breathing pattern.

Apneustic and pneumotaxic centers in the pons also influence the breathing pattern. Stimulation of the lower pontine apneustic center (by trauma, tumor, or cerebrovascular accident, for example) produces forceful inspiratory gasps alternating with weak expiration. This pattern doesn't occur if the vagus nerve is intact. The apneustic center continuously excites the medullary inspiratory center and thereby facilitates inspiration. Signals from the pneumotaxic center and afferent impulses

from the vagus nerve inhibit the apneustic center and “turn off” inspiration.

PaO₂ and pH balances, as well as the pH of cerebrospinal fluid (CSF), influence output from the respiratory control center. CO₂ entering the CSF lowers the pH of CSF. This stimulates central chemoreceptors and increases ventilation.

The respiratory center also receives information from peripheral chemoreceptors in the carotid and aortic bodies. Although these chemoreceptors respond primarily to a decreased PaO₂ level, they also respond to reduced pH. Either change spurs respiratory drive within minutes.

Several other factors can alter the respiratory pattern. During exercise, stretch receptors in lung tissue and the diaphragm prevent the lungs from overdistending. During eating and drinking, the cortex can interrupt automatic control of ventilation. During sleep, the respiratory drive fluctuates, producing hypoventilation and periods of apnea. External sensations, drugs, chronic hypercapnea, and increased or decreased body heat can also alter the respiratory pattern.

Assessment

A complete respiratory assessment helps you identify existing and potential respiratory problems. It begins with a patient history followed by a physical examination.

Obtain the history

Ask the patient to describe his respiratory problem. How long has he had it? How long does each attack last? Does one attack differ from another? Does any activity in particular bring on an attack or make it worse? Does it occur at rest? What relieves the symptoms?

Always ask about previous and current smoking habits: what the patient smokes, his daily use, and the number of years as a smoker. Record this information in pack years—the number of packs of cigarettes smoked daily multiplied by the number of years he has smoked. Remember to ask about the patient's occupation, hobbies, and travel. Some activities may expose him to toxic or allergenic substances.

If the patient has dyspnea, find out whether it occurs during activity or rest. Does any specific position cause or worsen his dyspnea? How far can he walk? How many stairs can he climb? Can he relate dyspnea to allergies or environmental conditions?

If the patient has a cough, ask about its severity, persistence, and duration. If the cough produces sputum, ask the patient to describe its color, amount, and character. Ask whether his cough and sputum have changed recently.

Observe the patient

Look for telltale signs of respiratory disease. The patient's appearance may provide clues. If he's frail or cachectic, he may have a chronic disease that impairs appetite. If he's diaphoretic, restless, irritable, or protective of a painful body part, he may be in acute distress. Also, assess behavior changes that may indicate hypoxia or hypercapnea. Confusion, lethargy, bizarre behavior, or quiet sleep from which he can't be aroused may signal hypercapnea. Restlessness, anxiety, or interrupted speech may indicate hypoxia. Watch for marked cyanosis, indicated by bluish or ashen skin (usually best seen on the lips, tongue, earlobes, and nail beds), which may result from hypoxemia or poor tissue perfusion.

CULTURAL TIP Cyanosis may be difficult to detect in dark-skinned patients. The best way to detect cyanosis is by inspecting areas of lightest pigmentation, such as the nail beds, conjunctiva, palms, and soles.

Check chest configuration at rest and during ventilation. You may notice the following deviations:

- u pigeon chest—anteriorly displaced sternum
- u barrel chest—increased anteroposterior diameter
- u funnel chest—depressed lower sternum
- u kyphoscoliosis—raised shoulder and scapula, thoracic convexity, flared interspaces, and altered chest configuration (which, in turn, restricts breathing).

Assess the muscles used during inspiration with the patient in a semi-Fowler or flat position. Then note which muscles he uses when he breathes. If the epigastric area rises during inspiration, he's using his diaphragm. Use of the upper chest and neck muscles is normal only during physical stress.

Observe the patient's breathing rate and pattern. Certain disorders produce characteristic changes in breathing patterns such as the following:

- u An acute respiratory disorder can produce tachypnea (rapid breathing), hypopnea (shallow breathing), or hyperpnea (deep breathing).
- u Intracranial lesions can produce Cheyne-Stokes respirations (arrhythmic increase followed by decline in respiration followed by periods of apnea) or Biot's respirations (irregular respiratory rate with apnea occurring at 4 to 5 cycles).
- u Increased intracranial pressure can produce central hyperventilation and apneustic or ataxic breathing.
- u Metabolic disorders can produce Kussmaul's respirations (rapid, deep breathing).
- u Airway obstruction can produce prolonged forceful expiration and pursed-lip breathing.

Observe posture and carriage. A patient with chronic obstructive pulmonary disease, for example, usually supports rib cage movement by placing his arms on the sides of a chair to increase expansion and leans forward during exhalation to help expel air. (See [Recognizing common respiratory patterns.](#))

Perform a physical examination

Techniques such as palpation, percussion, and auscultation are used to assess the respiratory system.

Palpation of the chest wall can help you detect masses, tender areas, and changes in fremitus (palpable vocal vibrations) or crepitus (air in subcutaneous tissues). To assess chest excursion and symmetry, place your hands bilaterally and horizontally on the posterior chest. Be sure your thumbs press lightly against the spine (as if to squeeze the skin over the spine into a fold or a pleat). As the patient takes a deep breath, move your thumbs quickly and equally away from the spine. Repeat this with your hands placed anteriorly, at the costal margins (lower lobes) and clavicles (apices). Unequal movement indicates expansion differences, which occur in atelectasis, diaphragm or chest-wall muscle disease, and splinting with pain. (See [Sequences for chest palpation.](#))

Percussion is used to detect resonance over lung fields not covered by the heart or bony structures. This technique relies on vibrations (resulting from precise finger taps) that strike underlying structures and rebound to the surface, where you can feel and hear them. The quality of the vibration demarcates underlying chest structures. Dull percussion sounds typically signal consolidation or pleural disease. (See [Ensuring orderly percussion and auscultation](#), and [Characterizing and interpreting percussion sounds.](#))

Auscultation normally detects soft, vesicular breath sounds throughout most of the lung fields. When you auscultate your patient's lungs for normal and abnormal breath sounds, compare both lungs as you proceed from the apices to the bases. Note the pitch, intensity, quality, and duration of the breath sounds. Also evaluate for crackles, rhonchi, and wheezes. Adventitious breath sounds (or no breath sounds) may indicate fluid in the small airways or interstitial lung disease (crackles), secretions in the medium-sized and large airways (rhonchi), and airflow obstruction (wheezes).

After characterizing breath sounds, have the patient whisper words while you auscultate peripheral lung fields. Whispering produces vibrations that you can hear on the chest's surface. Categorize these whispered sounds as:

Follow this guide to conduct a thorough chest palpation. The numerical sequence ensures that all areas are examined and that bilateral findings can be easily compared.

POSTERIOR

ANTERIOR

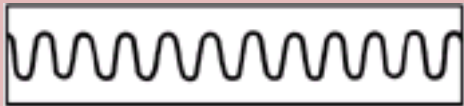

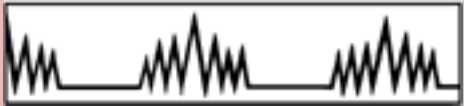

- u *bronchophony*—normally a low-pitched sound that intensifies as the patient talks louder, although words can't be deciphered. If you can hear words distinctly over the lung periphery, suspect consolidation or fluid.
- u *egophony*—ordinarily a low-pitched sound that should clearly sound like “eee” when the patient says the letter “e.” If the sound resembles a high-pitched “ate,” fluid may be compressing the lung (as in pleural effusion). Normal egophony sound intensifies over the affected lung area.

ADVANCED PRACTICE

Recognizing common respiratory patterns

Use this chart as a visual guide to respiratory rate, rhythm, and depth patterns.

PATTERN		CHARACTERISTICS
Eupnea		Normal respiratory rate and rhythm u for adults and teenagers: 12 to 20 breaths/minute u for children ages 2 to 12: 20 to 30 breaths/minute u for infants and children under age 2: 20 to 40 breaths/minute u for neonates: 30 to 50 breaths/minute Occasional deep inspirations at the rate of 2 to 3 breaths/minute are also normal.
Tachypnea		Increased respiratory rate, such as that seen in fever. Respiratory rate increases about 4 breaths/minute for every degree Fahrenheit above normal.
Bradypnea		Slower but regular respirations. Can occur when an opiate, a tumor, alcohol, a metabolic disorder, or respiratory decompensation affects the brain's respiratory control center. This pattern is normal during sleep.
Apnea		Arrested breathing. May be periodic.
Hyperpnea		Deeper respirations.
Cheyne-Stokes respirations		Respirations gradually become faster and deeper than normal and then slower over 30 to 170 seconds. Apneic periods may occur for 20 to 60 seconds.
Biot's respirations		Faster and deeper respirations than normal, with abrupt pauses. Each breath has the same depth. May occur with spinal meningitis or other central nervous system abnormalities.
Kussmaul's respirations		Faster and deeper respirations without pauses; in adults, more than 20 breaths/minute. Breathing usually sounds labored (deep breaths resemble sighs). Can occur with, or result from, renal failure or metabolic acidosis.
Apneustic breathing		Prolonged, gasping inspiration followed by extremely short, inefficient expiration. Can occur with, or result from, lesions in the brain's respiratory control center.

Ensuring orderly percussion and auscultation

Percussion and auscultation can help you identify various lung abnormalities. To conduct a complete examination, percuss and auscultate along the points shown on the posterior shoulders. Then follow the sequence shown here. Remember to compare findings from one side of the body with those from the other side.

POSTERIOR ANTERIOR LEFT LATERAL LEFT LATERAL

u *whispered pectoriloquy*—normally a high-pitched sound that renders the patient's words indistinct. If you hear clearly whispered words over peripheral lung fields, suspect consolidation. Again, sound intensity increases over the affected area.

Diagnostic tests

When physical assessments are complete, the patient may undergo various respiratory tests.

- u *Chest X-rays* are used to identify lesions or such conditions as atelectasis, pleural effusion, infiltrates, pneumothorax, mediastinal shifts, and pulmonary edema.
- u *Computed tomography scan* provides a three-dimensional picture that is 100 times more sensitive than chest X-ray films.
- u *Lung scan*, ordered primarily to detect pulmonary emboli, demonstrates ventilation and perfusion patterns.
- u *Magnetic resonance imaging* is used to identify obstructed vessels and to highlight tissue perfusion.
- u *Sputum analysis* is used to evaluate sputum quantity, color, viscosity, and odor. Stains and cultures can be used to identify infectious organisms. Cytologic studies can be used to detect abnormal respiratory cells.
- u *Pulmonary function tests* are used to measure lung volumes, flow rates, and compliance. Normal values are determined by body stature and age and are reported as a percentage of the normal predicted value. (See [Defining static and dynamic values.](#))
- u *Pulse oximetry* is used to continuously monitor arterial oxygen saturation (Sao₂).
- u *Exercise stress tests* are used to evaluate the lungs' ability to transport O₂ and remove CO₂ as metabolic demand increases.
- u *Polysomnography* can reveal sleep disorders.
- u *Bronchoscopy* permits direct visualization of the trachea and the mainstem, lobar, segmental, and subsegment bronchi. This procedure may help localize the site of lung hemorrhage, visualize masses in the airways, and collect respiratory tract secretions. This procedure allows biopsy.
- u *Thoracentesis* permits removal of pleural fluid for analysis.

Characterizing and interpreting percussion sounds

lung hemorrhage, visualize masses in the airways, and collect respiratory tract secretions. This procedure allows biopsy.

- u *Thoracentesis* permits removal of pleural fluid for analysis.

Characterizing and interpreting percussion sounds				
Several kinds of sounds may emanate from percussion. Known as flat, dull, resonant, hyperresonant, or tympanic, these sounds determine the location and density of various structures. During percussion, determining other tonal characteristics, such as pitch, intensity, and quality, also help you identify respiratory structures. Use this chart as a guide to interpreting percussion sounds.				
CHARACTER				IMPLICATIONS
Sound	Pitch	Intensity	Quality	
Flatness	High	Soft	Extremely dull	These sounds are normal over the sternum. Over the lung, they may indicate atelectasis or pleural effusion.
Dullness	Medium	Medium	Thudlike	Normal over the liver, heart, and diaphragm, these sounds over the lung may point to pneumonia, tumor, atelectasis, or pleural effusion.
Resonance	Low	Moderate to loud	Hollow	When percussed over the lung, these sounds are normal.
Hyperresonance	Lower than resonance	Very loud	Booming	These are normal findings with percussion over a child's lung. Over an adult lung, these findings may indicate emphysema, chronic bronchitis, asthma, or pneumothorax.
Tympany	High	Loud	Musical, drumlike	Over the stomach, these are normal findings; over the lung, they suggest tension pneumothorax.

- u *Pleural biopsy* allows removal of pleural tissue for histologic examination and culture. This test can be used to detect pleural neoplasms or granulomatous infections.
- u *Transtacheal aspiration* is used to obtain secretions from the trachea and proximal bronchi for microbiological analysis.
- u *Arterial blood gas (ABG) analysis* is used to evaluate gas exchange in the lungs by measuring the Pa O₂, Paco₂, Sao₂ bicarbonate (HCO₃⁻) level, and pH of an arterial blood sample. PaO₂ and Sao₂ indicate how much oxygen the lungs are delivering to the blood; Paco₂, indicates how efficiently the lungs are eliminating CO₂. The pH reflects the blood's acid-base level. By evaluating pH, Paco₂, and HCO₃⁻ in a patient's arterial blood, you can determine his acid-base balance.

Respiratory care

The patient hospitalized with respiratory disease may require oxygen administration, respiratory treatments, an artificial upper airway, chest tubes, mechanical ventilation, and chest physiotherapy.

Establishing an airway

In cardiopulmonary arrest, establishing an airway always takes precedence. Airway obstruction usually results when the tongue slides back and blocks the posterior pharynx. The head-tilt maneuver or—in suspected or confirmed cervical fracture or arthritis—the jaw-thrust maneuver can immediately move the tongue forward and relieve such obstruction. In some patients, endotracheal intubation and, sometimes, a tracheotomy is needed.

Using chest tubes

To remove air or drain fluid from the pleural space, the patient may need a chest tube. This device allows a collapsed lung to reexpand to fill the evacuated pleural space. It also allows removal of pleural fluid for culture and analysis. Conditions that necessitate a chest tube include thoracic surgery, penetrating chest wounds, pleural effusion, and empyema. A chest tube facilitates evacuation of pneumothorax, hydrothorax, or hemothorax. Sometimes it's used to instill sclerosing drugs into the pleural space to prevent recurrent malignant pleural effusions.

The chest tube usually is placed in the sixth or seventh intercostal space, in the axillary region. Occasionally, in pneumothorax, the tube is placed in the second or third intercostal space, in the midclavicular region.

At times, the patient may have two chest tubes inserted, depending on the type of drainage required. One tube enters the chest anteriorly near the lung apex to drain air; the other tube is placed near the lung base to drain fluid.

The chest tube always connects to a system that provides a one-way valve mechanism to prevent outside air from entering the pleural space. Typically, this is a water seal, although waterless variations and flutter-valve styles are also available. Common plastic molded systems provide a water seal, a collection chamber for pleural fluid, and a suction chamber for medically ordered suction. (See [Using a chest tube at home](#).)

When caring for a patient with chest tubes, follow these guidelines:

- u Monitor changes in suction pressure.
- u Maintain tube patency by draining the tubes every 1 to 2 hours.
- u Fasten tubing to the bed in a way that prevents dependent loops of tubing. To accommodate position changes, be sure to allow slack in the tube.
- u Ensure that all system connections are tightly joined and secured with tape over the insertion sites.
- u Check for air leaks, and add water to the suction system as needed. Don't clamp the tube if an air leak occurs.
- u Record the amount, color, and consistency of drainage. When drainage appears to be excessive, be alert for signs of shock, such as tachycardia and hypotension.
- u Always keep two hemostats at the bedside in case of chest tube disconnection, but keep in mind the risk related to using the hemostats: Tension pneumothorax may develop.
- u If chest drainage proceeds by gravity rather than by suction, keep the collection chamber below chest level.
- u Change the chest tube dressing if necessary and according to facility policy, assessing the site for signs and symptoms of infection each time. Be sure to apply an occlusive dressing at each change.

Defining static and dynamic values
The results of your patient's pulmonary function tests reflect static and dynamic values.
Static values
Test findings related to pulmonary volume are known as static values. They include: <ul style="list-style-type: none">u <i>tidal volume (V_T)</i>—volume of air contained in a normal breathu <i>functional residual capacity (FRC)</i>—volume of air remaining in the lungs after normal expirationu <i>vital capacity (VC)</i>— volume of air that can be exhaled after maximal inspirationu <i>residual volume (RV)</i>—amount of air remaining in the kings after maximal expirationu <i>total lung capacity (TLC)</i>—volume of air in the lungs after maximal inspiration.
Dynamic values
These findings characterize the movement of air into and out of the lungs and show changes in lung mechanics. They include: <ul style="list-style-type: none">u <i>forced expiratory volume in 1 second (FEV₁)</i>— maximum volume of air that can be expired in 1 second from TLC

Dynamic values

- These findings characterize the movement of air into and out of the lungs and show changes in lung mechanics. They include:
- *forced expiratory volume in 1 second (FEV₁)*— maximum volume of air that can be expired in 1 second from TLC
 - *maximal voluntary ventilation (MVV)*—volume of air that can be expired in 1 minute with the patient's maximum voluntary effort
 - *forced vital capacity (FVC)*—maximum volume of air that the patient can exhale from TLC.

- Tell the patient to cough once every hour, and have him take several deep breaths to enhance drainage and lung function.
- When the chest tube connects to a suction system, continuous bubbling in the water-seal chamber warns you that the system has an air leak. Locate the leak's source, and correct it or report it.
- If a chest tube dislodges from the patient's chest, apply petroleum gauze to the insertion site and notify the doctor.

Providing mechanical ventilation

When the patient has respiratory problems related to the CNS, hypoxemia, or failure of the normal bellows action provided by the diaphragm and rib cage, he may need help from a mechanical ventilator.

A volume-cycled ventilator delivers a preset volume of gas. The tidal volume is set at 10 to 15 cc/kg of ideal body weight. You can use positive endexpiratory pressure (PEEP) to retain a certain amount of pressure in the lungs at the end of expiration, increasing functional residual capacity and improving gas exchange. PEEP is especially beneficial for patients with adult respiratory distress syndrome.

HOME CARE

Using a chest tube at home

A patient may need to continue using the chest tube after discharge. A Heimlich valve may be used to evacuate air from the pleural space. This valve is attached to the external end of the chest tube and opens when the internal pressure is greater than the atmosphere pressure and then closes when the internal pressure is less than the atmosphere pressure. This system doesn't typically connect to a drainage system and permits freedom of movement of the patient.

The primary hazards of PEEP include the increased incidence of pneumothorax and reduced venous return related to elevated intrathoracic pressure. High-frequency jet ventilation delivers small tidal volumes at high rates, resulting in low airway and intrathoracic pressures.

You can use several methods to wean a patient from a ventilator. Weaning begins when the patient meets specific criteria, which include stable ABG levels, tidal volume greater than 10 cc/kg, and a vital capacity greater than 15 cc/kg.

One weaning method calls for disconnecting the patient from the ventilator and using a T-piece (endotracheal tube oxygen adapter) that provides supplemental O₂ and humidification. The device allows the patient to breathe spontaneously without the ventilator for gradually increasing periods.

With another weaning method—intermittent mandatory ventilation—the ventilator supplies only a certain number of breaths while the patient breathes spontaneously between ventilator breaths. The frequency of ventilator breaths gradually decreases until the patient breathes entirely on his own.

Throughout weaning, assess the patient's status by monitoring vital signs, ABG levels, pulse oximetry values, symptoms, and other physical findings.

Performing chest physiotherapy

In respiratory conditions marked by excessive accumulation of lung secretions, chest physiotherapy can help remove the secretions. Chest physiotherapy includes chest assessment, effective breathing and coughing exercises, postural drainage, percussion, vibration, and evaluation of the therapy's effectiveness. Before beginning, review X-ray and assessment findings to locate the exact areas of secretions.

- *Deep breathing* maintains diaphragmatic tone, increases negative intrathoracic pressure, and promotes venous return. It's especially important when pain or dressings restrict chest movement. An incentive spirometer can provide positive visual reinforcement and further promote deep breathing.
- *Pursed-lip breathing* is used primarily in obstructive disease to slow expiration and prevent small-airway collapse. Such breathing funnels air through a narrow opening, creating a positive back-pressure that keeps the airways open.
- *Segmental breathing (or lateral costal breathing)* is used after lung resection or for a localized disorder. Place your hand over the affected lung area. Have the patient take a deep breath—deep enough to push that portion of his chest against your hand. If he's successful, you should feel the effort with your hand.
- *Coughing* that is controlled and staged gradually increases intrathoracic pressure, reducing the pain and bronchospasm of explosive coughing. When wound pain prevents effective coughing, splint the wound with a pillow, towel, or your hand during coughing exercises.
- *Postural drainage* uses gravity to drain secretions into larger airways, from which they can be expectorated. This technique is used in patients with copious or tenacious secretions. Before postural drainage, auscultate the chest and review chest X-rays to determine the best position for maximum drainage. To reduce the patient's risk of vomiting, schedule postural drainage before or at least 1 hour after his meals.
- *Percussion* moves air against the chest wall to loosen lung secretions. It's contraindicated in severe pain, extreme obesity (which prevents effective contact with the chest wall), cancer that has metastasized to the ribs, crushing chest injuries, bleeding disorders, spontaneous pneumothorax, spinal compression fractures, unstable head injury, osteoporosis, and pulmonary embolism.
- *Vibration* can be used with percussion or alone when percussion is contraindicated.

To evaluate therapy, auscultate the lung fields before and after therapy, and compare sputum findings.

Pediatric disorders

Pediatric disorders include croup, a severe inflammation of the upper airway, and epiglottitis, an acute inflammation of the epiglottis that affects mainly young children. They also include respiratory distress syndrome, which is marked by widespread alveolar collapse and occurs mainly in premature infants, and sudden infant death syndrome, which strikes apparently healthy infants.

CROUP

Croup is a severe inflammation and obstruction of the upper airway. This childhood disease affects boys more often than girls (typically between ages 3 months and 3 years).

Croup usually occurs in the winter as acute laryngotracheobronchitis (the most common form), laryngitis, or acute spasmodic laryngitis. It must be distinguished from epiglottitis. Usually mild and self-limiting, acute laryngotracheobronchitis appears mostly in children ages 3 months to 3 years. Acute spasmodic laryngitis affects children between ages 1 and 3, particularly those with allergies and a family history of croup. Overall, up to 15% of patients have a family history of croup. Recovery is usually complete.

Causes

Croup usually results from a viral infection. Parainfluenza viruses cause about two-thirds of such infections; adenoviruses, respiratory syncytial virus, influenza viruses, measles viruses, and bacteria (pertussis and diphtheria) account for the rest.

Complications

Causes

Croup usually results from a viral infection. Parainfluenza viruses cause about two-thirds of such infections; adenoviruses, respiratory syncytial virus, influenza viruses, measles viruses, and bacteria (pertussis and diphtheria) account for the rest.

Complications

Airway obstruction, respiratory failure, and dehydration are complications of croup. Latent complications are ear infection and pneumonia.

Assessment findings

Typically, the child or his parents report a recent upper respiratory tract infection preceding croup.

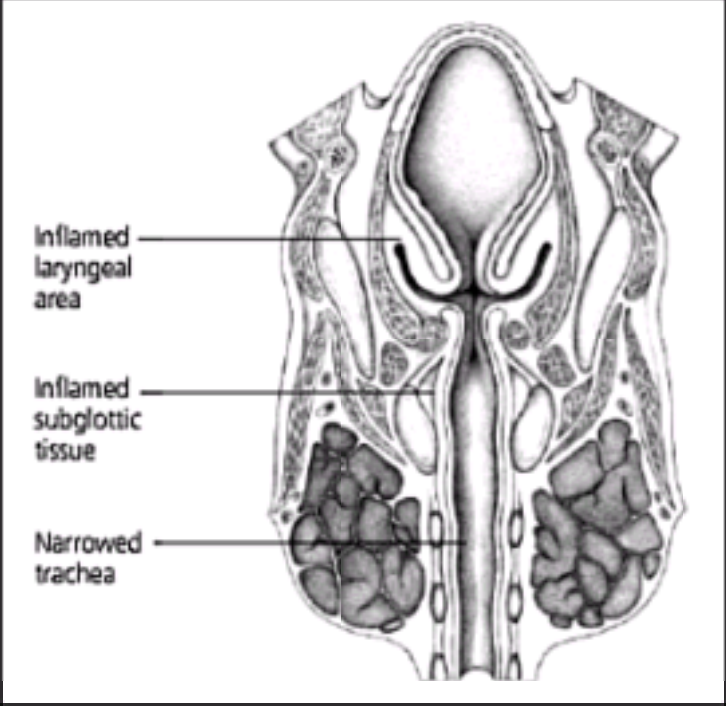

On inspection, you may observe the use of accessory muscles with nasal flaring during breathing. You typically hear the child's sharp, barklike cough and hoarse or muffled vocal sounds. As croup progresses, the patient may display further upper airway obstruction with severely compromised ventilation. (See [How croup affects the upper airways.](#))

PATHOPHYSIOLOGY

How croup affects the upper airways

In croup, inflammatory swelling and spasms constrict the larynx, thereby reducing airflow. This cross-sectional drawing (from chin to chest) shows the upper airway changes caused by croup. Inflammatory changes almost completely obstruct the larynx (which includes the epiglottis) and significantly narrow the trachea.

Auscultation may disclose inspiratory stridor and diminished breath sounds. These signs and symptoms may last for only a few hours, or they may persist for 1 to 2 days.

Each form of croup has additional characteristics.

u In *laryngotracheobronchitis*, the patient may complain of fever and breathing problems that occur more often at night. Typically, the child becomes frightened because he can't breathe out (because inflammation causes edema in the bronchi and bronchioles).

During auscultation, you may hear diffusely decreased breath sounds, expiratory rhonchi, and scattered crackles.

u In *laryngitis*, which results from vocal cord edema, the patient usually reports mild signs and symptoms and no respiratory distress. If the patient is an infant, however, some respiratory distress may occur. In children, the history may include such signs and symptoms as a sore throat and cough that, rarely, may progress to marked hoarseness.

HOME CARE

Home care for a patient with croup

If the patient is being treated for croup at home, tell the parents that bed rest is essential to conserve energy and limit oxygen needs. To ease the patient's breathing, advise the parents to use pillows to prop him into a sitting or semi-sitting (semi-Fowler's) position. Warn the parents never to rest a child or an infant with croup flat on his back. Advise them that keeping him quiet and comfortable reduces his oxygen needs. Holding him as often as possible soothes and comforts the patient.

Urge parents to ensure adequate hydration by giving the patient plenty of fluids. Suggest fluid electrolyte replacement (such as Pedialyte, flavored gelatin dissolved in water, or ginger ale with the bubbles stirred out). Fluids should be at room temperature. Instruct the parents to avoid thicker, milk-based fluids. To relieve sore throat, suggest fruit sorbet or ice pops. Instruct the parents to withhold solid food until the child can breathe and swallow more easily. The child may have little or no appetite until he feels better.

Warn parents not to give aspirin to reduce fever because of its link to Reye's syndrome.

Suggest using a cool-mist humidifier (vaporizer) in the home, and teach the parents how to use one if necessary. To relieve acute croupy spells at home, instruct the parents to carry the child to the bathroom, shut the door, turn on the hot water, and allow steam to fill the air. Breathing warm, moist air should quickly ease an acute croup spell.

Inspection may disclose suprasternal and intercostal retractions, inspiratory stridor, dyspnea, diminished breath sounds, restlessness and, in later stages, severe dyspnea and exhaustion.

u In *acute spasmodic laryngitis*, the patient history may reveal mild to moderate hoarseness and nasal discharge, followed by the characteristic cough and noisy inspiration that often awaken the child at night. As the child understandably becomes anxious, this leads to increasing dyspnea and transient cyanosis.

Inspection may disclose labored breathing with retractions and clammy skin. Palpation may reveal a rapid pulse rate. These severe signs diminish after several hours but reappear in a milder form on the next one or two nights.

Diagnostic tests

Inspection may disclose labored breathing with retractions and clammy skin. Palpation may reveal a rapid pulse rate. These severe signs diminish after several hours but reappear in a milder form on the next one or two nights.

Diagnostic tests

In evaluating the patient with croup, diagnosis should rule out the possibility of masses, cysts, and foreign body obstruction—common causes of croupy cough in young children.

Throat cultures can identify infecting organisms and their sensitivity to antibiotics when bacterial infection is the cause. Throat cultures can also rule out diphtheria.

Blood cultures can distinguish between bacterial and viral infections, X-ray studies of the neck may show upper airway narrowing and edema in subglottic folds, and laryngoscopy may reveal inflammation and obstruction in epiglottal and laryngeal areas.

Treatment

For most children with croup, home care with rest, cool humidification during sleep, and antipyretic drugs such as acetaminophen relieve signs and symptoms. However, respiratory distress that interferes with oral hydration usually requires hospitalization and parenteral fluid replacement to prevent dehydration. If the patient has croup from a bacterial infection, he needs antibiotic therapy. Oxygen therapy may also be required.

For moderately severe croup, aerosolized racemic epinephrine may temporarily reduce airway swelling. Intubation is performed only if other means of preventing respiratory failure are unsuccessful.

Several studies support the practice of prescribing corticosteroids for acute laryngotracheobronchitis.

Nursing diagnoses

- u Anxiety
- u Fear
- u Hyperthermia
- u Impaired gas exchange
- u Ineffective airway clearance
- u Knowledge deficit

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient's temperature will be within normal range.
- u The patient will maintain a patent airway.
- u The child and family members will demonstrate an understanding of what has been taught.
- u The child and family members will use available support systems to assist with coping.

Nursing interventions

- u Monitor cough and breath sounds, hoarseness, severity of retractions, inspiratory stridor, cyanosis, respiratory rate and character (especially prolonged and labored respirations), restlessness, fever, and heart rate.
- u Keep the child as quiet as possible, but avoid sedation, which may depress respiration. If the patient is an infant, position him in an infant seat or prop him up with a pillow; place an older child in Fowler's position. If an older child requires a cool-mist tent to help him breathe, describe it to him and his parents and explain why it's needed.
- u Change bed linens as necessary to keep the patient dry.
- u Control the patient's energy output and oxygen demand by providing age-appropriate diversional activities to keep him quietly occupied.
- u If possible, isolate patients suspected of having respiratory syncytial virus and parainfluenza infections. Wash your hands carefully before leaving the room, to avoid transmitting germs to other patients, particularly infants.
- u Control fever with sponge baths and antipyretics. Keep a hypothermia blanket on hand if the patient's temperature rises above 102° F (38.9° C). Watch for seizures in infants and young children with high fevers. Give I.V. antibiotics as ordered.
- u Relieve sore throat with soothing, water-based ices, such as fruit sherbet and ice pops. Avoid thicker, milk-based fluids if the patient has thick mucus or swallowing difficulties. Apply petroleum jelly or another ointment around the nose and lips to decrease irritation from nasal discharge and mouth breathing.
- u Institute measures to prevent the patient's crying, which increases respiratory distress. As necessary, adapt treatment to conserve the patient's energy and to include parents, who can provide reassurance.
- u Reassure parents that they made the right decision by bringing their child to the emergency department—especially at night when the evening air may improve the child's breathing significantly, leaving the parents wondering if they overreacted. (The doctor may ask the nurse to take the child outside for a few minutes to relieve the patient's croupiness.).
- u Watch for signs of complete airway obstruction, such as increased heart and respiratory rates, use of respiratory accessory muscles in breathing, nasal flaring, and increased restlessness.

Patient teaching

- u Because croup may be treated at home or in a health care facility, you need to tailor your teaching accordingly. Because this disease primarily affects young children, patient teaching usually centers on the parents. (See [Home care for a patient with croup.](#))
- u If the patient is hospitalized, advise the parents that he may be placed in a cool-mist tent (with or without oxygen) to provide high humidity.
- u Explain that the hospitalized child may require hydration with I.V. fluids if he can't be hydrated orally.
- u Warn parents that ear infections and pneumonia may complicate croup. These disorders may follow croup about 5 days after recovery. Urge the parents to seek immediate medical attention if the patient has an earache, productive cough, high fever, or increased shortness of breath.

EPIGLOTTIDITIS

Epiglottitis, an acute inflammation of the epiglottis and surrounding area, is a life-threatening emergency that rapidly causes edema and induration. Untreated, epiglottitis results in complete airway obstruction. Epiglottitis can occur from infancy to adulthood in any season. It's fatal in 8% to 12% of patients, typically children between ages 2 and 8.

Causes

Epiglottitis usually results from infection with the bacteria *Haemophilus influenzae* type B and, occasionally, pneumococci or group A streptococci.

Complications

Airway obstruction and death may occur within 2 hours of onset.

Assessment findings

The patient or his parents may report an earlier upper respiratory tract infection. Additional complaints include sore throat, dysphagia, and the sudden onset of a high fever.

On inspection, the patient may be febrile, drooling, pale or cyanotic, restless, apprehensive, and irritable. You may also observe nasal flaring. The patient may sit in a tripod position: upright, leaning forward with the chin thrust out, mouth open, and tongue protruding. This position helps relieve severe respiratory distress. The patient's voice usually sounds thick and muffled.

Because manipulation may trigger sudden airway obstruction, attempt throat inspection only when immediate intubation can be performed if necessary (See [Airway crisis.](#)) The patient's throat appears red and inflamed.

WARNING

patient's voice usually sounds thick and muffled.

Because manipulation may trigger sudden airway obstruction, attempt throat inspection only when immediate intubation can be performed if necessary (See [Airway crisis](#).) The patient's throat appears red and inflamed.

WARNING

Airway crisis

Epiglottitis can progress to complete airway obstruction within minutes. To prepare for this medical emergency, keep the following tips in mind:

- u Watch for increasing restlessness, tachycardia, fever, dyspnea, and intercostal and substernal retractions. These are warning signs of total airway obstruction and the need for an emergency tracheotomy.
- u Keep the following equipment available at the patient's bedside in case of sudden, complete airway obstruction: a tracheotomy tray, endotracheal tubes, manual resuscitation bag, oxygen equipment, and a laryngoscope with blades of various sizes.
- u Remember that using a tongue blade or throat culture swab can initiate sudden, complete airway obstruction.
- u Before examining the patient's throat, request trained personnel (such as an anesthesiologist) to stand by if emergency airway insertion is needed.

Auscultation of the lung fields may reveal rhonchi and diminished breath sounds, usually transmitted from the upper airway.

Diagnostic tests

Lateral neck X-rays show an enlarged epiglottis and distended hypopharynx.

Direct laryngoscopy reveals the hallmark of acute epiglottitis: a swollen, beefy-red epiglottis. The throat examination should follow X-ray studies and, in most cases, shouldn't be performed if significant obstruction is suspected or if immediate intubation isn't possible.

Additional X-rays of the chest and cervical trachea help to confirm the diagnosis.

Treatment

A patient with acute epiglottitis and airway obstruction requires emergency hospitalization. He should be placed in a cool-mist tent with added oxygen. If complete or near-complete airway obstruction occurs, he may also need emergency endotracheal intubation or a tracheotomy. Arterial blood gas (ABG) monitoring or pulse oximetry may be used to assess his progress.

Treatment may also include parenteral fluids to prevent dehydration when the disease interferes with swallowing, and a 10-day course of parenteral antibiotics—usually ampicillin. If the patient is allergic to penicillin or could have ampicillin-resistant endemic *H. influenzae*, chloramphenicol or another antibiotic may be prescribed.

Although controversial, corticosteroids may be prescribed to reduce edema during early treatment. Oxygen therapy may also be used.

Keep in mind that preventive measures should be taken. In 1990, the American Academy of Pediatrics recommended that all children receive the haemophilus b conjugate vaccine, preferably at age 2 months. As more children become immunized, epiglottitis rates should decline.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Fear u Fluid volume deficit u Impaired gas exchange u Impaired verbal communication u Ineffective airway clearance

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain adequate fluid volume.
- u The patient will maintain a patent airway.
- u The patient will use alternate means of communication.
- u The patient will use support systems to assist with coping.

Nursing interventions

- u Place the patient in a sitting position to ease his respiratory difficulty unless he finds another position more comfortable.
- u Place the patient in a cool-mist tent. Change the sheets frequently because they quickly become saturated.
- u Encourage the parents to remain with their child. Offer reassurance and support to relieve family members' anxiety and fear.
- u Monitor the patient's temperature, vital signs, and respiration rate and pattern frequently. Also monitor ABG levels (to detect hypoxia and hypercapnea) and pulse oximetry values (to detect decreasing oxygen saturation). Report any changes.
- u Observe the patient continuously for signs of impending airway closure, which may develop at any time.
- u Calm the patient during X-ray studies of his chest and cervical trachea.
- u Minimize external stimuli.
- u Start an I.V. line for antibiotic therapy and fluid replacement if the patient can't maintain adequate fluid intake. Draw blood for laboratory analysis as ordered.
- u Record intake and output precisely to monitor and prevent dehydration.
- u If the patient has a tracheostomy, anticipate his needs because he's unable to cry or call out. Provide emotional support. Reassure him and his family members that a tracheostomy is a short-term intervention (usually 4 to 7 days). Monitor the patient for signs of secondary infection: increasing temperature, increasing pulse rate, and hypotension.

Patient teaching

- u Inform the patient and family that epiglottal swelling usually subsides after 24 hours of antibiotic therapy. The epiglottis usually returns to normal size within 72 hours.
- u If the patient's home care regimen includes oral antibiotic therapy, emphasize the need for completing the entire prescription. Explain proper administration. Discuss drug storage, dosage, adverse effects, and whether the medication can be taken with food or milk.
- u If the patient should require the haemophilus b conjugate vaccine, discuss the rationale for immunization, and help the family obtain the vaccine.

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS)—also called hyaline membrane disease—is the most common cause of neonatal death. The syndrome occurs almost exclusively in infants born before the 37th gestational week (and in about 60% of those born before the 28th week). It's most common in infants of diabetic mothers, those delivered by cesarean section, and those delivered suddenly after antepartum hemorrhage.

In RDS, the premature infant develops widespread alveolar collapse from a deficiency of surfactant. Untreated, the syndrome causes death within 72 hours of birth in up to 14% of infants weighing less than 5½ lb (2,500 g). Aggressive management assisted by mechanical ventilation can improve the prognosis. A few patients who survive are left with bronchopulmonary dysplasia. Mild cases of the syndrome slowly subside after about 3 days.

Causes and pathophysiology

In RDS, the premature infant develops widespread alveolar collapse from a deficiency of surfactant. Untreated, the syndrome causes death within 72 hours of birth in up to 14% of infants weighing less than 5½ lb (2,500 g). Aggressive management assisted by mechanical ventilation can improve the prognosis. A few patients who survive are left with bronchopulmonary dysplasia. Mild cases of the syndrome slowly subside after about 3 days.

Causes and pathophysiology

The immediate cause of RDS is lack of surfactant, a lipoprotein present in alveoli and respiratory bronchioles. In these structures, surfactant helps to lower surface tension, maintain alveolar patency, and prevent collapse, particularly at end expiration.

Although neonatal airways are developed by the 27th gestational week, the intercostal muscles are weak, and the alveoli and the capillary blood supplies are immature. Surfactant deficiency then leads to widespread atelectasis, which leads, in turn, to inadequate alveolar ventilation and shunting of blood through collapsed lung areas. The results are hypoxia and acidosis.

Complications

Respiratory insufficiency and shock can occur.

Assessment findings

The history typically indicates preterm birth (before 28 gestational weeks) or cesarean delivery. The maternal history may include diabetes or antepartum hemorrhage.

Although the neonate with RDS may breathe normally at first, within minutes to hours after birth inspection may reveal rapid, shallow respirations with intercostal, subcostal, or sternal retractions, nasal flaring, and audible expiratory grunting. The grunting is a natural compensatory mechanism that produces positive end-expiratory pressure (PEEP) to prevent further alveolar collapse.

Additional findings may include hypotension, peripheral edema, and oliguria. In severe disease, the patient may display apnea, bradycardia, and cyanosis (from hypoxemia, left-to-right shunting through the foramen ovale, or right-to-left shunting through atelectatic lung areas). Other clinical features are pallor, frothy sputum, and low body temperature (resulting from an immature nervous system and inadequate subcutaneous fat).

Auscultation typically discloses diminished air entry and crackles, although crackles are rare early in the syndrome.

Diagnostic tests

Despite warning signs suggesting RDS, the diagnosis must be confirmed by chest X-rays and arterial blood gas (ABG) analysis.

Chest X-ray findings may be normal for the first 6 to 12 hours in 50% of patients. However, later films show a fine reticulonodular pattern and dark streaks, indicating air-filled, dilated bronchioles.

ABG values show a diminished level of partial pressure of arterial oxygen (Pa O₂); normal, decreased, or increased level of partial pressure of arterial carbon dioxide; and reduced pH (a combination of respiratory and metabolic acidosis).

The lecithin-sphingomyelin ratio aids the assessment of prenatal lung development and RDS risk. The test is usually ordered if a cesarean section is to be performed before the 36th gestational week.

Treatment

The neonate with RDS requires vigorous respiratory support. Warm, humidified, oxygen-enriched gases are administered by oxygen hood or, if such treatment fails, by mechanical ventilation. The neonate with severe RDS may require mechanical ventilation with PEEP or continuous positive airway pressure (CPAP) administered by a tight-fitting face mask or, when necessary, endotracheal tube.

If the neonate can't maintain adequate gas exchange, high-frequency oscillation ventilation may be initiated to provide satisfactory minute volume (the total volume of air breathed in 1 minute) with lower airway pressures.

Treatment also may include:

- u a radiant warmer or an Isolette for thermoregulation
- u I.V. fluids and sodium bicarbonate to control acidosis and maintain fluid and electrolyte balance
- u tube feedings or total parenteral nutrition to maintain adequate nutrition if the neonate is too weak or unable to eat
- u drug therapy with pancuronium bromide (which paralyzes muscles to prevent spontaneous respirations during mechanical ventilation), prophylactic antibiotics, diuretics (to reduce pulmonary edema), and synthetic surfactant (to prevent atelectasis)
- u alternative drug therapy—for example, with vitamin E to prevent complications associated with oxygen therapy, and corticosteroids administered maternally to stimulate surfactant production in fetuses at high risk for preterm birth.

Nursing diagnoses

- u Impaired gas exchange
- u Impaired skin integrity
- u Ineffective airway clearance
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain a patent airway.
- u The patient will remain free from signs and symptoms of infection.
- u The patient's skin integrity will remain intact.
- u Members of the patient's family will identify factors that increase potential for injury.

Nursing interventions

- u Continually assess the neonate. Monitor ABG levels and fluid intake and output.
- u Check for arterial or venous hypotension, as appropriate, if the neonate has an umbilical catheter. Also watch for abnormal central venous pressure and for such complications as infection, thrombosis, and decreased circulation to the legs.
- u If the neonate has a transcutaneous PO₂ monitor (an accurate method for determining PaO₂), change the site of the lead placement every 2 to 4 hours to avoid burning the skin.
- u Use pulse oximetry to monitor levels of arterial oxygen saturation.
- u Weigh the infant once or twice daily.
- u Regularly assess skin color, rate and depth of respirations, severity of retractions, nostril flaring, frequency of expiratory grunting, frothing at the lips, and restlessness.
- u Regularly assess the effectiveness of oxygen or ventilator therapy. Evaluate every fraction of inspired oxygen (F IO₂) and PEEP or CPAP change by drawing arterial blood for analysis 20 minutes after each change. Be sure to adjust PEEP or CPAP as indicated by ABG levels.

ALERT When the neonate receives mechanical ventilation, watch carefully for signs of barotrauma (increase in respiratory distress, subcutaneous emphysema) and accidental disconnection from the ventilator. Check ventilator settings frequently. Be alert for signals of complications of PEEP or CPAP therapy, such as decreased cardiac output, pneumothorax, and pneumomediastinum.

- u Institute infection prevention measures if the infant receives mechanical ventilation.

ALERT When the neonate receives mechanical ventilation, watch carefully for signs of barotrauma (increase in respiratory distress, subcutaneous emphysema) and accidental disconnection from the ventilator. Check ventilator settings frequently. Be alert for signals of complications of PEEP or CPAP therapy, such as decreased cardiac output, pneumothorax, and pneumomediastinum.

- u Institute infection prevention measures if the infant receives mechanical ventilation.
- u Provide suction as necessary. Observe the oxygenation monitor or pulse oximeter before, during, and after suctioning to evaluate the patient's response to this therapy.
- u Inspect the skin frequently for signs of breakdown.
- u Provide mouth care every 2 hours. Lubricate the infant's nostrils and lips with water-soluble ointment.
- u Observe for signs and symptoms of infection resulting from invasive therapies and a weakened immune system.
- u As needed, arrange for follow-up care with a neonatal ophthalmologist to detect possible retinal damage from oxygen therapy.

ALERT Watch for additional complications of oxygen therapy, such as lung capillary damage, decreased mucus flow, impaired ciliary functioning, and widespread atelectasis. Additional problems include patent ductus arteriosus, heart failure, retinopathy, pulmonary hypertension, necrotizing enterocolitis, and neurologic abnormalities.

- u Help reduce mortality by detecting RDS early. Recognize intercostal retractions and grunting, especially in a premature infant, as signs of RDS. Make sure the patient receives immediate treatment.

Patient teaching

- u Explain RDS to the parents. If possible, let them participate in care (using aseptic technique) to promote normal bonding.
- u Explain the function of respiratory devices and equipment. Discuss alarm sounds and mechanical noise, and solicit parent feedback. Encourage them to ask questions and to express their fears and concerns.
- u Advise parents that full recovery may take up to 12 months. When the prognosis is poor, prepare the parents for the neonate's possible death and offer emotional support. When appropriate, refer parents and family to professional staff, such as pastoral counselors and social workers.

SUDDEN INFANT DEATH SYNDROME

Sudden infant death syndrome (SIDS), a medical mystery of early infancy, is the leading cause of death among apparently healthy infants ages 1 month to 1 year. Most deaths occur between 1 and 4 months of age. The syndrome, also called crib death, occurs at the rate of 2 in every 1,000 live births. Each year in the United States, about 7,000 infants die of SIDS. Although the syndrome was known in ancient times, its cause remains obscure.

The incidence declines rapidly between ages 4 and 12 months. About 60% of victims are male infants who die in their sleep, without warning, sound, or struggle. The incidence is slightly higher in preterm infants, Inuit infants, disadvantaged black infants, infants of mothers under age 20, and infants of multiple births.

CULTURAL TIP Incidence of SIDS is 2 to 3 times more likely in black children than in white children. Native American children are 5 times more susceptible than white children. Incidence is 10 times higher in SIDS siblings than in children without SIDS siblings. The occurrence of SIDS is slightly higher in infants whose mothers smoke than in children of mothers who don't smoke. It's up to 10 times more common in infants whose mothers are drug addicts than in children of non-drug-addicted mothers.

Infants most commonly succumb to SIDS in the fall and winter. Many have a history of respiratory tract infections, suggesting viral infection as a cause. Studies show conflicting data about abnormal hepatic or pancreatic function. Although the link between apneic episodes and SIDS remains unclear, about 60% of infants with near-miss respiratory events have second episodes of apnea. Some succumb to apnea.

Causes

At one time, SIDS was attributed to abuse or accidental suffocation during sleep. On postmortem examination, some SIDS-diagnosed infants show changes indicating chronic hypoxia, hypoxemia, and large-airway obstruction, leading researchers to suspect more than one cause.

Two leading hypotheses are the hypoxemia theory and the apnea theory. The hypoxemia theory suggests that SIDS occurs because of damage to the respiratory control center in the brain from chronichypoxemia. The apnea theory holds that the SIDS victim experiences prolonged periods of sleep apnea and eventually dies during an episode.

Another proposed cause involves *Clostridium botulinum* toxin, which has been linked to a few SIDS deaths. A disproved theory is an association between SIDS and diphtheria, tetanus, and pertussis vaccines. Bottle-feeding and advanced parental age don't cause the syndrome, although breast-fed infants are at decreased risk for SIDS.

Complications

Because the syndrome is always fatal, it has no complications.

Assessment findings

The patient history supplied by the parents may reveal that they found the infant wedged in a crib corner or with blankets wrapped around his head. Despite such findings, autopsy results rule out suffocation as the cause of death. The history may also note frothy, blood-tinged sputum found around the infant's mouth or on the crib sheets. However, autopsy findings show a patent airway, ruling out aspiration of vomitus as the cause of death.

Typically, the parents report that the infant didn't cry and showed no signs of disturbed sleep. Reports of the infant found in a peculiar position or tangled in his blankets suggest movement before death, possibly from terminal spasm. Occasionally, the history may reveal a respiratory tract infection.

Documentation of events before discovery of the infant's death should be part of the history. Often, bruising, possible fractured ribs, and the appearance of blood in the infant's mouth, nose, or ears from internal bleeding may be confused with abuse. Although this possibility shouldn't be dismissed, never assume that abuse caused the infant's death without obtaining further information. Avoid assessment questions that may suggest parental responsibility for the death.

Depending on how long the infant has been dead, inspection may reveal an infant with mottled complexion and extremely cyanotic lips and fingertips. You may also see pooled blood in the legs and feet. These markings may be mistaken for bruises. The infant's diaper may be wet and full of stools.

Diagnostic tests

Diagnosis of SIDS requires an autopsy to rule out other causes of death. Characteristic histologic findings on autopsy include small or normal adrenal glands and petechiae over the visceral surfaces of the pleura, within the thymus (which is enlarged), and in the epicardium. Autopsy also reveals well-preserved lymphoid structures; signs of chronic hypoxemia such as increased pulmonary artery smooth muscle; edematous, congestive lungs fully expanded; liquid (not clotted) blood in the heart; and stomach curd inside the trachea.

Treatment

Because most infants can't be resuscitated, treatment focuses on emotional support for the family. Any infant found apneic and successfully resuscitated, as well as any infant who has a sibling with apnea, may be at risk for SIDS. In such instances, a home apnea monitor may be recommended until the at-risk infant passes the age of vulnerability.

Nursing diagnoses

- u Altered family processes u Fear u Hopelessness u Knowledge deficit u Spiritual distress

Nursing diagnoses

- u Altered family processes
- u Fear
- u Hopelessness
- u Knowledge deficit
- u Spiritual distress

Key outcomes

- u Family members will use available support systems to assist in coping with fear.
- u Family members will share feelings about the event.
- u Family members will identify feelings of hopelessness regarding the current situation.
- u Family members will use effective coping strategies to ease spiritual discomfort.
- u Family members will seek appropriate support persons for assistance.

Nursing interventions

- u Make sure that both parents are present when the child's death is confirmed. The parents may lash out at emergency department personnel, the babysitter, or anyone else involved in the child's care—even at each other. Stay calm and let them express their feelings. Reassure them that they aren't to blame.
- u Let the parents see the infant in a private room. Allow them to express their grief. Stay in the room with them, if appropriate. Offer to call clergy, friends, or relatives. Return the infant's belongings to the parents.
- u If your facility's policy is to assign a home health nurse to the family, she is to provide the continuing reassurance and assistance the parents need. Assist her in gathering the information necessary to implement appropriate follow-up care.

Patient teaching

- u After the parents and other family members recover from the initial shock, explain the need for an autopsy to confirm the diagnosis. In some states, this is legally mandatory. At this time, provide the family with basic facts about SIDS, and encourage them to consent to the autopsy. Be sure they receive the autopsy report promptly.
- u Refer the parents and family to community and health care facility support services. Participants in such a program should contact the parents, ensure that they receive the autopsy report promptly, introduce them to a professional counselor, and maintain supportive telephone contact. Refer the parents to a local SIDS parents' group if one is available. Advise parents to contact the SIDS hot line (1-800-221-SIDS).
- u If the parents decide to have another child, provide appropriate information to help them cope with the pregnancy and the 1st year of the new infant's life.
- u Teach family members how to operate home apnea and cardiac monitors, if appropriate. If parents of healthy infants inquire about monitors for home use, explain that monitoring is recommended only for siblings of SIDS victims because of its high cost and sometimes disruptive effects on family dynamics.
- u Teach family members and caregivers how to perform one-person cardiopulmonary resuscitation or refer them to classes conducted by the American Red Cross if appropriate.

Acute disorders

Acute respiratory disorders require prompt treatment and nursing care. They range from acute respiratory failure in chronic obstructive pulmonary disease to sarcoidosis.

ACUTE RESPIRATORY FAILURE IN COPD

When the lungs can't adequately maintain arterial oxygenation or eliminate carbon dioxide (CO₂), acute respiratory failure results. If not checked and treated, the condition leads to tissue hypoxia. In patients with essentially normal lung tissue, acute respiratory failure usually produces a partial pressure of arterial CO₂ (Paco₂) greater than 50 mm Hg and a partial pressure of arterial oxygen (PaO₂) less than 50 mm Hg.

These limits, however, don't apply to patients with chronic obstructive pulmonary disease (COPD). These patients consistently have high Paco₂ (hypercapnia) and low PaO₂ (hypoxemia) levels. For patients with COPD, only acute deterioration in arterial blood gas (ABG) values and corresponding clinical deterioration signal acute respiratory failure.

Causes

Acute respiratory failure may develop in COPD patients from any condition that increases the work of breathing and decreases the respiratory drive. These conditions may result from respiratory tract infection (such as bronchitis or pneumonia), bronchospasm, or accumulated secretions secondary to cough suppression. Other common causes are related to ventilatory failure, in which the brain fails to direct respiration, and gas exchange failure, in which respiratory structures fail to function properly. (See [Mechanics of acute respiratory failure.](#))

Other causes of acute respiratory failure include:

- u central nervous system depression due to head trauma or injudicious use of sedatives, narcotics, tranquilizers, or oxygen
- u cardiovascular disorders (myocardial infarction, heart failure, or pulmonary emboli)
- u airway irritants, such as smoke or fumes
- u endocrine or metabolic disorders, such as myxedema or metabolic acidosis
- u thoracic abnormalities, such as chest trauma, pneumothorax, or thoracic or abdominal surgery.

Complications

Tissue hypoxia, metabolic acidosis, and respiratory and cardiac arrest are among possible complications.

Assessment findings

Because acute respiratory failure in COPD is life-threatening, you probably don't have time to conduct an in-depth patient interview. Instead, rely on family members or the patient's medical records to discover the precipitating incident.

On inspection, note cyanosis of the oral mucosa, lips, and nail beds; nasal flaring; and ashen skin. You may observe the patient yawning and using accessory muscles to breathe. He may appear restless, anxious, depressed, lethargic, agitated, or confused. Additionally, he usually exhibits tachypnea, which signals impending respiratory failure.

Palpation may reveal cold, clammy skin and asymmetrical chest movement, which suggests pneumothorax. If tactile fremitus is present, notice that it decreases over an obstructed bronchi or pleural effusion but increases over consolidated lung tissue.

Percussion—especially in patients with COPD—reveals hyperresonance. If acute respiratory failure results from atelectasis or pneumonia, percussion usually produces a dull or flat sound.

Auscultation typically discloses diminished breath sounds. In patients with pneumothorax, breath sounds may be absent. In other cases of respiratory failure, you may hear such adventitious breath sounds as wheezes (in asthma) and rhonchi (in bronchitis). If you hear crackles, suspect pulmonary edema as the cause of respiratory failure.

PATHOPHYSIOLOGY

Mechanics of acute respiratory failure

Mechanics of acute respiratory failure

Three major malfunctions account for impaired gas exchange and subsequent acute respiratory failure. They include alveolar hypoventilation, ventilation-perfusion mismatch, and intrapulmonary (right-to-left) shunting.

Alveolar hypoventilation

Decreased oxygen saturation may result when chronic airway obstruction reduces alveolar minute ventilation. In such cases, Pa O_2 levels fall and PaCO_2 levels rise, and hypoxia results.

Ventilation-perfusion mismatch

The most common cause of hypoxemia, imbalances in ventilation and perfusion occur when conditions such as pulmonary embolism or adult respiratory distress syndrome interrupt normal gas exchange in a specific lung region. Either too little ventilation with normal blood flow or too little blood flow with normal ventilation may cause the imbalance. Whichever happens, the result is the same: Pa O_2 levels fall.

Right-to-left shunting

Untreated ventilation or perfusion imbalances can lead to right-to-left shunting, in which blood passes from the heart's right side to its left without being oxygenated.

Implications

The hypoxemia and hypercapnia characteristic of respiratory failure stimulate strong compensatory responses by all body systems, including the respiratory, cardiovascular, and central nervous systems.

In response to hypoxemia, for example, the sympathetic nervous system triggers vasoconstriction, increases peripheral resistance, and boosts the heart rate.

The body responds to hypercapnia with cerebral depression, hypotension, circulatory failure, and an increased heartbeat and cardiac output. Hypoxemia or hypercapnia (or both) cause the brain's respiratory control center to first increase respiratory depth (tidal volume) and then increase the respiratory rate. As respiratory failure worsens, intercostal, supraclavicular, and suprasternal retractions may also occur.

Diagnostic tests

ABG analysis is the key to diagnosis (and subsequent treatment) of acute respiratory failure in patients with COPD. Progressively deteriorating ABG values and pH compared with the patient's normal values strongly suggest acute respiratory failure. In patients with essentially normal lung tissue, a pH less than 7.35 usually indicates acute respiratory failure. In patients with COPD, the pH deviation from the normal value is even lower.

Chest X-rays are used to identify underlying pulmonary diseases or conditions, such as emphysema, atelectasis, lesions, pneumothorax, infiltrates, and effusions.

Electrocardiography (ECG) can demonstrate arrhythmias. Common ECG patterns point to cor pulmonale and myocardial hypoxia.

indicates acute respiratory failure. In patients with COPD, the pH deviation from the normal value is even lower.

Chest X-rays are used to identify underlying pulmonary diseases or conditions, such as emphysema, atelectasis, lesions, pneumothorax, infiltrates, and effusions.

Electrocardiography (ECG) can demonstrate arrhythmias. Common ECG patterns point to cor pulmonale and myocardial hypoxia

Pulse oximetry reveals a decreasing arterial oxygen saturation.

Blood tests such as a white blood cell count are used to detect underlying causes. Abnormally low hematocrit and decreased hemoglobin levels signal blood loss, which indicates decreased oxygen-carrying capacity.

Serum electrolyte findings vary. Hypokalemia may result from compensatory hyperventilation, the body's attempt to correct alkalosis; hypochloremia usually occurs in metabolic alkalosis.

Pulmonary artery catheterization helps to distinguish pulmonary and cardiovascular causes of acute respiratory failure and is used to monitor hemodynamic pressures.

Additional tests, such as a blood culture, Gram stain, and sputum culture, may be used to identify the pathogen. (See [Identifying respiratory failure.](#))

Treatment

Acute respiratory failure in patients with COPD is an emergency. The patient needs cautious oxygen therapy (nasal prongs or a Venturi mask) to increase his Pa O₂. If significant respiratory acidosis persists, mechanical ventilation with an endotracheal or a tracheostomy tube may be necessary. High-frequency ventilation may be initiated if the patient doesn't respond to conventional mechanical ventilation. Treatment routinely includes antibiotics (for infection), bronchodilators and, possibly, corticosteroids.

If the patient also has cor pulmonale and decreased cardiac output, fluid restrictions and administration of positive inotropic agents, vasopressors, and diuretics may be ordered.

WARNING

Identifying respiratory failure

Use the following measurements to identify respiratory failure:

- vital capacity less than 15 cc/kg
- tidal volume less than 3 cc/kg
- negative inspiratory force under -25 cm H₂O
- respiratory rate more than twice the normal rate
- diminished PaO₂ despite increased FIO₂
- elevated Paco₂ with pH lower than 7.25.

Nursing diagnoses

▫ Altered nutrition: Less than body requirements ▫ Altered thought processes ▫ Altered tissue perfusion (cardiopulmonary) ▫ Anxiety ▫ Death anxiety ▫ Fatigue ▫ Fear ▫ Impaired gas exchange ▫ Impaired skin integrity ▫ Impaired verbal communication ▫ Ineffective airway clearance ▫ Ineffective breathing pattern ▫ Ineffective individual coping ▫ Sensory or perceptual alterations

Key outcomes

- The patient will maintain a patent airway.
- The patient will maintain adequate ventilation.
- The patient will use alternate means of communication.
- The patient will use support systems to assist with coping.
- The patient will maintain skin integrity.
- The patient will express feelings of comfort.
- The patient will regain a sense of orientation.
- The patient will modify his lifestyle to minimize risk of decreased tissue perfusion.

Nursing interventions

- Orient the patient to the treatment unit. Most patients with acute respiratory failure receive intensive care. Acquainting the patient with procedures, sounds, and sights helps to minimize his anxiety.
- To reverse hypoxemia, administer oxygen at appropriate concentrations to maintain Pa O₂ at a minimum pressure range of 50 to 60 mm Hg. The patient with COPD usually requires only small amounts of supplemental oxygen. Watch for a positive response, such as improved breathing, color, and ABG values.
- Maintain a patent airway. If your patient retains CO₂, encourage him to cough and breathe deeply with pursed lips. If he's alert, have him use an incentive spirometer.
- If he's intubated and lethargic, reposition him every 1 to 2 hours. Use postural drainage and chest physiotherapy to help clear secretions.
- Observe the patient closely for respiratory arrest. Auscultate chest sounds. Monitor ABG values, and report any changes immediately. Notify the doctor of any deterioration in oxygen saturation levels detected by pulse oximetry.
- Watch for treatment complications, especially oxygen toxicity and adult respiratory distress syndrome.
- Frequently monitor vital signs. Note and report an increasing pulse rate, increasing or decreasing respiratory rate, declining blood pressure, or febrile state.
- Monitor and record serum electrolyte levels carefully. Take steps to correct imbalances. Monitor fluid balance by recording the patient's intake and output and daily weight.
- Check the cardiac monitor for arrhythmias.
- Perform oral hygiene measures frequently.
- Apply soft wrist restraints for the confused patient if needed. This prevents him from disconnecting the oxygen setup. However, remember that these restraints can increase anxiety, fear, and agitation.
- Position the patient for comfort and optimal gas exchange. Place the call button within the patient's reach.
- Maintain the patient in a normothermic state to reduce the body's demand for oxygen.
- Pace patient care activities to maximize the patient's energy level and provide needed rest.

If the patient requires mechanical ventilation:

- Check ventilator settings, cuff pressures, and ABG values often to ensure correct fraction of inspired oxygen (F IO₂) settings, which are determined by ABG levels. Draw blood samples for ABG analysis 20 to 30 minutes after every change in the F IO₂ setting or as ordered.
- Suction the trachea as needed after oxygenation. Observe for any change in sputum quality, consistency, and color. Provide humidification to liquefy secretions.
- Watch for complications of mechanical ventilation, such as reduced cardiac output, pneumothorax or other barotrauma, increased pulmonary vascular resistance, diminished urine output, increased intracranial pressure, and GI bleeding.
- Routinely assess endotracheal tube position and patency. Make sure the tube is placed properly and taped securely. Immediately after intubation, check for accidental intubation of the esophagus or the mainstem bronchus, which may have occurred during endotracheal tube insertion. Also be alert for transtracheal or laryngeal perforation, aspiration, broken teeth, nosebleeds, arrhythmias, hypertension, and vagal reflexes such as bradycardia.

- u Suction the trachea as needed after oxygenation. Observe for any change in sputum quality, consistency, and color. Provide humidification to liquefy secretions.
- u Watch for complications of mechanical ventilation, such as reduced cardiac output, pneumothorax or other barotrauma, increased pulmonary vascular resistance, diminished urine output, increased intracranial pressure, and GI bleeding.
- u Routinely assess endotracheal tube position and patency. Make sure the tube is placed properly and taped securely. Immediately after intubation, check for accidental intubation of the esophagus or the mainstem bronchus, which may have occurred during endotracheal tube insertion. Also be alert for transtracheal or laryngeal perforation, aspiration, broken teeth, nosebleeds, arrhythmias, hypertension, and vagal reflexes such as bradycardia.
- u After tube placement, watch for complications, such as tube displacement, herniation of the tubes cuff, respiratory infection, and tracheal malacia and stenosis.
- u Prevent infection by using sterile technique while suctioning and by changing ventilator tubing every 24 hours.
- u Prevent tracheal erosion that can result from an overinflated artificial airway cuff compressing the tracheal wall's vasculature. Use the minimal-leak technique and a cuffed tube with high residual volume (low-pressure cuff), a foam cuff, or a pressure-regulating valve on the cuff. Measure cuff pressure every 8 hours.
- u Implement measures to prevent tissue necrosis. Position and maintain the nasotracheal tube midline within the nostrils and provide meticulous care. Periodically loosen the tape securing the tube to prevent skin breakdown. Reposition endotracheal tubing from side to side, and retape as needed. Make sure that the ventilator tubing has adequate support.
- u Monitor for signs of stress ulcers, which are common in intubated patients, especially those in the intensive care unit. Inspect gastric secretions for blood, especially if the patient has a nasogastric tube or reports epigastric tenderness, nausea, or vomiting. Also monitor hemoglobin and hematocrit levels, and check all stools for blood. Administer antacids or histamine receptor antagonists as ordered.
- u Help the patient communicate without words. Offer him a pen and tablet, a word chart, or an alphabet board.

Patient teaching

- u If applicable, teach the patient about the effects of smoking. Provide resources to help him stop smoking.
- u Describe all tests and procedures to the patient and family members. Discuss the reasons for suctioning, chest physiotherapy, blood tests and, if used, soft wrist restraints.
- u If the patient is intubated or has a tracheostomy, explain why he can't speak. Suggest alternative means of communication.
- u Identify reportable signs of respiratory infection.

ADULT RESPIRATORY DISTRESS SYNDROME

Adult respiratory distress syndrome (ARDS) is a form of pulmonary edema that can quickly lead to acute respiratory failure. It's also known as shock, stiff, white, wet, or Da Nang lung. It may follow direct or indirect lung injury.

Increased permeability of the alveolocapillary membranes allows fluid to accumulate in the lung interstitium, alveolar spaces, and small airways, causing the lung to stiffen. This impairs ventilation, reducing oxygenation of pulmonary capillary blood. Difficult to recognize, the disorder can prove fatal within 48 hours of onset if not promptly diagnosed and treated. (See [What happens in ARDS.](#))

This four-stage syndrome can progress to intractable and fatal hypoxemia; patients who recover may have little or no permanent lung damage.

In some patients, the syndrome may coexist with disseminated intravascular coagulation (DIC). It remains unclear whether ARDS stems from DIC or develops independently. Patients with three concurrent ARDS risk factors have an 85% probability of developing ARDS.

Causes

Trauma is the most common cause of ARDS, possibly because trauma-related factors, such as fat emboli, sepsis, shock, pulmonary contusions, and multiple transfusions, increase the likelihood of microemboli developing.

Other common causes of ARDS include anaphylaxis, aspiration of gastric contents, diffuse pneumonia (especially viral), drug overdose (for example, heroin, aspirin, and ethchlorvynol), idiosyncratic drug reaction (to ampicillin and hydrochlorothiazide), inhalation of noxious gases (such as nitrous oxide, ammonia, and chlorine), near-drowning, and oxygen toxicity.

Less common causes of ARDS include coronary artery bypass grafting, hemodialysis, leukemia, acute miliary tuberculosis, pancreatitis, thrombotic thrombocytopenic purpura, uremia, and venous air embolism.

Complications

Severe ARDS can lead to metabolic and respiratory acidosis and ensuing cardiac arrest.

Assessment findings

As you conduct your assessment, be alert for the patient's particular stage of ARDS. Each has its typical signs.

In *stage I*, the patient may complain of dyspnea, especially on exertion. Respiratory and pulse rates are normal to high. Auscultation may reveal diminished breath sounds.

In *stage II*, respiratory distress becomes more apparent. The patient may use accessory muscles to breathe and appear pallid, anxious, and restless. He may have a dry cough with thick, frothy sputum and bloody, sticky secretions. Palpation may disclose cool, clammy skin. Tachycardia and tachypnea may accompany elevated blood pressure. Auscultation may reveal basilar crackles. (Stage II signs and symptoms may be incorrectly attributed to other causes such as multiple traumas.)

In *stage III*, the patient struggles to breathe. Vital signs reveal tachypnea (more than 30 breaths/minute), tachycardia with arrhythmias (usually premature ventricular contractions), and a labile blood pressure. Inspection may reveal a productive cough and pale, cyanotic skin. Auscultation may disclose crackles and rhonchi. The patient needs intubation and ventilation.

In *stage IV*, the patient has acute respiratory failure with severe hypoxia. His mental status is deteriorating, and he may become comatose. His skin appears pale and cyanotic. Spontaneous respirations aren't evident. Bradycardia with arrhythmias accompanies hypotension. Metabolic and respiratory acidosis develop. When ARDS reaches this stage, the patient is at high risk for fibrosis. Pulmonary damage becomes life-threatening.

Diagnostic tests

Arterial blood gas (ABG) analysis (with the patient breathing room air) initially shows a reduced partial pressure of arterial oxygen (Pa O₂) of less than 60 mm Hg and a decreased partial pressure of arterial carbon dioxide (Pac O₂) of less than 35 mm Hg. Hypoxemia despite increased supplemental oxygen is the hallmark of ARDS. The resulting blood pH usually reflects respiratory alkalosis. As ARDS worsens, ABG values show respiratory acidosis (increasing Paco₂ [more than 45 mm Hg]) and metabolic acidosis (decreasing bicarbonate levels [less than 22 mEq/L]) and declining Pa O₂ despite oxygen therapy.

Pulmonary artery catheterization helps to identify the cause of pulmonary edema by measuring pulmonary artery wedge pressure (PAWP). This procedure also allows collection of samples of pulmonary artery, mixed venous blood that shows decreased oxygen saturation, reflecting tissue hypoxia. Normal PAWP values in ARDS are 12 mm Hg or less.

PATHOPHYSIOLOGY

What happens in ARDS

These illustrations depict the process and progress of adult respiratory distress syndrome (ARDS).

These illustrations depict the process and progress of adult respiratory distress syndrome (ARDS).

1 The body responds to insult

Injury reduces normal blood flow to the lungs, allowing platelets to aggregate. These platelets release substances, such as serotonin (S), bradykinin (B) and, especially, histamine (H), that inflame and damage the alveolar membrane and later increase capillary permeability. At this early stage, signs and symptoms of ARDS are undetectable.

2 Fluid shift causes symptoms

Histamines and other inflammatory substances increase capillary permeability, allowing fluid to shift into the interstitial space. As a result, the patient may experience tachypnea, dyspnea, and tachycardia.

3 Pulmonary edema results

As capillary permeability increases, proteins and more fluid leak out, increasing interstitial osmotic pressure and causing pulmonary edema. At this stage, the patient may experience increased tachypnea, dyspnea, and cyanosis. Hypoxia (usually unresponsive to increased F_{IO_2}), decreased pulmonary compliance, and crackles and rhonchi may also develop.

4 Alveoli collapse

Fluid in the alveoli and decreased blood flow damage surfactant in the alveoli, reducing the cells' ability to produce more. Without surfactant, alveoli collapse, impairing gas exchange. Look for thick, frothy sputum and marked hypoxemia with increased respiratory distress.

5 Gas exchange slows

The patient breathes faster, but sufficient O_2 can't cross the alveolocapillary membrane. CO_2 , however, crosses more easily and is lost with every exhalation. Both O_2 and CO_2 levels in the blood decrease. Look for increased tachypnea, hypoxemia, and hypocapnia.

6 Metabolic acidosis occurs

Pulmonary edema worsens. Meanwhile, inflammation leads to fibrosis, which further impedes gas exchange. The resulting hypoxemia leads to metabolic acidosis. At this stage, look for increased $Paco_2$, decreased pH and PaO_2 , decreased HCO_3^- levels, and mental confusion.

Serial chest X-rays in early stages show bilateral infiltrates. In later stages, findings demonstrate lung fields with a ground-glass appearance and, eventually (with irreversible hypoxemia), “whiteouts” of both lung fields.

Differential diagnosis must rule out cardiogenic pulmonary edema, pulmonary vasculitis, and diffuse pulmonary hemorrhage. Etiologic tests may involve sputum analyses (including Gram stain and culture and sensitivity); blood cultures (to identify infectious organisms); toxicology tests (to screen for drug ingestion); and various serum amylase tests (to rule out pancreatitis).

Treatment

Therapy focuses on correcting the cause of the syndrome, if possible, and preventing progression of life-threatening hypoxemia and respiratory acidosis. Supportive care consists of administering humidified oxygen by a tightly fitting mask, which facilitates the use of continuous positive airway pressure (CPAP). However, this therapy alone seldom fulfills the ARDS patient's ventilatory requirements. If the patient's hypoxemia doesn't subside with this treatment, he may require intubation, mechanical ventilation, and positive end-expiratory pressure (PEEP). Other supportive measures include fluid restriction, diuretic therapy, and correction of electrolyte and acid-base imbalances.

When a patient with ARDS needs mechanical ventilation, sedatives, narcotics, or neuromuscular blocking agents (such as vecuronium) may be ordered to minimize restlessness (and thereby oxygen consumption and carbon dioxide production) and to facilitate ventilation.

When ARDS results from fatty emboli or a chemical injury, a short course of high-dose corticosteroids may help if given early. Treatment with sodium bicarbonate may be necessary to reverse severe metabolic acidosis, and fluids and vasopressors may be needed to maintain blood pressure. Nonviral infections require treatment with antimicrobial drugs.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered tissue perfusion (cardiopulmonary) u Anxiety u Decreased cardiac output u Fatigue u Fear u Impaired gas exchange u Impaired physical mobility u Impaired verbal communication u Risk for impaired skin integrity u Risk for infection

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain a patent airway.
- u The patient will use alternate means of communication.
- u The patient will use support systems to assist with coping.
- u The patient will maintain skin integrity.
- u The patient will express feelings of comfort.

Nursing interventions

- u Frequently assess the patient's respiratory status. Be alert for inspiratory retractions. Note respiratory rate, rhythm, and depth. Watch for dyspnea and accessory muscle use. Listen for adventitious or diminished breath sounds. Check for clear, frothy sputum (indicating pulmonary edema).
- u Evaluate and document the patient's level of consciousness, noting confusion or mental sluggishness.
- u Be alert for signs of treatment-induced complications, including arrhythmias, DIC, GI bleeding, infection, malnutrition, paralytic ileus, pneumothorax, pulmonary fibrosis, renal failure, thrombocytopenia, and tracheal stenosis.
- u Maintain a patent airway by suctioning. Use sterile, nontraumatic technique. Ensure adequate humidification to help liquefy tenacious secretions.
- u Closely monitor heart rate and blood pressure. Watch for arrhythmias that may result from hypoxemia, acid-base disturbances, or electrolyte imbalance.
- u With pulmonary artery catheterization, know the desired PAWP level; check readings often, and watch for decreasing mixed venous oxygen saturation. Change dressings according to facility guidelines, using strict aseptic technique.
- u Monitor serum electrolyte levels, and correct imbalances. Measure intake and output. Weigh the patient daily.
- u Check ventilator settings frequently, and drain condensation from the tubing promptly to ensure maximum oxygen delivery. Monitor ABG levels; document and report changes in arterial oxygen saturation as well as metabolic and respiratory acidosis and Pa O₂ changes.
- u Be prepared to administer CPAP to the patient with severe hypoxemia.
- u Give sedatives, as ordered, to reduce restlessness. Monitor and record the patient's response to medication.

ALERT Because PEEP may lower cardiac output, check for hypotension, tachycardia, and decreased urine output. To maintain PEEP, suction only as needed. High-frequency jet ventilation and pressure-controlled ventilation may also be required.

- u Reposition the patient often.
- u Record any increase in secretions, temperature, or hypotension that may indicate a deteriorating condition.
- u Monitor the patient's nutritional intake, and record caloric intake. Administer tube feedings and parenteral nutrition as ordered. Plan patient care to allow periods of uninterrupted sleep. To promote health and prevent fatigue, arrange for alternate periods of rest and activity.
- u Maintain joint mobility by performing passive range-of-motion exercises. If possible, help the patient perform active range-of-motion exercises.
- u Provide meticulous skin care. To prevent skin breakdown, reposition the endotracheal tube from side to side every 24 hours.
- u Provide emotional support. Answer the patient's and family's questions as completely as possible to allay their fears and concerns.
- u Watch for and immediately report all respiratory changes in the patient with injuries that may adversely affect the lungs—especially in the first few days after the injury when the patient's condition may appear to be improving.
- u Provide alternative communication means for the patient on mechanical ventilation.

Patient teaching

- u Explain the disorder to the patient and family members. Tell them what signs and symptoms may occur, and review the treatment that may be required.
- u Orient the patient and family members to the unit and health care facility surroundings. Provide them with simple explanations and demonstrations of treatments.
- u Tell the recuperating patient that recovery takes some time and that he'll feel weak for a while. Urge him to share his concerns with the staff.

ASTHMA

Asthma is a chronic reactive airway disorder that involves episodic, reversible airway obstruction resulting from bronchospasms, increased mucus secretions, and mucosal edema. Signs and symptoms range from mild wheezing and dyspnea to life-threatening respiratory failure. Signs and symptoms of bronchial airway obstruction may or may not persist between acute episodes.

This common respiratory condition can strike at any age, but about half of all patients with asthma are under age 10. In this age group, asthma affects twice as many boys as girls. About one-third of patients experience asthma onset between ages 10 and 30. In this group, incidence is the same in both sexes. Hereditary factors are also important: About one-third of all patients with asthma share the disease with at least one immediate family member.

Asthma may result from sensitivity to specific external allergens (extrinsic) or from internal, nonallergenic factors (intrinsic). Allergens that cause *extrinsic asthma* (atopic asthma) include pollen, animal dander, house dust or mold, kapok or feather pillows, food additives containing sulfites, and any other sensitizing substance. Extrinsic asthma begins in children and is commonly accompanied by other manifestations of atopy (type I, immunoglobulin E [IgE]-mediated allergy), such as eczema

also important: About one-third of all patients with asthma share the disease with at least one immediate family member.

Asthma may result from sensitivity to specific external allergens (extrinsic) or from internal, nonallergenic factors (intrinsic). Allergens that cause *extrinsic asthma* (atopic asthma) include pollen, animal dander, house dust or mold, kapok or feather pillows, food additives containing sulfites, and any other sensitizing substance. Extrinsic asthma begins in children and is commonly accompanied by other manifestations of atopy (type I, immunoglobulin E [IgE]-mediated allergy), such as eczema and allergic rhinitis.

In *intrinsic asthma* (nonatopic asthma), no extrinsic substance can be identified. Most episodes are preceded by a severe respiratory tract infection (especially in adults). Irritants, emotional stress, fatigue, endocrine changes, temperature and humidity variations, and exposure to noxious fumes may aggravate intrinsic asthma attacks. In many asthmatics, especially children, intrinsic and extrinsic asthma coexist.

Causes and pathophysiology

In asthma, the tracheal and bronchial linings overreact to various stimuli, causing episodic smooth-muscle spasms that severely constrict the airways. Mucosal edema and thickened secretions further block the airways.

IgE antibodies, attached to histamine-containing mast cells and receptors on cell membranes, initiate intrinsic asthma attacks. When exposed to an antigen such as pollen, the IgE antibody combines with the antigen. On subsequent exposure to the antigen, mast cells degranulate and release mediators.

These mediators cause the bronchoconstriction and edema of an asthma attack. As a result, expiratory airflow decreases, trapping gas in the airways and causing alveolar hyperinflation. Atelectasis may develop in some lung regions. The increased airway resistance initiates labored breathing. (See [What happens in asthma.](#))

Several factors may contribute to bronchoconstriction. These include hereditary predisposition; sensitivity to allergens or irritants such as pollutants; viral infections; aspirin, beta-adrenergic blockers, nonsteroidal anti-inflammatory drugs, and other drugs; tartrazine (a yellow food dye); psychological stress; cold air; and exercise.

Complications

Asthma can produce status asthmaticus and respiratory failure.

Assessment findings

An asthma attack may begin dramatically, with simultaneous onset of severe, multiple symptoms, or insidiously, with gradually increasing respiratory distress. Typically, the patient reports exposure to a particular allergen followed by sudden onset of dyspnea, wheezing, and tightness in the chest accompanied by a cough that produces thick, clear or yellow sputum.

The patient may complain of feeling suffocated. He may be visibly dyspneic and able to speak only a few words before pausing for breath. You may also observe accessory respiratory muscle use. He may sweat profusely, and you may note an increased anteroposterior thoracic diameter.

Percussion may produce hyperresonance. Palpation may reveal vocal fremitus. Auscultation may disclose tachycardia, tachypnea, mild systolic hypertension, harsh respirations with both inspiratory and expiratory wheezes, prolonged expiratory phase of respiration, and diminished breath sounds.

Cyanosis, confusion, and lethargy indicate the onset of life-threatening status asthmaticus and respiratory failure. (See [Determining asthma's severity.](#))

Diagnostic tests

Pulmonary function studies reveal signs of airway obstructive disease (decreased flow rates and forced expiratory volume in 1 second [FEV₁]), low-normal or decreased vital capacity, and increased total lung and residual capacities. Despite abnormal findings during asthmatic episodes, pulmonary function may be normal between attacks.

Typically, the patient has decreased partial pressure of arterial oxygen (Pa O₂) and partial pressure of arterial carbon dioxide (Pac O₂). However, in severe asthma, Paco₂ may be normal or increased, indicating severe bronchial obstruction. In fact, FEV₁ is most likely less than 25% of the predicted value. Initiating treatment tends to improve the airflow. However, even when the asthma attack appears controlled, the spirometric values (FEV₁ and forced expiratory flow between 25% and 75% of vital capacity) remain abnormal, necessitating frequent arterial blood gas (ABG) analyses or pulse oximetry measurements. Residual volume remains abnormal for up to 3 weeks after the attack.

Serum IgE levels may increase from an allergic reaction, and complete blood count with differential reveals increased eosinophil count.

Chest X-rays can be used to diagnose or monitor the progress of asthma. X-rays may show hyperinflation with areas of focal atelectasis.

ABG analysis is used to detect hypoxemia and guides treatment.

Skin testing may be used to identify specific allergens. Test results are ready in 1 to 2 days to detect an early reaction and then again after 4 or 5 days to reveal a late reaction.

PATHOPHYSIOLOGY

What happens in asthma

These drawings show the pathophysiologic processes that occur during an asthma attack.

1 When the patient inhales a substance to which he's hypersensitive, abnormal (IgE) antibodies stimulate mast cells in the lung interstitium to release both histamine (H) and the slow-reacting substance of anaphylaxis (SRS-A). At this early stage, the patient has no detectable signs or symptoms.

2 Histamine attaches to receptor sites in the larger bronchi, where it causes swelling in smooth muscles. Mucous membranes become inflamed, irritated, and swollen. The patient may experience dyspnea, prolonged expiration, and increased respiratory rate.

3 SRS-A attaches to receptor sites in the smaller bronchi and causes swelling of smooth muscle there. It also causes fatty acids called prostaglandins to travel by way of the bloodstream to the lungs, where they enhance histamine's effects. Listen to the patient's cough for wheezing. The higher the pitch, the narrower the bronchial lumen.

3 SRS-A attaches to receptor sites in the smaller bronchi and causes swelling of smooth muscle there. It also causes fatty acids called prostaglandins to travel by way of the bloodstream to the lungs, where they enhance histamine's effects. Listen to the patient's cough for wheezing. The higher the pitch, the narrower the bronchial lumen.

4 Histamine stimulates the mucous membranes to secrete excessive mucus, further narrowing the bronchial lumen (see top right). Goblet cells secrete a viscous mucus that is difficult to cough up. Listen for coughing, rhonchi, high-pitched wheezing, and increased respiratory distress.

5 On inhalation, the narrowed bronchial lumen can still expand slightly, allowing air to reach the alveoli. On exhalation, increased intrathoracic pressure closes the bronchial lumen completely. Air can get in but can't get out. Check for barrel chest, hyperresonance to percussion, and wheezing cessation.

6 Mucus fills the lung bases, inhibiting alveolar ventilation. Blood, shunted to alveoli in other lung parts, still can't compensate for diminished ventilation. Respiratory acidosis results. Look for signs of hypoxemia: reduced Pa O₂(despite increased FIO₂), elevated Paco₂, and decreased serum pH.

Determining asthma's severity

SIGNS AND SYMPTOMS DURING ACUTE PHASE

DIAGNOSTIC TEST RESULTS

OTHER ASSESSMENT FINDINGS

Mild asthma

<ul style="list-style-type: none">u Brief wheezing, coughing, dyspnea with activityu Infrequent nocturnal coughing or wheezingu Adequate air exchangeu Intermittent, brief (less than 1 hour) wheezing, coughing, or dyspnea once or twice a weeku Asymptomatic between attacks	<ul style="list-style-type: none">u Forced expiratory volume in 1 second (FEV₁) or peak flow 80% of normal valuesu pH normal or increasedu PaO₂ normal or decreasedu Paco₂ normal or decreasedu Chest X-ray normal	<ul style="list-style-type: none">u One attack per week (or none)u Positive response to bronchodilator therapy within 24 hoursu No signs of asthma between episodesu No sleep interruptionu No hyperventilationu Minimal evidence of airway obstructionu Minimal or no increase in lung volume

<ul style="list-style-type: none">▫ Marked respiratory distress▫ Marked wheezing or absent breath sounds▫ Pulsus paradoxus greater than 10 mm Hg▫ Chest wall contractions▫ Continuous symptoms▫ Frequent exacerbations	<ul style="list-style-type: none">▫ FEV₁ or peak flow less than 60% of normal values; may normally vary 20% to 30% with routine medications and up to 50% with exacerbations▫ pH normal or reduced▫ PaO₂, decreased▫ Paco₂ normal or increased▫ Chest X-ray that may show hyperinflation	<ul style="list-style-type: none">▫ Frequent severe attacks▫ Daily wheezing▫ Poor exercise tolerance▫ Frequent sleep interruption▫ Bronchodilator therapy that doesn't completely reverse airway obstruction▫ Markedly increased lung volumes

Bronchial challenge testing is used to evaluate the clinical significance of allergens identified by skin testing.

Treatment

The best treatment for asthma is prevention by identifying and avoiding precipitating factors, such as environmental allergens or irritants. Usually, such stimulants can't be removed entirely. Desensitization to specific antigens may be more helpful in children than in adults with bronchial asthma.

Drug therapy, which usually includes bronchodilators, is most effective when begun soon after the onset of signs and symptoms. Bronchodilators used include rapid-acting epinephrine, methylxanthines (theophylline and aminophylline), and beta ₂-adrenergic antagonists (albuterol and terbutaline) for the effect of decreasing bronchoconstriction. Corticosteroids (hydrocortisone sodium succinate, prednisone, methylprednisolones, and beclomethasone) are used for their anti-inflammatory and immunosuppressant effects), which decrease inflammation and edema of the airways. Cromolyn and nedocromil help prevent the release of the chemical mediators (histamine and leukotrienes) that cause bronchoconstriction. Anticholinergic bronchodilators (such as ipratropium) block acetylcholine, another chemical mediator. ABG measurements help to determine the severity of an asthma attack and the patient's response to treatment. For the most part, medical treatment of asthma must be tailored to the patient. (See [Tailoring treatments to types of asthma.](#))

ADVANCED PRACTICE

Tailoring treatments to types of asthma

For the most part, medical treatment of asthma attacks must be tailored to each patient. However, the following treatments are generally used.

Chronic mild asthma

A beta₂-adrenergic agonist by metered-dose inhaler is used (alone or with cromolyn) before exercise and exposure to an allergen or other stimuli to prevent symptoms. The beta₂-adrenergic agonist is used every 3 to 4 hours if symptoms occur.

Chronic moderate asthma

Initial treatment may include an inhaled beta-adrenergic bronchodilator, an inhaled corticosteroid, and cromolyn. Anticholinergic bronchodilators may also be added. If symptoms persist, the inhaled corticosteroid dose may be increased, and sustained-release theophylline or an oral beta ₂-adrenergic agonist (or both) may be added. Short courses of oral corticosteroids may also be used.

Chronic severe asthma

Initially, around-the-clock oral bronchodilator therapy with a long-acting theophylline or a beta ₂-adrenergic agonist may be required, supplemented with an inhaled corticosteroid with or without cromolyn. An oral corticosteroid such as prednisone may be added in acute exacerbations.

Acute asthma attack

Acute attacks that don't respond to self-treatment may require hospital care, beta₂-adrenergic agonists by inhalation or subcutaneous injection (in three doses over 60 to 90 minutes) and, possibly, oxygen for hypoxemia. If the patient responds poorly, systemic corticosteroids and, possibly, subcutaneous epinephrine may help. Beta₂-adrenergic agonist inhalation continues hourly. I.V. aminophylline may be added to the regimen, and I.V. fluid therapy is started. Patients who don't respond to this treatment, whose airways remain obstructed, and who have increasing respiratory difficulty are at risk for status asthmaticus and may require mechanical ventilation.

Status asthmaticus

Treatment consists of aggressive drug therapy: a beta₂-adrenergic agonist by nebulizer over 30 to 60 minutes, possibly supplemented with subcutaneous epinephrine, I.V. corticosteroids, I.V. aminophylline, oxygen administration, I.V. fluid therapy, and intubation and mechanical ventilation for hypercapnia respiratory failure (Paco₂ of 40 mm Hg or more).

In addition, low-flow oxygen may be required, as may antibiotics if infection exists. Fluid replacement may also be needed.

Status asthmaticus must be treated promptly to prevent progression to fatal respiratory failure. The patient with increasingly severe asthma that doesn't respond to drug therapy is usually admitted to the intensive care unit for treatment with corticosteroids, epinephrine, sympathomimetic aerosol sprays, and I.V aminophylline. He needs frequent ABG analysis and pulse oximetry to assess respiratory status, especially after ventilator therapy or a change in oxygen concentration. The patient may require endotracheal intubation and mechanical ventilation if his Paco ₂ increases.

Nursing diagnoses

▫ Anxiety ▫ Fear ▫ Impaired gas exchange ▫ Ineffective airway clearance ▫ Ineffective breathing pattern ▫ Knowledge deficit

Key outcomes

- The patient will maintain adequate ventilation.
- The patient will maintain a patent airway.
- The patient will maintain a breath rate at ± from baseline.
- The patient will use support systems to assist with coping.
- The patient will express feelings of comfort, either verbally or through behavior.
- The patient and family members will indicate verbally or through demonstration that they learned what was taught.
- The patient will maintain skin integrity.

Nursing interventions

During an acute attack:

- First assess the severity of asthma.
- Administer the prescribed treatments, and assess the patient's response.
- Place the patient in high Fowler's position. Encourage pursed-lip and diaphragmatic breathing. Help him to relax.

During an acute attack:

- u First assess the severity of asthma.
- u Administer the prescribed treatments, and assess the patient's response.
- u Place the patient in high Fowler's position. Encourage pursed-lip and diaphragmatic breathing. Help him to relax.
- u Monitor the patient's vital signs. Keep in mind that developing or increasing tachypnea may indicate worsening asthma and that tachycardia may indicate worsening asthma or drug toxicity. Blood pressure readings may reveal pulsus paradoxus, indicating severe asthma. Hypertension may indicate asthma-related hypoxemia.
- u Administer prescribed humidified oxygen by nasal cannula at 2 L/minute to ease breathing and increase arterial oxygen saturation (Sao₂). Later, adjust oxygen according to the patient's vital signs and ABG values.
- u Anticipate intubation and mechanical ventilation if the patient fails to maintain adequate oxygenation.
- u Monitor serum theophylline levels to ensure they're in the therapeutic range. Observe the patient for signs of theophylline toxicity (vomiting, diarrhea, headache) and subtherapeutic dosage (respiratory distress, increased wheezing).
- u Observe the frequency and severity of the patient's cough, and note whether it's productive. Auscultate his lungs, noting adventitious or absent sounds. If his cough isn't productive and rhonchi are present, teach him effective coughing techniques. If the patient can tolerate postural drainage and chest percussion, perform these procedures to clear secretions. Suction an intubated patient as needed.
- u Treat dehydration with I.V. fluids until the patient can tolerate oral fluids, which helps loosen secretions.
- u If conservative treatment fails to improve the airway obstruction, anticipate bronchoscopy or bronchial lavage when the area of collapse is a lobe or larger.

During long-term care:

- u Monitor the patient's respiratory status to detect baseline changes, assess response to treatment, and prevent or detect complications.
- u Auscultate the lungs frequently, noting the degree of wheezing and quality of air movement.
- u Review ABG levels, pulmonary function test results, and Sao₂ readings.
- u If the patient is taking systemic corticosteroids, observe for complications, such as elevated blood glucose levels, friable skin, and bruising.
- u Cushingoid effects resulting from long-term use of corticosteroids may be minimized by alternate-day dosage or use of prescribed inhaled corticosteroids.
- u If the patient is taking corticosteroids by inhaler, watch for signs of candidal infection in the mouth and pharynx. Using an extender device and rinsing the mouth afterward may prevent this.

HOME CARE

Using a metered-dose inhaler

When instructing your patient about proper metered-dose inhaler (MDI) use, include the following points:

- u Shake the MDI well before use.
- u Exhale normally. Then place the mouthpiece in your mouth and close your lips around it.
- u Begin slow, steady inspirations through the mouth until your lungs feel full.
- u While inhaling slowly, squeeze firmly on the MDI to deliver the dose while continuing to breathe in one deep steady breath, not several shallow ones.
- u Hold the breath for several seconds before exhaling.
- u Exhale slowly through pursed lips.
- u Gargle with normal saline solution, if desired.

Note: When using an extender or a spacer device, follow the same routine as above, with the MDI mouthpiece inserted in one end of the spacer and the other end placed in the mouth. Many spacers are equipped with a small whistle that sounds if the dose is being inhaled too fast.

- u For patients with moderate to severe chronic disease, regular use of an extender device may facilitate better delivery of inhaled medications.
- u Observe the patient's anxiety level. Keep in mind that measures to reduce hypoxemia and breathlessness should relieve anxiety.
- u Keep the room temperature comfortable, and use an air conditioner or a fan in hot, humid weather.
- u Control exercise-induced asthma by instructing the patient to use a bronchodilator or cromolyn 30 minutes before exercise. Also instruct him to use pursed-lip breathing while exercising.

Patient teaching

For all patients:

- u Teach the patient and family members to avoid known allergens and irritants.
- u Describe prescribed drugs, including their names, dosages, actions, adverse effects, and special instructions.
- u Teach the patient how to use a metered-dose inhaler. If he has difficulty using an inhaler, he may need an extender device to optimize drug delivery and lower the risk of candidal infection with orally inhaled corticosteroids. (See [Using a metered-dose inhaler.](#))

HOME CARE

Coping with asthma

Use these guidelines to help your patient cope with asthma at home:

- u Teach the parents and child about triggers of an attack. Evaluate their home to detect triggers, and help minimize them.
- u Assess the child's compliance with the medication regimen, and suggest ways to improve it.
- u Teach the parents and child how to use inhalers with spacer devices. First, show them how to set up the device, and stress the need for a tight seal around the mouthpiece. After demonstrating its use, watch the child use it. (He should press down to release medication into the chamber, inhale slowly, hold his breath for 5 seconds, exhale, and repeat the sequence again.) Explain the need to clean the mouthpiece with warm running water once a day and to dry it completely before placing it in its case.
- u Instruct the parents to replace the mouthpiece every 6 months and the reservoir bag every 2 to 3 weeks or as needed. If the bag develops a hole or tear, tell them to replace it immediately.
- u Suggest keeping a spare device available.
- u Discuss the signs of an impending attack and identify measures to minimize it.
- u If the child must take methylxanthines such as theophylline, advise the parents to call the doctor if adverse reactions occur and to return for follow-up laboratory tests.
- u If the child must take a corticosteroid, monitor for cushingoid effects. If such effects occur, tell the parents not to discontinue the drug abruptly but to gradually reduce the dosage.
- u Encourage the parents to let the child perform whatever activities he feels comfortable doing.
- u Recommend community resources, such as the American Lung Association or the Asthma and Allergy Foundation of America.

- u If the patient has moderate to severe asthma, explain how to use a peak-flow meter to measure the degree of airway obstruction. Tell him to keep a record of peak-flow readings and to bring it to medical appointments. Explain the importance of calling the doctor immediately if the peak flow drops suddenly. (A drop can signal severe respiratory problems.)
- u Tell the patient to notify the doctor if he develops a temperature higher than 100° F (37.8° C), chest pain, shortness of breath without coughing or exercising, or uncontrollable coughing. An uncontrollable asthma attack requires immediate attention.
- u Teach the patient diaphragmatic and pursed-lip breathing as well as effective coughing techniques.

- u If the patient has moderate to severe asthma, explain how to use a peak-flow meter to measure the degree of airway obstruction. Tell him to keep a record of peak-flow readings and to bring it to medical appointments. Explain the importance of calling the doctor immediately if the peak flow drops suddenly. (A drop can signal severe respiratory problems.).
- u Tell the patient to notify the doctor if he develops a temperature higher than 100° F (37.8° C), chest pain, shortness of breath without coughing or exercising, or uncontrollable coughing. An uncontrollable asthma attack requires immediate attention.
- u Teach the patient diaphragmatic and pursed-lip breathing as well as effective coughing techniques.
- u Urge the patient to drink at least 3 L (3.2 qt) of fluids daily to help loosen secretions and maintain hydration. (See [Coping with asthma.](#))

ATELECTASIS

In atelectasis, alveolar clusters (lobules) or lung segments that expand incompletely may produce a partial or complete lung collapse. This phenomenon effectively removes certain regions of the lung from gas exchange. This allows unoxygenated blood to pass unchanged through these regions and produces hypoxia.

Atelectasis may be chronic or acute. The disorder occurs to some degree in many patients undergoing upper abdominal or thoracic surgery. The prognosis depends on prompt removal of any airway obstruction, relief of hypoxia, and reexpansion of the collapsed lung.

Causes

Atelectasis can result from bronchial occlusion by mucus plugs (a special problem in patients with chronic obstructive pulmonary disease), bronchiectasis, or cystic fibrosis. Mucus plugs may also affect lung expansion in patients who smoke heavily (smoking increases mucus production and damages cilia). The disorder may also result from occlusion caused by foreign bodies, bronchogenic carcinoma, and inflammatory lung disease.

Other causes include idiopathic respiratory distress syndrome of the newborn (hyaline membrane disease), oxygen toxicity, and pulmonary edema, in which changes in alveolar surfactant cause increased surface tension and permit complete alveolar deflation.

External compression, which inhibits full lung expansion, or any condition that makes deep breathing painful may also cause atelectasis. Such compression or pain may result from upper abdominal surgical incisions, rib fractures, pleuritic chest pain, tight chest dressings, and obesity (which elevates the diaphragm and reduces tidal volume).

Lung collapse or reduced expansion may accompany prolonged immobility (which promotes ventilation of one lung area over another) or mechanical ventilation (which supplies constant small tidal volumes without intermittent deep breaths). Central nervous system depression (resulting from drug overdose, for example) eliminates periodic sighing and predisposes the patient to progressive atelectasis.

Complications

Atelectasis can cause hypoxemia and acute respiratory failure. Additionally, static secretions from atelectasis may lead to pneumonia.

Assessment findings

Clinical effects vary with the causes of lung collapse, the degree of hypoxia, and the underlying disease. If atelectasis affects a small lung area, the patient's symptoms may be minimal and transient. With massive collapse, the patient may report severe symptoms, such as dyspnea and pleuritic chest pain.

Inspection may disclose decreased chest wall movement, cyanosis, diaphoresis, substernal or intercostal retractions, and anxiety.

Palpation may reveal decreased fremitus and mediastinal shift to the affected side. Percussion may disclose dullness or flatness over lung fields. Auscultation findings may include crackles during the last part of inspiration and decreased (or absent) breath sounds with major lung involvement. Auscultation may also disclose tachycardia.

Diagnostic tests

Chest X-rays are the primary diagnostic tool, although extensive areas of “microatelectasis” can exist without abnormalities appearing on the films. In widespread atelectasis, X-ray findings define characteristic horizontal lines in the lower lung zones. With segmental or lobar collapse, the films reveal characteristic dense shadows (commonly associated with hyperinflation of neighboring lung zones).

Bronchoscopy may be used to rule out an obstructing neoplasm or a foreign body if the cause of atelectasis can't be determined.

Arterial blood gas analysis may reveal respiratory acidosis and hypoxemia resulting from atelectasis.

Pulse oximetry may show deteriorating levels of arterial oxygen saturation.

Treatment

Incentive spirometry, chest percussion, postural drainage, and frequent coughing and deep-breathing exercises may improve oxygenation in the patient with atelectasis. If these measures fail, bronchoscopy may help remove secretions. Humidity and bronchodilator medications can improve mucociliary clearance and dilate airways. These drugs may be administered by nebulizer or by a face mask device that establishes continuous positive airway pressure. Alternatively, intermittent positive-pressure breathing therapy may be prescribed.

If the patient has atelectasis secondary to an obstructing neoplasm, he may need surgery or radiation therapy. To minimize the risk for atelectasis after thoracic and abdominal surgery, the patient requires analgesics to facilitate deep breathing.

Nursing diagnoses

- u Anxiety u Fear u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will maintain adequate ventilation.
- u The patient will express feelings of comfort, either verbally or through behavior.
- u The patient will express an understanding of the illness.
- u The patient will use support systems to assist with anxiety and fear.

Nursing interventions

- u Encourage the patient recovering from surgery (or other patients at high risk for atelectasis) to perform coughing and deep-breathing exercises every 1 to 2 hours. To minimize pain during these exercises, hold a pillow tightly over the patient's incisional area. Teach the patient how to do this for himself. Gently reposition the patient often, and help him walk as soon as possible. Administer adequate analgesics to control pain.
- u Monitor mechanical ventilation. Maintain tidal volume at 10 to 15 cc/kg of the patient's body weight to ensure adequate lung expansion. Use the sigh mechanism on the ventilator, if appropriate, to intermittently increase tidal volume at the rate of 3 to 4 sighs/hour.
- u Monitor pulmonary pulse oximetry for decreases in oxygenation.
- u Help the patient use an incentive spirometer to encourage deep breathing.
- u Humidify inspired air, and encourage adequate fluid intake to mobilize secretions. Use postural drainage and chest percussion to remove secretions.
- u For the intubated or uncooperative patient, provide suctioning as needed. Administer sedatives with care because these medications depress respirations and the cough reflex. They also suppress sighs. Keep in mind that the patient is able to cooperate minimally (or not at all) with treatment if he has pain.
- u Assess breath sounds and respiratory status frequently. Report any changes immediately.

- u Monitor pulmonary pulse oximetry or decreases in oxygenation.
- u Help the patient use an incentive spirometer to encourage deep breathing.
- u Humidify inspired air, and encourage adequate fluid intake to mobilize secretions. Use postural drainage and chest percussion to remove secretions.
- u For the intubated or uncooperative patient, provide suctioning as needed. Administer sedatives with care because these medications depress respirations and the cough reflex. They also suppress sighs. Keep in mind that the patient is able to cooperate minimally (or not at all) with treatment if he has pain.
- u Assess breath sounds and respiratory status frequently. Report any changes immediately.
- u Offer ample reassurance and emotional support because the patient's limited breathing capacity may frighten him.

Patient teaching

- u Teach the patient how to use the spirometer. Urge him to use it every 1 to 2 hours.
- u Show the patient and family members how to perform postural drainage and percussion. Instruct the patient to maintain each position for 10 minutes and then perform chest percussion. Let him know when to cough. Teach coughing and deep-breathing techniques to promote ventilation and mobilize secretions.
- u Encourage the patient to stop smoking, lose weight, or do both, if needed. Refer him to appropriate support groups for help.
- u Demonstrate comfort measures to promote relaxation and conserve energy. Advise the patient and family members to alternate periods of rest and activity to promote energy and prevent fatigue.

HEMOTHORAX

Hemothorax occurs when blood enters the pleural cavity from damaged intercostal, pleural, or mediastinal vessels (or occasionally from the lung's parenchymal vessels). Depending on the amount of blood and the underlying cause of bleeding, hemothorax can cause varying degrees of lung collapse. About 25% of patients with chest trauma (blunt or penetrating) experience hemothorax. Pneumothorax (air in the pleural cavity) commonly accompanies hemothorax.

Causes

Hemothorax usually results from either blunt or penetrating chest trauma. Less often, it occurs as a consequence of thoracic surgery, pulmonary infarction, neoplasm, dissecting thoracic aneurysm, or anticoagulant therapy.

Complications

Hemothorax can result in mediastinal shift, ventilatory compromise, lung collapse and, without successful intervention, cardiopulmonary arrest.

Assessment findings

The patient history typically reflects recent trauma. In addition, the patient may complain of chest pain and sudden difficulty breathing, which may be mild to severe depending on the amount of blood in the pleural cavity.

Inspection typically discloses a patient with tachypnea, dusky skin color, diaphoresis, and hemoptysis (bloody, frothy sputum). If hemothorax progresses to respiratory failure, the patient may show restlessness, anxiety, cyanosis, and stupor. As the chest rises and falls, you may notice that the affected side may expand and stiffen; the unaffected side may rise with the patient's gasping respirations.

Percussion may disclose dullness over the affected side of the chest. Auscultation may detect decreased or absent breath sounds over the affected side, tachycardia, and hypotension.

Diagnostic tests

Thoracentesis performed for diagnosis and therapy may yield blood or serosanguineous fluid. Fluid specimens may be sent to the laboratory for analysis.

Chest X-rays display pleural fluid and reveal mediastinal shift, and arterial blood gas (ABG) analysis is used to document respiratory failure.

Hemoglobin levels may be decreased, depending on blood loss.

Treatment

In hemothorax, the goal of treatment is to stabilize the patient's condition, stop the bleeding, evacuate blood from the pleural cavity, and reexpand the affected lung. Mild hemothorax usually clears in 10 to 14 days, requiring only observation for further bleeding. In severe hemothorax, treatment includes thoracentesis to remove blood and other fluids from the pleural cavity and then insertion of a chest tube into the sixth intercostal space in the posterior axillary line. The diameter of a typical chest tube is large to prevent clots from blocking it. Suction may also be used. If the chest tube doesn't improve the patient's condition, the surgeon may need to perform a thoracotomy to evacuate blood and clots and control bleeding.

Autotransfusion may be used if the patient's blood loss approaches or exceeds 1 L. (See [Using autotransfusion for chest wounds.](#))

Other treatment measures include oxygen therapy, I.V. therapy to restore fluid volume, and analgesics.

Using autotransfusion for chest wounds

Autotransfusion is used most often in patients with chest wounds, especially those that involve hemothorax. Through autotransfusion, a patient's own blood is collected, filtered, and reinfused. The procedure may also be used when two or three units of pooled blood can be recovered, such as in cardiac or orthopedic surgery.

Autotransfusion eliminates the patient's risk of transfusion reaction or blood-borne disease, such as cytomegalovirus, hepatitis, and human immunodeficiency virus. It's contraindicated in patients with sepsis or cancer.

How autotransfusion works

A large-bore chest tube connected to a closed drainage system is used to collect the patient's blood from a wound or chest cavity. This blood passes through a filter, which catches most potential thrombi, including clumps of fibrin and damaged red blood cells (RBCs). The filtered blood passes into a collection bag. From the bag, the blood is reinfused immediately, or it may be processed in a commercial cell washer that reduces anticoagulated whole blood to washed RBCs for later infusion.

Assisting with autotransfusion

- u Set up the blood collection system as you would any closed chest drainage system. Attach the collection bag according to the manufacturer's instructions.
- u If ordered, inject an anticoagulant, such as heparin or acid citrate dextrose solution, into the self-sealing port on the connector of the patient's drainage tubing.
- u During reinfusion, monitor the patient for complications, such as blood clotting, hemolysis, coagulopathies, thrombocytopenia, particulate and air emboli, sepsis, and citrate toxicity (from the acid citrate dextrose solution).

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fluid volume deficit u Impaired gas exchange u Ineffective breathing pattern u Pain u Risk for infection

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain fluid volume balance.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will express an understanding of the illness.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Listen to the patient's fears and concerns. Offer reassurance as appropriate. Remain with the patient during periods of stress and anxiety. Encourage him to identify actions and care measures that promote comfort and relaxation. Be sure to perform these measures and encourage the patient and family members to do so as well. Include the patient and family members in care-related decisions whenever possible.
- u As ordered, give oxygen by face mask or nasal cannula.
- u Administer blood transfusions as ordered, using a large-bore needle.
- u To treat shock, give I.V. fluids and blood transfusions as ordered. Use a central venous pressure line to monitor treatment progress.
- u Monitor ABG levels often. Also check hemoglobin levels and hematocrit, white blood cell count, and coagulation studies to determine blood replacement needs.
- u Watch for complications signaled by pallor and gasping respirations.
- u Monitor the patient's vital signs diligently. Watch for increasing pulse and respiratory rates and decreasing blood pressure, which may indicate shock or massive bleeding. Be prepared to ready the patient for surgery.
- u Give pain medication as ordered, and record its effectiveness.
- u Assist with thoracentesis.
- u Observe chest tube drainage carefully. Record the volume, color, and character of drainage at least hourly. Immediately report a chest tube that is warm and full of blood and a rapidly rising bloody fluid level in the drainage collection chamber. The patient may need emergency surgery.
- u Follow your facility's policy for milking the chest tube. If you can see bloody drainage or clots, milking may be permitted to keep the tube patent.
- u Keep petroleum gauze at the bedside in case the chest tube dislodges. If it does, place the gauze over the chest tube site, taking care not to cover the wound so tightly that tension pneumothorax results.
- u Don't clamp the chest tube; this may create tension pneumothorax.
- u Change the chest tube dressing as necessary and according to facility policy. Watch for signs of infection at the insertion site.
- u Avoid all tubing kinks, tape all chest tube connections, and tape the tube securely to the patient's chest.

Patient teaching

- u Explain all procedures to the patient and family members to allay their fears. Encourage the patient to ask questions about his care. Answer all questions as honestly as you can.
- u If appropriate, provide preoperative and postoperative teaching. Explain and prepare the patient and family members for mechanical ventilation if necessary.
- u Encourage the patient to perform deep-breathing exercises every hour whenever he's awake to promote gas exchange.
- u Instruct the patient not to cough during thoracentesis.
- u Discuss the rationale for chest tube therapy with the patient and family members.
- u Instruct the patient to breathe deeply every hour when awake.

PLEURAL EFFUSION AND EMPYEMA

Normally, the pleural space contains a small amount of extracellular fluid that lubricates the pleural surfaces, but if fluid builds up from either increased production or inadequate removal, pleural effusion results. An accumulation of pus and necrotic tissue in the pleural space results in empyema, a type of pleural effusion. Blood (hemothorax) and chyle (chylothorax) may also collect in this space.

The incidence of pleural effusion increases with heart failure (the most common cause), parapneumonia, cancer, and pulmonary embolism.

Causes and pathophysiology

A transudative pleural effusion—an ultrafiltrate of plasma containing a low concentration of protein—may result from heart failure, hepatic disease with ascites, peritoneal dialysis, hypoalbuminemia, and disorders that increase intravascular volume.

The effusion stems from an imbalance of osmotic and hydrostatic pressures. Normally, the balance of these pressures in parietal pleural capillaries causes fluid to move into the pleural space; balanced pressure in visceral pleural capillaries promotes reabsorption of this fluid. But when excessive hydrostatic pressure or decreased osmotic pressure causes excessive fluid to pass across intact capillaries, a transudative pleural effusion results.

Exudative pleural effusions can result from tuberculosis, subphrenic abscess, pancreatitis, bacterial or fungal pneumonitis or empyema, cancer, parapneumonia, pulmonary embolism (with or without infarction), collagen disease (lupus erythematosus and rheumatoid arthritis), myxedema, intra-abdominal abscess, esophageal perforation, and chest trauma.

Such an effusion occurs when capillary permeability increases, with or without changes in hydrostatic and colloid osmotic pressures, allowing protein-rich fluid to leak into the pleural space.

Empyema usually stems from an infection in the pleural space. The infection may be idiopathic or may be related to pneumonitis, carcinoma, perforation, penetrating chest trauma, or esophageal rupture.

Complications

Large pleural effusions may result in atelectasis, infection, and hypoxemia.

Assessment findings

The patient's history characteristically shows underlying pulmonary disease. If he has a large amount of effusion, he typically complains of dyspnea. If he has pleurisy, he may report pleuritic chest pain. If he has empyema, he may also complain of a general feeling of malaise.

Inspection may indicate that the trachea has deviated away from the affected side. With empyema, the patient may also have a fever.

On palpation, you may note decreased tactile fremitus with a large amount of effusion. Percussion may disclose dullness over the effused area that doesn't change with respiration.

When you auscultate the chest, you may hear diminished or absent breath sounds over the effusion and a pleural friction rub during both inspiration and expiration. (This pleural friction rub is transitory, however, and disappears as fluid accumulates in the pleural space.) You also hear bronchial breath sounds, sometimes with the patient's pronunciation of the letter “e” sounding like the letter “a.”

Diagnostic tests

Chest X-rays show radiopaque fluid independent regions (usually with fluid accumulation of more than 250 ml).

Thoracentesis allows analysis of aspirated fluid and may show the following:

- Transudative effusion usually has a specific gravity less than 1.015 and contains less than 3 g/dl of protein.
- Exudative effusion has a ratio of protein in the fluid to serum of greater than or equal to 0.5, pleural fluid lactate dehydrogenase (LD) of greater than or equal to 200 IU, and a ratio of LD in pleural fluid to LD in serum of greater than or equal to 0.6.
- Aspirated fluid in empyema contains acute inflammatory white blood cells and microorganisms and shows leukocytosis.
- Fluid in empyema and rheumatoid arthritis, which can be the cause of an exudative pleural effusion, shows an extremely decreased pleural fluid glucose level.
- Pleural effusion that results from esophageal rupture or pancreatitis usually has fluid amylase levels higher than serum levels.

Aspirated fluid may also be tested for lupus erythematosus cells, antinuclear antibodies, and neoplastic cells. It may also be analyzed for color and consistency; acid-fast bacillus, fungal, and bacterial cultures; and triglycerides (in chylothorax).

Other diagnostic tests may also be ordered. A negative tuberculin skin test helps to rule out tuberculosis as a cause. If thoracentesis doesn't provide a definitive diagnosis in exudative pleural effusion, a pleural biopsy can help confirm tuberculosis or cancer.

Treatment

Depending on the amount of fluid present, symptomatic effusion may require thoracentesis to remove fluid or careful monitoring of the patient's own reabsorption of the fluid. Chemical pleurodesis—the instillation of a sclerosing agent, such as tetracycline, bleomycin, or nitrogen mustard through the chest tube to create adhesions between the two pleurae—may prevent recurrent effusions.

The patient with empyema needs one or more chest tubes inserted after thoracentesis. These tubes allow purulent material to drain. The patient may also need decortication (surgical removal of the thick coating over the lung) or rib resection to allow open drainage and lung expansion. He also requires parenteral antibiotics and, if he has hypoxia, oxygen administration.

Hemothorax requires drainage to prevent fibrothorax formation.

Nursing diagnoses

- Anxiety
- Impaired gas exchange
- Ineffective breathing pattern
- Knowledge deficit
- Risk for infection

Key outcomes

- The patient will maintain adequate ventilation.
- The patient's airway will remain patent.
- The patient will remain free from signs and symptoms of infection.
- The patient will express an understanding of the illness.
- The patient will consume a specific number of calories daily.
- The patient will use support systems and develop adequate coping mechanisms.

Nursing interventions

- During thoracentesis, remind the patient to breathe normally and avoid sudden movements, such as coughing or sighing. Monitor his vital signs, and watch for syncope. Also be alert for bradycardia, hypotension, pain, pulmonary edema, and cardiac arrest, which indicate that fluid is being removed too quickly. Reassure the patient throughout the procedure.
- After thoracentesis, watch for respiratory distress and signs of pneumothorax (sudden onset of dyspnea and cyanosis).
- Allow enough time between premedications and the procedure. Postoperative sedatives and analgesics aren't nearly as effective.
- Administer oxygen and, in empyema, antibiotics as ordered. Record the patient's response to these care measures.
- Use an incentive spirometer to promote deep breathing, and encourage the patient to perform deep-breathing exercises to promote lung expansion.
- Provide meticulous chest tube care, and use aseptic technique for changing dressings around the tube insertion site in the patient with empyema. Ensure tube patency by watching for bubbles in the underwater-seal chamber. Record the amount, color, and consistency of any tube drainage.
- Follow your facility's policy for milking the tube. Keep petroleum gauze at the bedside in case of chest tube dislodgment.
- Don't clamp the chest tube; this may cause tension pneumothorax.
- If the patient has open drainage through a rib resection or intercostal tube, use precautions. The patient usually needs weeks of such drainage to obliterate the space, so make home health nurse referrals if he's to be discharged with the tube in place.
- Throughout therapy, listen to the patient's fears and concerns and remain with him during periods of extreme stress and anxiety. Encourage him to identify care measures and actions that make him comfortable and relaxed. Perform these measures, and encourage the patient to do so as well.

Patient teaching

- Explain all tests and procedures to the patient, including thoracentesis, and answer any questions he has.
- Before thoracentesis, tell the patient to expect a stinging sensation from the local anesthetic and a feeling of pressure when the needle is inserted. Instruct him to tell you immediately if he feels uncomfortable or has trouble breathing during the procedure.
- If the patient developed pleural effusion because of pneumonia or influenza, tell him to seek medical attention promptly whenever he gets a chest cold.
- Teach the patient the signs and symptoms of respiratory distress. If any of these develop, tell him to notify his doctor.
- Fully explain the medication regimen, including adverse effects. Emphasize the importance of completing the prescribed drug regimen.
- If the patient smokes, urge him to stop.

PLEURISY

Also called pleuritis, pleurisy is an inflammation of the visceral and parietal pleurae that line the inside of the thoracic cage and envelop the lungs. The disorder causes the pleurae to become swollen and congested, hampering pleural fluid transport and increasing friction between the pleural surfaces.

Causes

Pleurisy can result from pneumonia, tuberculosis, viruses, systemic lupus erythematosus, rheumatoid arthritis, uremia, Dressler's syndrome, cancer, pulmonary

infarction, and chest trauma.

Complications

Extensively inflamed pleural membranes may result in permanent adhesions that can restrict lung expansion. The inflammation can also stimulate excessive production and hinder reabsorption of pleural fluid, leading to pleural effusion.

Assessment findings

The patient may report a sudden, sharp, stabbing pain that worsens on inspiration, the result of inflammation or irritation of sensory nerve endings in the parietal pleura that rub against one another during respiration. The patient may experience pain that is so severe it limits his movement on the affected side during breathing. He may also have dyspnea. Other symptoms vary depending on the underlying pathological process.

When you auscultate the chest, you may hear a characteristic pleural friction rub—a coarse, creaky sound heard during late inspiration and early expiration—directly over the area of pleural inflammation. Palpation over the affected area may reveal coarse vibration.

Diagnostic tests

Although diagnosis generally rests on the patient's history and your respiratory assessment, diagnostic tests help rule out other causes and pinpoint the underlying disorder. Electrocardiography rules out coronary artery disease as the source of the patient's pain, and chest X-rays can identify pneumonia.

Treatment

Symptomatic treatment includes anti-inflammatory agents, analgesics, and bed rest. Severe pain may require an intercostal nerve block of two or three intercostal nerves. Pleurisy with pleural effusion calls for thoracentesis as both a diagnostic and a therapeutic measure.

Nursing diagnoses

- Activity intolerance
- Anxiety
- Impaired gas exchange
- Ineffective airway clearance
- Ineffective breathing pattern
- Pain

Key outcomes

- The patient will maintain adequate ventilation.
- The patient will maintain a patent airway.
- The patient will express feelings of comfort and relief of pain.
- The patient will demonstrate skill in conserving energy while carrying out activities of daily living to tolerance level.
- The patient will use support systems to assist with coping.

Nursing interventions

- Assess the patient for pain every 3 hours, and administer antitussives and pain medication. Make sure you don't overmedicate. Pain relief allows for maximum chest expansion.
- Encourage the patient to take deep breaths and to cough. To minimize pain, apply firm pressure at the site of the pain while the patient coughs.
- Encourage the use of incentive spirometry every hour and instruct the patient on proper use.
- Position the patient in high Fowler's position to help lung expansion. Lying him on the affected side may aid in splinting.
- Assess the patient's respiratory status at least every 4 hours to detect early signs of compromise. Monitor for such complications as fever, increased dyspnea, and changes in breath sounds.
- Plan your care to allow the patient as much uninterrupted rest as possible.
- Pain can impair the patient's mobility, so help him perform active and passive range-of-motion exercises to prevent contractures and promote muscle strength.
- If the patient needs thoracentesis, remind him to breathe normally and avoid sudden movements, such as coughing or sighing, during the procedure. Monitor his vital signs, and watch for syncope. Also watch for indications that fluid is being removed too quickly: bradycardia, hypotension, pain, pulmonary edema, and cardiac arrest. Reassure the patient throughout the procedure.

ALERT After thoracentesis, watch for respiratory distress and signs of pneumothorax (sudden onset of dyspnea and cyanosis).

- Throughout therapy, listen to the patient's fears and concerns, and answer any questions he has. Remain with him during periods of extreme stress and anxiety. Encourage him to identify actions and care measures that help make him comfortable and relaxed. Perform these measures, and encourage the patient to do so as well.
- Whenever possible, include the patient in care decisions, and include family members in all phases of the patient's care.

Patient teaching

- Explain all procedures to the patient and family members.
- If the patient requires thoracentesis, explain the procedure. Tell him to expect a stinging sensation from the local anesthetic and a feeling of pressure as the needle is inserted. Instruct him to tell you immediately if he feels uncomfortable or has trouble breathing during the procedure.
- If the patient about to be discharged receives a prescription for a narcotic analgesic for pain, warn him about the dangers of overuse. Explain that the drug depresses coughing and respiration and decreases alertness. Teach him about the drug's other possible adverse effects, and tell him to call his doctor if such effects occur.
- Teach the patient how to splint and perform deep-breathing exercises.
- Emphasize the need for regular rest periods.
- Teach the patient the signs and symptoms of possible complications, such as increased shortness of breath, fever, increasing fatigue, or any change in the quality or quantity of secretions. Tell him to call his doctor if such signs or symptoms occur.
- Reassure the patient that the pain should subside after several days.

PNEUMONIA

Pneumonia is an acute infection of the lung parenchyma that often impairs gas exchange. Pneumonia can be classified in several ways. Based on microbiological etiology, it may be viral, bacterial, fungal, protozoal, mycobacterial, mycoplasmal, or rickettsial in origin.

Based on location, pneumonia may be classified as bronchopneumonia, lobular pneumonia, or lobar pneumonia. Bronchopneumonia involves distal airways and alveoli; lobular pneumonia, part of a lobe; and lobar pneumonia, an entire lobe.

The infection is also classified as one of three types—primary, secondary, or aspiration pneumonia. Primary pneumonia results directly from inhalation or aspiration of a pathogen, such as bacteria or a virus; it includes pneumococcal and viral pneumonia. Secondary pneumonia may follow initial lung damage from a noxious chemical or other insult (superinfection) or may result from hematogenous spread of bacteria from a distant area. Aspiration pneumonia results from inhalation of foreign matter, such as vomitus or food particles, into the bronchi. It's more likely to occur in elderly or debilitated patients, those receiving nasogastric tube feedings, and those with an impaired gag reflex, poor oral hygiene, or a decreased level of consciousness.

Pneumonia occurs in both sexes and at all ages. More than 3 million cases of pneumonia occur annually in the United States. The infection carries a good prognosis for patients with normal lungs and adequate immune systems. In debilitated patients, however, bacterial pneumonia ranks as the leading cause of death. Pneumonia

is also the leading cause of death from infectious disease in the United States.

Causes and pathophysiology

In bacterial pneumonia, which can occur in any part of the lungs, an infection initially triggers alveolar inflammation and edema. Capillaries become engorged with blood, causing stasis. As the alveolocapillary membrane breaks down, alveoli fill with blood and exudate, resulting in atelectasis. In severe bacterial infections, the lungs assume a heavy, liverlike appearance, as in adult respiratory distress syndrome (ARDS).

Viral infection, which typically causes diffuse pneumonia, first attacks bronchiolar epithelial cells, causing interstitial inflammation and desquamation. It then spreads to the alveoli, which fill with blood and fluid. In advanced infection, a hyaline membrane may form. As with bacterial infection, severe viral infection may clinically resemble ARDS.

In aspiration pneumonia, aspiration of gastric juices or hydrocarbons triggers similar inflammatory changes and also inactivates surfactant over a large area. Decreased surfactant leads to alveolar collapse. Acidic gastric juices may directly damage the airways and alveoli. Particles with the aspirated gastric juices may obstruct the airways and reduce airflow, which, in turn, leads to secondary bacterial pneumonia.

Certain predisposing factors increase the risk of pneumonia. For bacterial and viral pneumonia, these include chronic illness and debilitation, cancer (particularly lung cancer), abdominal and thoracic surgery, atelectasis, common colds or other viral respiratory infections, chronic respiratory disease (chronic obstructive pulmonary disease, asthma, bronchiectasis, cystic fibrosis), influenza, smoking, malnutrition, alcoholism, sickle cell disease, tracheostomy, exposure to noxious gases, aspiration, and immunosuppressive therapy. (See [Causes of pneumonia.](#))

Complications

Without proper treatment, pneumonia can lead to such life-threatening complications as septic shock, hypoxemia, and respiratory failure. The infection can also spread within the patient's lungs, causing empyema or lung abscess. (see [Lung abscess.](#)). It also may spread by way of the bloodstream or by cross-contamination to other parts of the body, causing bacteremia, endocarditis, pericarditis, or meningitis.

Assessment findings

In bacterial pneumonia, the patient may report pleuritic chest pain, a cough, excessive sputum production, and chills.

Causes of pneumonia		
CHARACTERISTICS	DIAGNOSTIC TESTS	TREATMENT
Viral pneumonias		
Influenza		
⌵ Prognosis poor even with treatment ⌵ 50% mortality from cardiopulmonary collapse ⌵ Signs and symptoms: cough (initially nonproductive; later, purulent sputum), marked cyanosis, dyspnea, high fever, chills, substernal pain and discomfort, moist crackles, frontal headache, myalgia	⌵ Chest X-ray: diffuse bilateral bronchopneumonia radiating from hilus ⌵ White blood cell (WBC) count: normal to slightly elevated ⌵ Sputum smears: no specific organisms	⌵ Supportive treatment for respiratory failure includes endotracheal intubation and ventilator assistance; for fever, hypothermia blanket or antipyretics; for influenza A, amantadine
Adenovirus		
⌵ Insidious onset ⌵ Generally affects young adults ⌵ Good prognosis; usually clears without residual effects ⌵ Signs and symptoms: sore throat, fever, cough, chills, malaise, small amounts of mucoid sputum, retrosternal chest pain, anorexia, rhinitis, adenopathy scattered crackles, rhonchi	⌵ Chest X-ray: patchy distribution of pneumonia, more severe than indicated by physical examination ⌵ WBC count: normal to slightly elevated	⌵ Treatment goal is to relieve symptoms.
Respiratory syncytial virus		
⌵ Most prevalent in infants and children ⌵ Complete recovery in 1 to 3 weeks ⌵ Signs and symptoms: listlessness, irritability, tachypnea with retraction of intercostal muscles, slight sputum production, fine moist crackles, fever, severe malaise, possibly cough or croup	⌵ Chest X-ray: patchy bilateral consolidation ⌵ WBC count: normal to slightly elevated	⌵ Supportive treatment includes modified air, oxygen, and antimicrobials (often given until viral cause is confirmed).
Measles (rubeola)		
⌵ Signs and symptoms: fever, dyspnea, cough, small amounts of sputum, coryza, rash, cervical adenopathy	⌵ Chest X-ray: reticular infiltrates, sometimes with hilar lymph node enlargement ⌵ Lung tissue specimen: characteristic giant cells	⌵ Supportive treatment includes bed rest, adequate hydration, antimicrobials and, if necessary, assisted ventilation.
Chickenpox (varicella)		
⌵ Uncommon in children but present in 30% of adults with varicella ⌵ Signs and symptoms: characteristic rash, cough, dyspnea, cyanosis, tachypnea, pleuritic chest pain, hemoptysis and rhonchi 1 to 6 days after onset of rash	⌵ Chest X-ray: more extensive pneumonia than indicated by examination; bilateral, patchy, diffuse, nodular infiltrates ⌵ Sputum analysis: predominant mononuclear cells and characteristic intranuclear inclusion bodies	⌵ Supportive treatment includes adequate hydration and, in critically ill patients, oxygen therapy.
Cytomegalovirus		
⌵ Difficult to distinguish from other nonbacterial pneumonias. In adults with healthy lung tissue, resembles mononucleosis	⌵ Chest X-ray: in early stages, variable patchy infiltrates; later, bilateral, nodular, and more	⌵ Supportive treatment includes adequate hydration and nutrition, oxygen therapy, and bed rest.

<ul style="list-style-type: none"> Difficult to distinguish from other nonbacterial pneumonias. In adults with healthy lung tissue, resembles mononucleosis and is generally benign; in neonates, occurs as devastating multisystemic infection; in immunocompromised hosts, varies from clinically inapparent to fatal infection Signs and symptoms: fever, cough, shaking chills, dyspnea, cyanosis, weakness, diffuse crackles 	<ul style="list-style-type: none"> Chest X-ray: in early stages, variable patchy infiltrates; later, bilateral, nodular, and more predominant in lower lobes Percutaneous aspiration of lung tissue, transbronchial biopsy or open lung biopsy: typical intranuclear and cytoplasmic inclusions on microscopic examination (the virus can be cultured from lung tissue) 	<ul style="list-style-type: none"> Supportive treatment includes adequate hydration and nutrition, oxygen therapy, and bed rest.
---	---	---

CHARACTERISTICS	DIAGNOSTIC TESTS	TREATMENT
-----------------	------------------	-----------

Protozoan pneumonia

Pneumocystis carinii

<ul style="list-style-type: none"> Occurs in immunocompromised patients Symptoms: dyspnea, nonproductive cough, anorexia, weight loss, fatigue, low-grade fever 	<ul style="list-style-type: none"> Fiber optic bronchoscopy: obtains specimen for histology studies Chest X-ray: for specific infiltrations, nodular lesions, or spontaneous pneumothorax 	<ul style="list-style-type: none"> Antimicrobial therapy consists of co-trimoxazole (Bactrim, Septra) or pentamidine by I.V. or inhalation Supportive treatment includes oxygen, improved nutrition, and mechanical ventilation
---	---	---

Bacterial pneumonias

Streptococcus

<ul style="list-style-type: none"> Caused by <i>Streptococcus pneumoniae</i> Signs and symptoms: sudden onset of a single, shaking chill and sustained temperature of 102° to 104° F (38.9° to 40° C); often preceded by upper respiratory tract infection 	<ul style="list-style-type: none"> Chest X-ray: areas of consolidation, often lobar WBC count: elevated Sputum culture: possibly gram-positive <i>S. pneumoniae</i> 	<ul style="list-style-type: none"> Antimicrobial therapy consists of penicillin G or, if the patient is allergic to penicillin, erythromycin; therapy begun after obtaining culture specimen but without waiting for results and continues for 7 to 10 days.
--	--	---

Klebsiella

<ul style="list-style-type: none"> More likely in patients with chronic alcoholism, pulmonary disease, and diabetes Signs and symptoms: fever and recurrent chills; cough producing rusty, bloody, viscous sputum (currant jelly); cyanosis of lips and nail beds from hypoxemia; shallow, grunting respirations 	<ul style="list-style-type: none"> Chest X-ray: typically, but not always, consolidation in the upper lobe that causes bulging of fissures WBC count: elevated Sputum culture and Gram stain: possibly gram-negative cocci <i>Klebsiella</i> 	<ul style="list-style-type: none"> Antimicrobial therapy consists of an aminoglycoside and, in serious infections, a cephalosporin.
--	---	--

Staphylococcus

<ul style="list-style-type: none"> Commonly occurs in patients with viral illness, such as influenza or measles, and in those with cystic fibrosis Signs and symptoms: temperature of 102° to 104° F, recurrent shaking chills, bloody sputum, dyspnea, tachypnea, hypoxemia 	<ul style="list-style-type: none"> Chest X-ray: multiple abscesses and infiltrates; frequently empyema WBC count: elevated Sputum culture and Gram stain: possibly gram-positive staphylococci 	<ul style="list-style-type: none"> Antimicrobial therapy consists of nafcillin or oxacillin for 14 days if staphylococci are penicillinase-producing. A chest tube drains empyema.
--	---	--

Aspiration pneumonia

<ul style="list-style-type: none"> Results from vomiting and aspiration of gastric or oropharyngeal contents into trachea and lungs or from ineffective swallowing muscles Noncardiogenic pulmonary edema possible with damage to respiratory epithelium from contact with gastric acid Subacute pneumonia possible with cavity formation Lung abscess possible if foreign body present Signs and symptoms: crackles, dyspnea, cyanosis, hypotension, tachycardia 	<ul style="list-style-type: none"> Chest X-ray: location of areas of infiltrates (suggests diagnosis) 	<ul style="list-style-type: none"> Antimicrobial therapy consists of penicillin G or clindamycin. Supportive therapy includes oxygen therapy, suctioning, coughing, deep breathing, adequate hydration, and I.V. corticosteroids.
--	--	---

On assessment, you may note that the patient has a fever. During inspection, you may observe that the patient is shaking and coughs up sputum. Creamy yellow sputum suggests staphylococcal pneumonia; green sputum denotes pneumonia caused by *Pseudomonas* organisms; and sputum that looks like currant jelly indicates pneumonia caused by *Klebsiella*. (Clear sputum means that the patient doesn't have an infective process.)

In advanced cases of all types of pneumonia, you hear dullness when you percuss. Auscultation may disclose crackles, wheezing, or rhonchi over the affected lung area as well as decreased breath sounds and decreased vocal fremitus.

Diagnostic tests

Chest X-rays disclose infiltrates, confirming the diagnosis.

Sputum specimen for Gram stain and culture and sensitivity tests shows acute inflammatory cells.

White blood cell count indicates leukocytosis in bacterial pneumonia and a normal or low count in viral or mycoplasmal pneumonia. Blood cultures reflect bacteremia and help to determine the causative organism.

Arterial blood gas (ABG) levels vary depending on the severity of pneumonia and the underlying lung state. Bronchoscopy or transtracheal aspiration allows the collection of material for culture. Pleural fluid culture may also be obtained.

Pulse oximetry may show a reduced level of arterial oxygen saturation.

Treatment

The patient needs antimicrobial therapy based on the causative agent. Therapy should be reevaluated early in the course of treatment.

Supportive measures include humidified oxygen therapy for hypoxia, bronchodilator therapy, antitussives, mechanical ventilation for respiratory failure, a high-calorie diet and adequate fluid intake, bed rest, and an analgesic to relieve pleuritic chest pain. A patient with severe pneumonia on mechanical ventilation may need positive end-expiratory pressure to maintain adequate oxygenation.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Impaired gas exchange
- u Ineffective airway clearance
- u Pain
- u Risk for fluid volume deficit
- u Risk for infection

Lung abscess

Lung abscess is a localized bacterial infection that causes purulence and tissue destruction. Bacteria may spread and cause multiple abscesses throughout the lungs.

Lung abscess may be secondary to localized pneumonia or necrosis from a neoplasm that can't drain. Other causes include necrotizing infections or cysts, cavitary infarctions or cancers, and necrotic lesions from pneumoconiosis.

The patient history includes coughing, sometimes with bloody or purulent sputum, and pleuritic chest pain and dyspnea. Headache, anorexia, malaise, diaphoresis, chills, fever, and clubbing of the fingers may occur. You may detect dullness over affected lung tissue, crackles, and decreased and cavernous breath sounds.

Chest X-rays show a solid mass or localized infiltrate with clear spaces that contain air and fluid. Causative organisms are identified through blood and sputum cultures and gram staining. White blood cell count is elevated. Computed tomography scan helps to differentiate the type of lesion. Bronchoscopy may be necessary later to collect specimens and identify obstruction.

Treatment includes extensive antibiotic therapy and, possibly, postural drainage and oxygen therapy. Massive hemoptysis, cancer, or bronchiectasis may necessitate lesion or lobe resection. All patients require rigorous follow-up and serial chest X-rays.

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain adequate fluid balance.
- u The patient will express feelings of comfort and relief of pain.
- u The patient will consume a specific number of calories daily.
- u The patient will use support systems to assist with coping.

Nursing interventions

- u Maintain a patent airway and adequate oxygenation. Measure the patient's ABG levels, especially if he's hypoxic. Administer supplemental oxygen if his partial pressure of arterial oxygen falls below 55 to 60 mm Hg. If he has an underlying chronic lung disease, give oxygen cautiously.
- u In severe pneumonia that requires endotracheal intubation or a tracheostomy with or without mechanical ventilation, provide thorough respiratory care and suction often using sterile technique to remove secretions.

PREVENTION

Preventing pneumonia

Teach patients the following ways to prevent pneumonia:

- u Urge all bedridden and postoperative patients to perform deep-breathing and coughing exercises frequently. Position such patients properly to promote full aeration and drainage of secretions.
- u Advise patients to avoid using antibiotics indiscriminately for minor infections. Doing so could result in upper airway colonization with antibiotic-resistant bacteria. If pneumonia develops, the organisms that produce the pneumonia may require treatment with more toxic antibiotics.
- u Encourage the high-risk patient to ask his doctor about an annual influenza vaccination and the pneumococcal pneumonia vaccination, which the patient would receive only once.
- u Discuss ways to avoid spreading the infection to others. Remind the patient to sneeze and cough into tissues and to dispose of the tissues in a waxed or plastic bag. Advise him to wash his hands thoroughly after handling contaminated tissues.

- u Obtain sputum specimens as needed. Use suction if the patient can't produce a specimen. Collect the specimens in a sterile container and deliver them promptly to the microbiology laboratory.
- u Administer antibiotics as ordered and pain medication as needed. Administer I.V. fluids and electrolyte replacement, if needed, for fever and dehydration.
- u Provide a high-calorie, high-protein diet of soft foods to offset the calories the patient uses to fight the infection. If necessary, supplement oral feedings with nasogastric tube feedings or parenteral nutrition.
- u To prevent aspiration during nasogastric tube feedings, elevate the patient's head, check the tube position, and administer the feeding slowly. Don't give large volumes at one time because this can cause vomiting.
- u If the patient has an endotracheal tube, inflate the tube cuff before feeding. Keep his head elevated for at least 30 minutes after feeding.
- u Monitor the patient's fluid intake and output.
- u To control the spread of infection, dispose of secretions properly. Tell the patient to sneeze and cough into a disposable tissue, and tape a waxed bag to the side of the bed for used tissues. (See [Preventing pneumonia.](#))
- u Provide a quiet, calm environment, with frequent rest periods. Make sure the patient has diversionary activities appropriate to his age.
- u Listen to the patient's fears and concerns, and remain with him during periods of severe stress and anxiety. Encourage him to identify actions and care measures that promote comfort and relaxation.
- u When possible, include patient in care decisions.
- u Include family members in all phases of the patient's care, and encourage them to visit.

Patient teaching

- u Explain all procedures (especially intubation and suctioning) to the patient and family members.
- u Emphasize the importance of adequate rest to promote full recovery and prevent a relapse. Explain that the doctor will advise the patient when he can resume full

- activity and return to work.
- u Review the patient's medication. Stress the need to take the entire course of medication, even if he feels better, to prevent a relapse.
 - u Teach the patient procedures to clear lung secretions, such as deep-breathing and coughing exercises as well as home oxygen therapy. Explain deep breathing and pursed-lip breathing.
 - u Urge the patient to drink 2 to 3 L (2.1 to 3.2 qt) of fluid a day to maintain adequate hydration and keep mucus secretions thin for easier removal.
 - u Teach the patient and family members about chest physiotherapy. Explain that postural drainage, percussion, and vibration help to mobilize and remove mucus from the lungs.
 - u Urge the patient to avoid irritants that stimulate secretions, such as cigarette smoke, dust, and significant environmental pollution. If necessary, refer him to community programs or agencies that can help him stop smoking.

PNEUMOTHORAX

Pneumothorax is characterized by an accumulation of air or gas between the parietal and visceral pleurae. The amount of air or gas trapped in the intrapleural space determines the degree of lung collapse. The most common types of pneumothorax are open, closed, and tension. Many factors contribute to pneumothorax.

Causes

The following conditions and procedures can trigger pressure changes that cause open, closed, or tension pneumothorax.

Open pneumothorax

- u Penetrating chest injury, such as a gunshot or knife wound
- u Insertion of a central venous catheter
- u Chest surgery
- u Transbronchial biopsy
- u Thoracentesis or closed pleural biopsy

Closed pneumothorax

- u Blunt chest trauma
- u Air leakage from ruptured, congenital blebs adjacent to the visceral pleural space
- u Rupture of emphysematous bullae
- u Rupture resulting from barotrauma caused by high intrathoracic pressures during mechanical ventilation
- u Tubercular or cancerous lesions that erode into the pleural space
- u Interstitial lung disease such as eosinophilic granuloma

Tension pneumothorax

- u Penetrating chest wound treated with an airtight dressing
- u Lung or airway puncture by a fractured rib associated with positive-pressure ventilation
- u Mechanical ventilation (after chest injury) that forces air into the pleural space through damaged areas
- u High-level positive end-expiratory pressure that causes alveolar blebs to rupture
- u Chest tube occlusion or malfunction

Complications

Extensive pneumothorax and tension pneumothorax can lead to fatal pulmonary and circulatory impairment.

Assessment findings

The patient history reveals sudden, sharp, pleuritic pain. The patient may report that chest movement, breathing, and coughing exacerbate the pain. He may also report shortness of breath.

Inspection typically reveals asymmetrical chest wall movement with overexpansion and rigidity on the affected side. The patient may appear cyanotic. In tension pneumothorax, he may have distended neck veins and pallor, and he may exhibit anxiety. (Test results may confirm increased central venous pressure.)

Palpation may reveal crackling beneath the skin, indicating subcutaneous emphysema (air in tissues) and decreased vocal fremitus. In tension pneumothorax, palpation may disclose tracheal deviation away from the affected side and a weak and rapid pulse. Percussion may demonstrate hyperresonance on the affected side, and auscultation may disclose decreased or absent breath sounds over the collapsed lung. The patient may be hypotensive with tension pneumothorax. Spontaneous pneumothorax that releases only a small amount of air into the pleural space may not cause any signs or symptoms.

Diagnostic tests

Chest X-rays reveal air in the pleural space and, possibly, a mediastinal shift, which confirms the diagnosis.

Pulse oximetry results may show early decline. Arterial blood gas studies may show hypoxemia, possibly accompanied by respiratory acidosis and hypercapnea. Levels of arterial oxygen saturation may decrease initially but typically return to normal within 24 hours.

Treatment

Typically, treatment is conservative for spontaneous pneumothorax with no signs of increased pleural pressure (indicating tension pneumothorax), with lung collapse less than 30%, and with no dyspnea or other indications of physiologic compromise. Such treatment consists of bed rest, careful monitoring (blood pressure and pulse and respiratory rates), oxygen administration and, possibly, aspiration of air with a large-bore needle attached to a syringe or insertion of a Heimlich valve.

If more than 30% of the lung collapses, treatment to reexpand the lung includes placing a thoracostomy tube in the second or third intercostal space in the midclavicular line. The thoracostomy tube then connects to an underwater seal or to low-pressure suction.

Recurring spontaneous pneumothorax requires thoracotomy and pleurectomy. These procedures prevent recurrence by causing the lung to adhere to the parietal pleura. Traumatic and tension pneumothorax require chest tube drainage; traumatic pneumothorax may also require surgical repair. Analgesics may be prescribed.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fear u Impaired gas exchange u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will express feelings of comfort and a decrease in pain.
- u The patient will remain free from signs and symptoms of infection.

- u The patient will use support systems to assist with coping.
- u The patient will express an understanding of the illness.

Nursing interventions

- u Listen to the patient's fears and concerns. Offer reassurance as appropriate. Remain with the patient during periods of extreme stress and anxiety. Encourage him to identify actions and care measures that promote comfort and relaxation, and be sure to perform these measures and encourage the patient and family members to do so as well. Include the patient and family members in care-related decisions whenever possible.
- u Keep the patient as comfortable as possible, and administer analgesics as necessary. The patient with pneumothorax usually feels most comfortable sitting upright.
- u Watch for complications signaled by pallor, gasping respirations, and sudden chest pain. Carefully monitor vital signs at least every hour for indications of shock, increasing respiratory distress, or mediastinal shift. Listen for breath sounds over both lungs.
- u Be sure the suction set-up is functioning appropriately when the patient has a chest tube inserted. Watch for signs of tension pneumothorax. These include decreasing blood pressure and increasing pulse and respiratory rates, which could be fatal without prompt treatment. If the patient doesn't have a chest tube to suction (also called water seal drainage), monitor for recurrence of pneumothorax and recollapse of the lung. If this occurs, a portable chest X-ray should be obtained immediately and the chest tube reconnected to suction.

For chest tube insertion:

- u To facilitate chest tube insertion, place the patient in high Fowler's position, semi-Fowler's position, supine, or have him lie on his unaffected side with his arms overhead. During chest tube insertion, urge him to control the urge to cough and gasp. However, after the chest tube is placed, encourage him to cough and breathe deeply (at least once an hour) to facilitate lung expansion.
- u Change the dressings around the chest tube insertion site at least every 24 hours. Keep the insertion site clean, and watch for signs of infection. Be careful not to reposition or dislodge the tube. If the tube dislodges, immediately place a petroleum gauze dressing over the opening to prevent rapid lung collapse; however, use extreme caution. If the lung has a hole or tear (evidenced by bubbling in the water-seal chamber), tension pneumothorax may be created by a tight dressing placement.
- u Watch for continuing air leakage (bubbling). This indicates the lung defect's failure to heal, which may necessitate surgery. Also, watch for increasing subcutaneous emphysema by checking around the neck or at the tube's insertion site for crackling beneath the skin. For the patient receiving mechanical ventilation, watch for difficulty in breathing in time with the ventilator. Also watch for pressure changes on the ventilator gauges.

For thoracotomy:

- u Urge the patient to control coughing and gasping during the procedure.
- u Monitor vital signs frequently after thoracotomy. Also, for the first 24 hours, assess respiratory status by checking breath sounds hourly. Observe the chest tube site for leakage, and note the amount and color of drainage. Walk the patient, as ordered (usually on the 1st postoperative day), to promote deep inspiration and lung expansion.

Patient teaching

- u Reassure the patient. Explain what pneumothorax is, what causes it, and all diagnostic tests and procedures.
- u If the patient is having surgery or chest tubes inserted, explain why he needs these procedures. Reassure him that the chest tubes are inserted to make him more comfortable.
- u Encourage the patient to perform deep-breathing exercises every hour when awake.
- u Discuss the potential for recurrent spontaneous pneumothorax, and review its signs and symptoms. Emphasize the need for immediate medical intervention if these should occur.

PULMONARY EDEMA

Pulmonary edema is a common complication of cardiac disorders. It's marked by an accumulation of fluid in extravascular spaces of the lung. The disorder may occur as a chronic condition, or it may develop quickly and rapidly become fatal.

Causes

Pulmonary edema usually results from left ventricular failure caused by arteriosclerotic, cardiomyopathic, hypertensive, or valvular heart disease. (See [Understanding pulmonary edema.](#))

Other factors that may predispose the patient to pulmonary edema include:

- u barbiturate or opiate poisoning
- u heart failure
- u infusion of excessive volumes of I.V. fluids or an overly rapid infusion
- u impaired pulmonary lymphatic drainage (from Hodgkin's disease or obliterative lymphangitis after radiation)
- u inhalation of irritating gases
- u mitral stenosis and left atrial myxoma (which impair left atrial emptying)
- u pneumonia
- u pulmonary veno-occlusive disease.

Complications

Acute pulmonary edema may progress to respiratory and metabolic acidosis with subsequent cardiac or respiratory arrest.

Assessment findings

The history may include a predisposing factor for pulmonary edema. The patient typically complains of a persistent cough. He may report getting a cold and being dyspneic on exertion. He may experience paroxysmal nocturnal dyspnea and orthopnea.

On inspection, you may note restlessness and anxiety. With severe pulmonary edema, the patient's breathing may be visibly labored and rapid. His cough may sound intense and produce frothy, bloody sputum. In advanced stages, the patient's level of consciousness decreases.

Typical palpation findings include neck vein distention. In acute pulmonary edema, the skin feels sweaty, cold, and clammy. Auscultation may reveal crepitant crackles and a diastolic (S₃) gallop. In severe pulmonary edema, you may hear wheezing as the alveoli and bronchioles fill with fluid. The crackles become more diffuse.

PATHOPHYSIOLOGY

Understanding pulmonary edema

Pulmonary edema results from either of two mechanisms: increased pulmonary capillary hydrostatic pressure or decreased colloid osmotic pressure. Normally, the two pressures are in balance. When this balance changes, pulmonary edema results.

If pulmonary capillary hydrostatic pressure increases, the compromised left ventricle requires increased filling pressures to maintain adequate output; these pressures are transmitted to the left atrium, pulmonary veins, and pulmonary capillary bed. This forces fluids and solutes from the intravascular compartment into the interstitium of the lungs. As the interstitium overloads with fluid, fluid floods the peripheral alveoli and impairs gas exchange.

If colloid osmotic pressure decreases, the natural pulling force that contains intravascular fluids is lost—nothing opposes the hydrostatic force. Thus, fluid flows freely into the interstitium and alveoli, resulting in pulmonary edema.

ASSESSMENT TIP If you detect inspiratory crackles, dry cough, or dyspnea, notify the doctor immediately. Chest X-ray results may not be available until 24 hours after you've assessed the patient. Don't wait for X-ray findings if you suspect pulmonary edema.

Additional findings include worsening tachycardia, decreasing blood pressure, thready pulse, and decreased cardiac output. In advanced pulmonary edema, breath sounds diminish.

Diagnostic tests

Clinical features of pulmonary edema permit a working diagnosis. Diagnostic tests provide the following information:

Arterial blood gas (ABG) analysis usually shows hypoxia with variable partial pressures of arterial carbon dioxide, depending on the patient's degree of fatigue. ABG results may also identify metabolic acidosis.

Chest X-rays show diffuse haziness of the lung fields and, usually, cardiomegaly and pleural effusion; pulse oximetry may reveal decreasing levels of arterial oxygen saturation.

Pulmonary artery catheterization is used to identify left ventricular failure (indicated by elevated pulmonary artery wedge pressures). These findings help to rule out adult respiratory distress syndrome, in which wedge pressure usually remains normal.

Electrocardiography may disclose evidence of previous or current myocardial infarction.

Treatment

The goals of treatment are to reduce extravascular fluid, improve gas exchange and myocardial function and, if possible, correct underlying disease. High concentrations of oxygen can be administered by cannula or mask. (Typically, the patient with pulmonary edema doesn't tolerate a mask.) If the patient's arterial oxygen levels remain too low, assisted ventilation can improve oxygen delivery to the tissues and usually improves his acid-base balance. A bronchodilator such as aminophylline may decrease bronchospasm and enhance myocardial contractility. Diuretics, such as furosemide, ethacrynic acid, and bumetanide, increase urination, which helps to mobilize extravascular fluid.

Treatment of myocardial dysfunction includes positive inotropic agents, such as a digitalis glycoside and amrinone, to enhance contractility. Pressor agents may be given to enhance contractility and to promote vasoconstriction in peripheral vessels.

Antiarrhythmics may also be given, particularly in arrhythmias related to decreased cardiac output. Occasionally, arterial vasodilators such as nitroprusside can decrease peripheral vascular resistance, preload, and afterload.

Morphine may reduce anxiety and dyspnea and dilate the systemic venous bed, promoting blood flow from pulmonary circulation to the periphery.

ALERT Using morphine sulfate in the patient with respiratory distress can also compromise respirations. Have resuscitation equipment available in case the patient stops breathing.

Other treatments include rotating tourniquets and phlebotomy (both reduce preload). Phlebotomy also removes hemoglobin, which can worsen the patient's hypoxemia.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fear u Fluid volume excess u Impaired gas exchange u Knowledge deficit

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain adequate fluid balance.
- u The patient will express an understanding of the condition.
- u The patient will maintain adequate cardiac output and circulation.
- u The patient will express decreased anxiety and fear.
- u The patient will develop adequate coping mechanisms.

Nursing interventions

- u Help the patient relax to promote oxygenation, control bronchospasm, and enhance myocardial contractility.
- u Reassure the patient, who is likely to be frightened by his inability to breathe normally. Provide emotional support to family members as well.
- u Place him in high Fowler's position to enhance lung expansion.
- u Administer oxygen as ordered.
- u Assess the patient's condition frequently, and document his responses to treatment. Monitor ABG and pulse oximetry values, oral and I.V. fluid intake, urine output and, in the patient with a pulmonary artery catheter, pulmonary end-diastolic and artery wedge pressures. Check the cardiac monitor often. Report changes immediately.
- u Watch for complications of treatment such as electrolyte depletion. Also watch for complications of oxygen therapy and mechanical ventilation.
- u Monitor vital signs every 15 to 30 minutes while administering nitroprusside in dextrose 5% in water by I.V. drip. During use, protect the solution from light by wrapping the bottle or bag with aluminum foil. Discard unused nitroprusside solution after 4 hours. Watch for arrhythmias in patients receiving digitalis and for marked respiratory depression in those receiving morphine.
- u Carefully record the time morphine is given and the amount administered.

Patient teaching

- u Urge the patient to comply with the prescribed medication regimen to avoid future episodes of pulmonary edema.
- u Explain all procedures to the patient and family members.
- u Emphasize reporting early signs of fluid overload.
- u Explain the reasons for sodium restrictions. List high-sodium foods and drugs.
- u Review all prescribed medications with the patient. If he takes digoxin, show him how to monitor his own pulse rate and warn him to report signs of toxicity.

Encourage consumption of potassium-rich foods to lower the risk of toxicity and cardiac arrhythmias. If he takes a vasodilator, teach him the signs of hypotension and emphasize the need to avoid alcohol.

- u Discuss ways to conserve physical energy.

PULMONARY EMBOLISM

Pulmonary embolism is an obstruction of the pulmonary arterial bed that occurs when a mass—such as a dislodged thrombus—lodges in a pulmonary artery branch, partially or completely obstructing it. This causes a ventilation-perfusion mismatch, resulting in hypoxemia, as well as intrapulmonary shunting.

The prognosis varies. Although the pulmonary infarction that results from embolism may be so mild that it's asymptomatic, massive embolism (more than 50% obstruction of pulmonary arterial circulation) and infarction can cause rapid death.

Causes

In most patients, pulmonary embolism results from a dislodged thrombus (blood clot) that originates in the leg veins. More than half of such thrombi arise in the deep veins of the legs; usually multiple thrombi arise. Other, less common sources of thrombi include the pelvic, renal, and hepatic veins, the right side of the heart, and the upper extremities. (See [Understanding thrombus formation.](#))

Rarely, pulmonary embolism results from other types of emboli, including bone, air, fat, amniotic fluid, tumor cells, or a foreign object, such as a needle, a catheter part, or talc (from drugs intended for oral administration that are injected I.V. by addicts).

The risk increases with long-term immobility, chronic pulmonary disease, heart failure or atrial fibrillation, thrombophlebitis, polycythemia vera, thrombocytosis, cardiac arrest, defibrillation, cardioversion, autoimmune hemolytic anemia, sickle cell disease, varicose veins, recent surgery, age over 40, osteomyelitis, pregnancy, lower-extremity fractures or surgery, burns, obesity, vascular injury, cancer, and oral contraceptive use. (See [Who's at risk for pulmonary embolism?.](#))

Complications

If the embolus totally obstructs the arterial blood supply, pulmonary infarction (lung tissue death) occurs, a complication that affects about 10% of pulmonary embolism patients. It's more likely to occur if the patient has chronic cardiac or pulmonary disease.

PATHOPHYSIOLOGY

Understanding thrombus formation

Thrombus formation results from vascular wall damage, venous stasis, or hypercoagulability of the blood. Trauma, clot dissolution, sudden muscle spasm, intravascular pressure changes, or a change in peripheral blood flow can cause the thrombus to loosen or fragmentize. Then, the thrombus—now called an embolus—floats to the heart's right side and enters the lung through the pulmonary artery. There, the embolus may dissolve, continue to fragmentize, or grow.

By occluding the pulmonary artery, the embolus prevents alveoli from producing enough surfactant to maintain alveolar integrity. As a result, alveoli collapse and atelectasis develops. If the embolus enlarges, it may clog most or all pulmonary vessels and cause death.

Other complications include emboli extension, which blocks further vessels; hepatic congestion and necrosis; pulmonary abscess; shock and adult respiratory distress syndrome; massive atelectasis; venous overload; ventilation-perfusion mismatch; and death from massive embolism.

Assessment findings

The patient's history may reveal a predisposing condition. He may also complain of shortness of breath for no apparent reason, as well as pleuritic or anginal pain. The severity of these symptoms depends on the extent of damage. The signs and symptoms produced by small or fragmented emboli depend on their size, number, and location. If the embolus totally occludes the main pulmonary artery, the patient has severe signs and symptoms.

When you begin your assessment, you may find tachycardia. The patient may also have a low-grade fever. If circulatory collapse has occurred, he has a weak, rapid pulse rate and hypotension.

On inspection, you may note a productive cough, possibly producing blood-tinged sputum. Less commonly, you may observe chest splinting, massive hemoptysis, leg edema and, with a large embolus, cyanosis, syncope, and distended neck veins. If you observe restlessness—a sign of hypoxia—the patient may have circulatory collapse.

Palpation may reveal a warm, tender area in the extremities, a possible area of thrombosis. On auscultation, you may hear transient pleural friction rub and crackles at the embolus site. You may also note an S₃ and S₄ gallop, with increased intensity of the pulmonic component of S₂.

ADVANCED PRACTICE

Who's at risk for pulmonary embolism?

Many disorders and treatments heighten the risk for pulmonary embolism. At particular risk are surgical patients. For example, the anesthetic used during surgery can injure lung vessels, and surgery or prolonged bed rest can promote venous stasis, which compounds the risk.

Predisposing disorders

- u Lung disorders, especially chronic types
- u Cardiac disorders
- u Infection
- u Diabetes mellitus
- u History of thromboembolism, thrombophlebitis, or vascular insufficiency
- u Sickle cell disease
- u Autoimmune hemolytic anemia
- u Polycythemia
- u Osteomyelitis
- u Long-bone fracture
- u Manipulation or disconnection of central lines

Venous stasis

- u Prolonged bed rest or immobilization
- u Obesity
- u Age over 40
- u Burns
- u Recent childbirth
- u Orthopedic casts

Venous injury

- u Surgery, particularly of the legs, pelvis, abdomen, or thorax
- u Leg or pelvic fractures or injuries
- u I.V. drug abuse
- u I.V. therapy

Increased blood coagulability

- u Cancer
- u Use of high-estrogen oral contraceptives

In pleural infarction, the patient's history may include heart disease and left ventricular failure. He may complain of sudden, sharp pleuritic chest pain accompanied by progressive dyspnea. On inspection, you may note that the patient has a fever and is coughing up blood-tinged sputum. Auscultation may reveal a pleural friction rub.

Diagnostic tests

Lung perfusion scan (lung scintiscan) can show a pulmonary embolus, and ventilation scan (usually performed with a lung perfusion scan) confirms the diagnosis.

Pulmonary angiography may show a pulmonary vessel filling defect or an abrupt vessel ending, both of which indicate pulmonary embolism. Although this is the most definitive test, it's only used if the diagnosis can't be confirmed any other way and anticoagulant therapy would put the patient at significant risk.

Electrocardiography (ECG) helps to distinguish pulmonary embolism from myocardial infarction. If the patient has an extensive embolism, the ECG shows right axis deviation, right bundle-branch block, tall peaked P waves, depressed ST segments, T-wave inversions (a sign of right ventricular heart strain), and supraventricular tachyarrhythmias.

Chest X-ray helps to rule out other pulmonary diseases, although it's inconclusive in the 1 to 2 hours after embolism. It may also show areas of atelectasis, an elevated diaphragm, pleural effusion, a prominent pulmonary artery and, occasionally, the characteristic wedge-shaped infiltrate that suggests pulmonary infarction.

Arterial blood gas (ABG) analysis sometimes reveals decreased levels of the partial pressures of arterial oxygen and carbon dioxide from tachypnea.

Thoracentesis may rule out empyema, a sign of pneumonia, if the patient has pleural effusion.

Magnetic resonance imaging can identify blood flow changes that point to an embolus or identify the embolus itself.

Treatment

The goal of treatment is to maintain adequate cardiovascular and pulmonary function until the obstruction resolves and to prevent any recurrence. (Most emboli resolve within 10 to 14 days.)

Treatment for an embolism caused by a thrombus generally consists of oxygen therapy as needed and anticoagulation with heparin to inhibit new thrombus formation. The patient on heparin therapy needs daily or frequent coagulation studies (partial thromboplastin time). The patient may also receive warfarin for 3 to 6 months depending on his risk factors. This patient's prothrombin time should be monitored daily and then biweekly.

If the patient has a massive pulmonary embolism and shock, he may need fibrinolytic therapy with urokinase, streptokinase, or alteplase. Initially, these thrombolytic agents dissolve clots within 12 to 24 hours. Seven days later, these drugs lyse clots to the same degree as heparin therapy alone.

If the embolus causes hypotension, the patient may need a vasopressor. A septic embolus requires antibiotic therapy, not anticoagulants, and evaluation for the infection's source, most likely endocarditis.

If the patient can't take anticoagulants or develops recurrent emboli during anticoagulant therapy, surgery is needed. Surgery consists of vena caval ligation, plication, or insertion of a device (umbrella filter) to filter blood returning to the heart and lungs. Angiographic demonstration of pulmonary embolism should take place before surgery.

To prevent postoperative venous thromboembolism, the patient may require a vascular compression device applied to his legs. Or he can receive a combination of heparin and dihydroergotamine, which is more effective than heparin alone.

If the patient has a fat embolus, oxygen therapy is needed. He may also need mechanical ventilation, corticosteroids and, if pulmonary edema arises, diuretics.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (cardiopulmonary)
- u Anxiety
- u Decreased cardiac output
- u Diversional activity deficit
- u Fear
- u

Impaired gas exchange u Ineffective airway clearance u Knowledge deficit u Pain u Risk for injury

Key outcomes

- u The patient will maintain adequate ventilation.
- u Cardiac output will remain adequate.
- u The patient will express feelings of comfort and relief of pain.
- u The patient will maintain a patent airway.
- u The patient will consume a specific amount of calories a day.
- u The patient will use support systems to assist with coping.

Nursing interventions

- u As ordered, give oxygen by nasal cannula or mask. If the patient has worsening dyspnea, check his ABG levels. If breathing is severely compromised, provide endotracheal intubation with assisted ventilation as ordered.
- u Administer heparin as ordered by I.V push or continuous drip. Monitor coagulation studies frequently. Effective heparin therapy raises partial thromboplastin time to about 2 to 2½ times normal.
- u During heparin therapy, watch closely for epistaxis, petechiae, and other signs of abnormal bleeding. Also check the patient's stools for occult blood. Don't administer I.M. injections.
- u After the patient stabilizes, encourage him to move about, and assist with isometric and range-of-motion exercises. Check his temperature and the color of his feet to detect venous stasis. Never vigorously massage his legs; that could cause thrombi to dislodge.
- u Apply antiembolism stockings to promote venous return.
- u If the patient needs surgery, make sure he ambulates as soon as possible afterward to prevent venous stasis.
- u Provide the patient with adequate nutrition and fluids to promote healing.
- u Watch for possible anticoagulant treatment complications, including gastric bleeding, cerebrovascular accident, and hemorrhage.
- u If the patient has pleuritic chest pain, administer the ordered analgesic.
- u If needed, provide incentive spirometry to help the patient with deep breathing. Provide tissues and a bag for easy disposal of tissues.
- u Provide the patient with diversional activities to promote rest and relieve restlessness.

Patient teaching

- u Explain all procedures and treatments to the patient and family members.
- u Teach the patient and family members the signs and symptoms of thrombophlebitis and pulmonary embolism.
- u Teach the patient on anticoagulant therapy the signs of bleeding to watch for (bloody stools, blood in urine, large bruises).
- u Tell the patient he can help prevent bleeding by shaving with an electric razor and by brushing his teeth with a soft toothbrush.
- u Make sure the patient understands the importance of taking his medication exactly as ordered. Tell him not to take any other medications, especially aspirin, without asking the doctor.
- u Stress the importance of follow-up laboratory tests such as prothrombin time to monitor anticoagulant therapy.
- u Tell the patient that he must inform all his health care providers—including dentists—that he's receiving anticoagulant therapy.
- u Instruct the patient taking warfarin not to significantly vary the amount of vitamin K he ingests daily. Doing so could interfere with anticoagulation stabilization.
- u To prevent pulmonary emboli in a high-risk patient, encourage him to walk and exercise his legs and to wear support or antiembolism stockings. Tell him not to cross or massage his legs.

PULMONARY HYPERTENSION

In both the rare primary form and the more common secondary form, a resting systolic pulmonary artery pressure (PAP) greater than 30 mm Hg and a mean PAP greater than 18 mm Hg indicates pulmonary hypertension.

Primary or idiopathic pulmonary hypertension is characterized by increased PAP and increased pulmonary vascular resistance, both without an obvious cause. This form is most common in women between ages 20 and 40 and is usually fatal within 3 to 4 years; mortality is highest in pregnant women.

Secondary pulmonary hypertension results from existing cardiac or pulmonary disease or both. The prognosis in secondary pulmonary hypertension depends on the severity of the underlying disorder.

Causes

The cause of primary pulmonary hypertension is unknown, but the tendency for the disease to occur in families points to a hereditary defect. It also occurs more commonly in those with collagen disease and is thought to result from altered immune mechanisms. (See [Understanding pulmonary hypertension.](#))

Complications

Pulmonary hypertension may ultimately lead to cor pulmonale, cardiac failure, and cardiac arrest.

Assessment findings

The patient with primary pulmonary hypertension may have no signs or symptoms until lung damage becomes severe. (In fact, the disorder may not be diagnosed until an autopsy.)

Usually, a patient with pulmonary hypertension complains of increasing dyspnea on exertion, weakness, syncope, and fatigue. He may also have difficulty breathing, feel short of breath, and report that breathing causes pain. Such signs may result from left ventricular failure.

Inspection may show signs of right ventricular failure, including ascites and neck vein distention. The patient may appear restless and agitated and have a decreased level of consciousness. He may even be confused and have memory loss. You may observe decreased diaphragmatic excursion and respiration, and the point of maximal impulse may be displaced beyond the midclavicular line.

On palpation, you may also note signs of right ventricular failure such as peripheral edema. The patient typically has an easily palpable right ventricular lift and a reduced carotid pulse. He may also have a palpable and tender liver and tachycardia.

Auscultation findings are specific to the underlying disorder but may include a systolic ejection murmur, a widely split S₂ sound, and S₃ and S₄ sounds. You may also hear decreased breath sounds and loud tubular sounds. The patient may have decreased blood pressure.

Diagnostic tests

Arterial blood gas (ABG) studies reveal hypoxemia (decreased partial pressure of arterial oxygen).

Electrocardiography, in right ventricular hypertrophy, shows right axis deviation and tall or peaked P waves in inferior leads.

Cardiac catheterization discloses increased PAP, with a systolic pressure greater than 30 mm Hg. It may also show an increased pulmonary artery wedge pressure

(PAWP) if the underlying cause is left atrial myxoma, mitral stenosis, or left ventricular failure; otherwise, PAWP is normal.

Pulmonary angiography reveals filling defects in pulmonary vasculature such as those that develop with pulmonary emboli. Pulmonary function tests may show decreased flow rates and increased residual volume in underlying obstructive disease; in underlying restrictive disease, they may show reduced total lung capacity.

Radionuclide imaging allows assessment of right and left ventricular functioning, and open lung biopsy may be used to determine the type of disorder.

Echocardiography allows the assessment of ventricular wall motion and possible valvular dysfunction. It can also demonstrate right ventricular enlargement, abnormal septal configuration consistent with right ventricular pressure overload, and a reduction in left ventricular cavity size.

Perfusion lung scan may produce normal or abnormal results, with multiple patchy and diffuse filling defects that don't suggest pulmonary thromboembolism.

Treatment

Oxygen therapy decreases hypoxemia and resulting pulmonary vascular resistance. For patients with right ventricular failure, treatment also includes fluid restriction, digitalis glycosides to increase cardiac output, and diuretics to decrease intravascular volume and extravascular fluid accumulation. Vasodilators and calcium channel blockers can reduce myocardial work load and oxygen consumption. Bronchodilators and beta-adrenergic agents may also be prescribed. A patient with primary pulmonary hypertension usually respond to epoprostenol (PGI₂) as a continuous home infusion.

For a patient with secondary pulmonary hypertension, treatment must also aim to correct the underlying cause. If that isn't possible and the disease progresses, the patient may need a heart-lung transplant.

Nursing diagnoses

- u Activity intolerance
- u Anxiety
- u Decreased cardiac output
- u Fear
- u Impaired gas exchange
- u Knowledge deficit

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will demonstrate skill in conserving energy while carrying out activities of daily living to tolerance level.
- u Cardiac output will remain adequate.
- u The patient will express an understanding of the illness.
- u The patient will use support systems to assist with coping.

Nursing interventions

- u Administer oxygen therapy as ordered, and observe the patient's response. Report any signs of increasing dyspnea so the doctor can adjust treatment accordingly.
- u Monitor ABG levels for acidosis and hypoxemia. Report any change in the patient's level of consciousness immediately.

PATHOPHYSIOLOGY

Understanding pulmonary hypertension

In primary pulmonary hypertension, the intimal lining of the pulmonary arteries thickens for no apparent reason. This narrows the artery and impairs distensibility, increasing vascular resistance.

Secondary pulmonary hypertension results from hypoxemia and can stem from any of the following:

- u *Alveolar hypoventilation.* This can result from diseases that cause alveolar destruction, such as chronic obstructive pulmonary disease (the most common cause in the United States), sarcoidosis, diffuse interstitial pneumonia, malignant metastases, and scleroderma. Or it can stem from obesity or kyphoscoliosis, which doesn't damage lung tissue but prevents the chest wall from expanding sufficiently to let air into the alveoli.
- u Either way, the decreased ventilation that results increases pulmonary vascular resistance. Hypoxemia resulting from this ventilation-perfusion mismatch also causes vasoconstriction, further increasing vascular resistance. The result is pulmonary hypertension.
- u *Vascular obstruction.* Such obstruction can arise from pulmonary embolism or vasculitis. It can also result from disorders that cause obstructions of small or large pulmonary veins, such as left atrial myxoma, idiopathic veno-occlusive disease, fibrosing mediastinitis, and mediastinal neoplasm.
- u *Primary cardiac disease.* Such disease may be congenital or acquired. Congenital defects that cause left-to-right shunting include patent ductus arteriosus and an atrial or a ventricular septal defect. This shunting into the pulmonary artery reroutes blood through the lungs twice, causing pulmonary hypertension.

Acquired cardiac diseases, such as rheumatic valvular disease and mitral stenosis, result in left ventricular failure that diminishes the flow of oxygenated blood from the lungs. This increases pulmonary vascular resistance and right ventricular pressure.

- u When caring for a patient with right ventricular failure, especially one receiving diuretics, record weight daily, carefully measure intake and output, and explain all medications and diet restrictions. Check for increasing neck vein distention, which may signal fluid overload.
- u Monitor the patient's vital signs, especially his blood pressure and heart rate. If hypotension or tachycardia develops, notify the doctor. If the patient has a pulmonary artery catheter, monitor his PAP and PAWP as ordered and report any changes.
- u Make sure the patient alternates periods of rest and activity to reduce the body's oxygen demand and prevent fatigue.
- u Arrange for diversional activities. The type of activity—whether active or passive—depends on the patient's physical condition.
- u Before discharge, help the patient adjust to the limitations imposed by this disorder.
- u Listen to the patient's fears and concerns, and remain with him during periods of extreme stress and anxiety.
- u Answer any questions the patient has as best you can. Encourage him to identify care measures and activities that make him comfortable and relaxed. Perform these measures, and encourage the patient to do so as well.
- u Include the patient in care decisions, and include family members in all phases of his care.

Patient teaching

- u Teach the patient what signs and symptoms to report to his doctor (increasing shortness of breath, swelling, increasing weight gain, increasing fatigue).
- u Fully explain the medication regimen.
- u If the patient smokes, encourage him to stop, and give him the names of programs to help him stop smoking.
- u If necessary, go over diet restrictions the patient should follow to maintain a low-sodium diet.
- u Teach the patient taking a potassium-wasting diuretic which foods are high in potassium.
- u Warn the patient not to overexert himself, and suggest frequent rest periods between activities.
- u If the patient needs special equipment for home use such as oxygen equipment, refer him to the social services department.

RESPIRATORY ACIDOSIS

Respiratory acidosis is an acid-base disturbance characterized by reduced alveolar ventilation and manifested by hypercapnea (partial pressure of arterial carbon dioxide [Paco_2] greater than 45 mm Hg). Respiratory acidosis can be acute (resulting from sudden failure in ventilation) or chronic (resulting from long-term pulmonary disease). (See [What happens in respiratory acidosis.](#))

The prognosis depends on the severity of the underlying disturbance and the patient's general clinical condition.

Causes

Factors that predispose a patient to respiratory acidosis include:

- u *drugs*, such as narcotics, anesthetics, hypnotics, and sedatives, which depress the respiratory control center's sensitivity
- u *central nervous system (CNS) trauma*, such as medullary injury, which may impair ventilatory drive
- u *chronic metabolic alkalosis*, which may occur when respiratory compensatory mechanisms attempt to normalize pH by decreasing alveolar ventilation
- u *neuromuscular diseases*, such as Guillain-Barré syndrome, myasthenia gravis, and poliomyelitis, in which respiratory muscles fail to respond properly to respiratory drive, reducing alveolar ventilation.

In addition, respiratory acidosis can result from an airway obstruction or parenchymal lung disease that interferes with alveolar ventilation or from chronic obstructive pulmonary disease (COPD), asthma, severe adult respiratory distress syndrome, chronic bronchitis, large pneumothorax, extensive pneumonia, and pulmonary edema.

Complications

Acute or chronic respiratory acidosis can produce shock and cardiac arrest.

Assessment findings

The patient may initially complain of headache and dyspnea. He may also have a predisposing condition for respiratory acidosis. On inspection, you may see that he's dyspneic and diaphoretic. He may report nausea and vomiting.

Palpation may detect bounding pulses. Auscultation may reveal rapid, shallow respirations, tachycardia and, possibly, hypotension.

Ophthalmoscopic examination may uncover papilledema. Neurologic examination may disclose a level of consciousness ranging from restlessness, confusion, and apprehension to somnolence, with a fine or flapping tremor (asterixis) and depressed reflexes.

Diagnostic tests

Arterial blood gas (ABG) analysis confirms respiratory acidosis when Paco_2 is greater than the normal 45 mm Hg; pH is typically below the normal range of 7.35 to 7.45; and bicarbonate levels are normal in acute respiratory acidosis but elevated in chronic respiratory acidosis.

PATHOPHYSIOLOGY

What happens in respiratory acidosis

These illustrations explain the basic pathophysiology of respiratory acidosis.

1 Pulmonary ventilation diminishes

When pulmonary ventilation decreases, retained carbon dioxide (CO_2) in the red blood cells combines with water (H_2O) to form excess carbonic acid (H_2CO_3). The H_2CO_3 dissociates to release free hydrogen (H^+) and bicarbonate ions (HCO_3^-). In this condition, arterial blood gas (ABG) studies show increased Paco_2 (over 45 mm Hg) and reduced blood pH (below 7.35).

2 Oxygen saturation decreases

As pH decreases and 2,3-diphosphoglycerate (2,3-DPG) increases in red blood cells, 2,3-DPG alters hemoglobin (Hb) so it releases oxygen (O_2). This reduced Hb, which is strongly basic, picks up H^+ and CO_2 , eliminating some free H^+ and excess CO_2 . At this stage, arterial oxygen saturation (Sao_2) levels decrease, and the Hb dissociation curve shifts to the right.

3 Respiratory rate rises

Whenever Paco_2 increases, CO_2 levels increase in all tissues and fluids, including the medulla and cerebrospinal fluid. CO_2 reacts with H_2O to form H_2CO_3 , which dissociates into H^+ and HCO_3^- . Elevated Paco_2 and H^+ have a potent stimulatory effect on the medulla, increasing respirations to blow off CO_2 . Look for rapid, shallow respirations and diminishing Paco_2 levels.

4 Blood flows to brain

The free H^+ and excess CO_2 dilate cerebral vessels and increase blood flow to the brain, causing cerebral edema and depressed central nervous system activity. At this stage, the patient experiences headache, confusion, lethargy, nausea, and vomiting.

5 Kidneys compensate

As respiratory mechanisms fail, increasing Paco_2 stimulates the kidneys to retain HCO_3^- and sodium ions (Na^+) and to excrete H^+ . As a result, more sodium bicarbonate (NaHCO_3) is available to buffer free H^+ . Ammonium ions (NH_4^+) also excreted to remove H^+ . A patient in this condition has increased urine acidity and ammonium levels, elevated serum pH and HCO_3^- levels, and shallow, depressed respirations.

6 Acid-base balance fails

As H^+ concentration overwhelms compensatory mechanisms, H^+ ions move into the cells and potassium ions (K^+) move out. Without sufficient O_2 , anaerobic metabolism produces lactic acid. Electrolyte imbalance and acidosis critically depress brain and cardiac function. ABG values in a patient in this condition show elevated $Paco_2$ and decreased PaO_2 and pH levels. The patient will experience hyperkalemia, arrhythmias, tremors, decreased level of consciousness and, possibly, coma.

Treatment

The goal of treatment is to correct the source of alveolar hypoventilation. If alveolar ventilation is significantly reduced, the patient may need mechanical ventilation until the underlying condition can be treated. This includes bronchodilators, oxygen, and antibiotics in COPD; drug therapy for conditions such as myasthenia gravis; removal of foreign bodies from the airway in cases of obstruction; antibiotics for pneumonia; dialysis to eliminate toxic drugs; and correction of metabolic alkalosis.

Dangerously low pH levels (less than 7.15) can produce profound CNS and cardiovascular deterioration and may require administration of I.V. sodium bicarbonate. In chronic lung disease, elevated carbon dioxide (CO_2) levels may persist despite treatment.

Nursing diagnoses

u Anxiety u Decreased cardiac output u Fear u Impaired gas exchange u Ineffective airway clearance u Risk for fluid volume deficit

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will maintain adequate ventilation.
- u The patient will use support systems to assist with coping.
- u The patient's fluid intake and output remain within established limits.
- u Cardiac output will remain adequate.

Nursing interventions

- u Be prepared to treat or remove the underlying cause such as an airway obstruction.
- u Be alert for critical changes in the patient's respiratory, CNS, and cardiovascular functions. Report any such changes immediately. Also report variations in ABG levels and electrolyte status.
- u Maintain adequate hydration by administering I.V. fluids.
- u Give oxygen (only at low concentrations in patients with COPD) if the level of the partial pressure of arterial oxygen drops.

ASSESSMENT TIP Be aware that pulse oximetry is used to monitor oxygen saturation but doesn't show increasing CO_2 levels.

- u Give aerosolized or I.V. bronchodilators. Monitor and record the patient's response to these medications.
- u Start mechanical ventilation if hypoventilation can't be corrected immediately. Continuously monitor ventilator settings.
- u Maintain a patent airway, and provide adequate humidification if acidosis requires mechanical ventilation.
- u Perform tracheal suctioning regularly and chest physiotherapy if ordered.
- u To detect developing respiratory acidosis, closely monitor patients with COPD and chronic CO_2 retention for signs of acidosis. Administer oxygen at low flow rates and closely monitor all patients who receive narcotics and sedatives.
- u Reassure the patient as much as possible, depending on his level of consciousness. Allay the fears and concerns of family members by keeping them informed about the patient's status.

Patient teaching

- u Instruct the patient who's recovering from a general anesthetic to turn, cough, and perform deepbreathing and coughing exercises frequently to prevent respiratory acidosis.
- u If the patient receives home oxygen therapy for COPD, stress the importance of maintaining the dose at the ordered flow rate.
- u Explain the reasons for ABG analysis. Discuss the technique used to draw blood and tell him that he may feel slight discomfort from the needle stick.
- u Alert the patient to possible adverse reactions of prescribed medications. Tell him to call the doctor if any signs and symptoms occur.

RESPIRATORY ALKALOSIS

Respiratory alkalosis results from alveolar hyperventilation. It's marked by a decrease in partial pressure of arterial carbon dioxide ($Pac O_2$) (less than 35 mm Hg) and an increase in blood pH over 7.45. Uncomplicated respiratory alkalosis leads to a decrease in hydrogen ion concentration, which raises the blood pH. Hypocapnia occurs when the lungs eliminate more carbon dioxide (CO_2) than the body produces at the cellular level. In the acute stage, respiratory alkalosis is also called hyperventilation syndrome.

Causes

Predisposing conditions to respiratory alkalosis include:

- u heart failure
- u central nervous system (CNS) injury to the respiratory control center
- u extreme anxiety
- u fever
- u overventilation during mechanical ventilation
- u pulmonary embolism
- u salicylate intoxication (early).

Complications

In extreme respiratory alkalosis, related cardiac arrhythmias may fail to respond to conventional treatment. Seizures may also occur.

Assessment findings

The patient history may reveal a predisposing factor associated with respiratory alkalosis. The patient might complain of light-headedness or paresthesia (numbness and tingling in his arms and legs).

On inspection, the patient may seem anxious, with visibly rapid breathing. In severe respiratory alkalosis, tetany may be apparent, with visible twitching and flexion of the wrists and ankles.

Auscultation may reveal tachycardia and deep, rapid breathing.

Diagnostic tests

Arterial blood gas (ABG) analysis confirms respiratory alkalosis and rules out compensation for metabolic acidosis. $Paco_2$ falls below 35 mm Hg; blood pH increases in proportion to a decrease in $Paco_2$ in the acute stage but drops toward normal in the chronic stage. The bicarbonate level is normal in the acute stage but below normal in the chronic stage.

Serum electrolyte studies detect metabolic acid-base disorders.

Treatment

In respiratory alkalosis, the goal of treatment is to eradicate the underlying condition; for example, by removing ingested toxins or by treating fever, sepsis, or CNS disease. In severe respiratory alkalosis, the patient may need to breathe into a paper bag, which helps relieve acute anxiety and increased CO_2 levels. Sedatives may also be necessary. If respiratory alkalosis results from anxiety, sedatives and tranquilizers may help the patient.

To prevent hyperventilation in patients receiving mechanical ventilation, ABG levels are monitored and dead-space or minute ventilation volume is adjusted.

Nursing diagnoses

- u Anxiety u Fatigue u Fear u Impaired gas exchange u Ineffective breathing pattern

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will maintain a breath rate at ± 5 from baseline.
- u The patient will use support systems to assist with coping.
- u The patient will identify measures to prevent or reduce fatigue.

Nursing interventions

- u Watch for and report changes in neurologic, neuromuscular, and cardiovascular functioning.
- u Remember that twitching and cardiac arrhythmias may be associated with alkalemia and electrolyte imbalances. Monitor ABG and serum electrolyte levels closely. Report any variations immediately.
- u Stay with the patient during periods of extreme stress and anxiety. Offer reassurance and maintain a calm, quiet environment. Monitor effects of any sedation given.
- u If the patient is coping with anxiety-induced respiratory alkalosis, help him identify factors that precipitate anxiety. Also help him to find coping mechanisms and activities that promote relaxation.

Patient teaching

- u Explain all care procedures to the patient. Allow ample time to answer questions.
- u Instruct the patient in anxiety-reducing techniques, such as guided imagery, meditation, or even yoga. Teach how to counter hyperventilation with a controlled breathing pattern.

SARCOIDOSIS

Sarcoidosis is a multisystemic, granulomatous disorder that characteristically produces lymphadenopathy, pulmonary infiltration, and skeletal, liver, eye, or skin lesions.

Sarcoidosis occurs most commonly in young adults ages 20 to 40. In the United States, sarcoidosis occurs predominantly among blacks and affects twice as many women as men. Acute sarcoidosis usually resolves within 2 years. Chronic, progressive sarcoidosis, which is uncommon, is associated with pulmonary fibrosis and progressive pulmonary disability.

Causes

The cause of sarcoidosis is unknown, but several possibilities exist. The disease may result from a hypersensitivity response—possibly from T-cell imbalance—to such agents as atypical mycobacteria, fungi, and pine pollen. The incidence is slightly higher within families, suggesting a genetic predisposition. Chemicals also may trigger the disease (zirconium or beryllium lead to illnesses that resemble sarcoidosis).

Although the exact mechanism of the disease is unknown, research suggests a T-cell problem and, more specifically, a lymphokine production problem. In other granulomatous diseases such as tuberculosis, granuloma formation occurs from inadequate pathogen clearance by macrophages. These macrophages require the help of T cells that secrete lymphokines, which, in turn, activate less effective macrophages to become aggressive phagocytes. Lack of lymphokine secretion by T cells may help explain granuloma formation in sarcoidosis.

Complications

Sarcoidosis can eventually lead to pulmonary fibrosis, with resultant pulmonary hypertension and cor pulmonale.

Assessment findings

The patient may report pain in the wrists, ankles, and elbows; general fatigue and a feeling of malaise; and unexplained weight loss. He may also complain of breathlessness and shortness of breath on exertion and have a nonproductive cough and substernal pain.

On inspection, you may observe erythema nodosum, subcutaneous skin nodules with maculopapular eruptions, and punched out lesions on the fingers and toes. You may also note weakness and cranial or peripheral nerve palsies. When you inspect the nose, you may see extensive nasal mucosal lesions. Inspection of the eyes commonly reveals anterior uveitis. Glaucoma and blindness occasionally occur in advanced disease.

You may be able to palpate bilateral hilar and right paratracheal lymphadenopathy and splenomegaly, and you may hear such arrhythmias as premature beats on auscultation.

Diagnostic tests

A positive Kveim-Siltzbach skin test points to sarcoidosis. In this test, the patient receives an intradermal injection of an antigen prepared from human sarcoidal spleen or lymph nodes from patients with sarcoidosis. If he has active sarcoidosis, granuloma develops at the injection site in 2 to 6 weeks. When coupled with a skin biopsy at the injection site that shows discrete epithelioid cell granuloma, the test confirms the disease.

Several other tests are used to support the diagnosis: For example, chest X-rays demonstrate bilateral hilar and right paratracheal adenopathy, with or without diffuse interstitial infiltrates. Occasionally, they show large nodular lesions in lung parenchyma.

Lymph node, skin, or lung biopsy discloses noncaseating granulomas with negative cultures for mycobacteria and fungi.

Pulmonary function tests indicate decreased total lung capacity and compliance and reduced diffusing capacity, and arterial blood gas (ABG) studies show a decreased partial pressure of arterial oxygen.

Tuberculin skin test, fungal serologies, sputum cultures (for mycobacteria and fungi), and biopsy cultures are negative and help rule out infection.

Treatment

Asymptomatic sarcoidosis requires no treatment. However, sarcoidosis that causes ocular, respiratory, central nervous system, cardiac, or systemic symptoms (such as fever and weight loss) requires treatment with systemic or topical corticosteroids. So does sarcoidosis that produces hypercalcemia or destructive skin lesions. Such therapy usually continues for 1 to 2 years, but some patients may need lifelong therapy. A patient with hypercalcemia also requires a low-calcium diet and protection from direct exposure to sunlight.

If the patient has a significant response to the tubercular skin tests, showing tuberculosis reactivation, he needs isoniazid therapy.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Anxiety u Dysfunctional grieving u Fear u Impaired gas exchange u Knowledge deficit u Risk for infection

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will use support systems to assist with coping.
- u The patient will consume a specific number of calories daily.
- u The patient will express an understanding of the illness.
- u The patient will perform activities of daily living within the confines of illness.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Watch for and report any complications. Also note any abnormal laboratory results (anemia, for example) that could alter patient care.
- u If the patient has arthralgia, administer analgesics as ordered. Record signs of progressive muscle weakness.
- u Provide a nutritious, high-calorie diet and plenty of fluids. If the patient has hypercalcemia, speak to the dietitian about a low-calcium diet. Weigh the patient regularly to detect weight loss.
- u Monitor the patient's respiratory function. Check chest X-rays for the extent of lung involvement, and note and record any increase in or bloody sputum. If the patient has pulmonary hypertension or end-stage cor pulmonale, monitor ABG levels, watch for arrhythmias, and administer oxygen as needed.

ALERT Because corticosteroids may induce or worsen diabetes mellitus, test the patient's blood via finger sticks for glucose and acetone at least every 12 hours at the beginning of corticosteroid therapy. Also, watch for other adverse effects, such as fluid retention, electrolyte imbalance (especially hypokalemia), moon face, hypertension, and personality changes.

- u During or after corticosteroid withdrawal (particularly if the patient has an infection or another stressor, such as emotional stress or an underlying condition), watch for and report vomiting, orthostatic hypotension, hypoglycemia, restlessness, anorexia, malaise, and fatigue. Remember that the patient on long-term or high-dose therapy is vulnerable to infection.
- u Listen to the patient's fears and concerns, and remain with him during periods of extreme stress and anxiety. Encourage him to identify actions and care measures that help make him comfortable and relaxed. Perform these measures, and encourage the patient to do so as well.
- u Whenever possible, include the patient in care decisions, and include family members in all phases of the patient's care.

Patient teaching

- u When preparing the patient for discharge, stress the need for compliance with the prescribed steroid therapy. Emphasize the importance of not skipping doses.
- u Instruct the patient to take steroids with food.
- u Make sure the patient understands the need for regular, careful follow-up examinations and treatment.
- u Teach the patient to wear a medical identification bracelet or necklace indicating his corticosteroid therapy.
- u Discuss the patient's increased vulnerability to infection, and review ways to minimize exposure to illness.
- u Refer the patient with failing vision to community support and resource groups, including the American Foundation for the Blind, if necessary.

Chronic disorders

Several factors can lead to chronic respiratory disorders. For instance, a genetic defect leads to cystic fibrosis, whereas damage to the bronchial wall results in bronchiectasis. Environmental factors cause chronic bronchitis and emphysema, infection causes pulmonary tuberculosis, and occupational hazards lead to such disorders as asbestosis, berylliosis, coal worker's pneumoconiosis, and silicosis.

ASBESTOSIS

Asbestosis is characterized by diffuse interstitial pulmonary fibrosis resulting from prolonged exposure to airborne asbestos particles. Asbestosis may develop many years (about 15 to 20) after regular exposure to asbestos ceases. Asbestos exposure also causes pleural plaques and mesotheliomas of the pleura and the peritoneum. A potent cocarcinogen, asbestos heightens a cigarette smoker's risk for lung cancer. In fact, an asbestos worker who smokes is 90 times more likely to develop lung cancer than a smoker who never worked with asbestos.

Causes

Asbestosis is a form of pneumoconiosis. It follows prolonged inhalation of respirable asbestos fibers (about 50 microns long and 0.5 microns wide). Sources of exposure include asbestos mining and milling, the construction industry (where asbestos is used in a prefabricated form), and the fireproofing and textile industries. Asbestos is also used in the production of paints, plastics, and brake and clutch linings. Asbestos-related diseases develop in families of asbestos workers as a result of exposure to fibrous dust shaken off workers' clothing at home. Such diseases develop in the general public as a result of exposure to fibrous dust or waste piles from nearby asbestos plants. (See [Understanding asbestosis](#).)

Complications

Asbestosis may progress to pulmonary fibrosis with respiratory failure and cardiovascular complications, including pulmonary hypertension and cor pulmonale.

Assessment findings

The patient typically relates a history of occupational, family, or neighborhood exposure to asbestos fibers. The average exposure time is about 10 years. He may report exertional dyspnea. With extensive fibrosis, he may report dyspnea even at rest. In advanced disease, the patient may complain of a dry cough (may be productive in smokers), chest pain (often pleuritic), and recurrent respiratory tract infections.

Inspection findings may include tachypnea and clubbing of the fingers. With auscultation, you may hear characteristic dry crackles in the lung bases.

Diagnostic tests

Chest X-rays may show fine, irregular, and linear diffuse infiltrates. If the patient has extensive fibrosis, X-rays may disclose lungs with a honeycomb or ground-glass appearance. Films may also show pleural thickening and pleural calcification, bilateral obliteration of costophrenic angles and, in later disease stages, an enlarged heart with a classic “shaggy” border.

Pulmonary function tests may identify decreased vital capacity, forced vital capacity (FVC), and total lung capacity; decreased or normal forced expiratory volume in 1 second (FEV₁); a normal ratio of FEV₁ to FVC; and reduced diffusing capacity for carbon monoxide when fibrosis destroys alveolar walls and thickens the alveolocapillary membrane.

Arterial blood gas analysis may reveal decreased partial pressures of arterial oxygen and carbon dioxide from hyperventilation.

Treatment

Chest physiotherapy techniques, such as controlled coughing and postural drainage with chest percussion and vibration, may be implemented to relieve respiratory signs and symptoms and, in advanced disease, manage hypoxia and cor pulmonale.

Aerosol therapy, inhaled mucolytics, and increased fluid intake (at least 3 L [3.2 qt] daily) may also help relieve respiratory symptoms. Hypoxia requires oxygen administration by cannula or mask (up to 2 L/minute) or by mechanical ventilation if the patient's arterial oxygen level can't be maintained above 40 mm Hg.

Diuretic agents, digitalis preparations, and salt restriction may be necessary for patients with cor pulmonale. Respiratory tract infections require prompt antibiotic therapy.

Nursing diagnoses

u Altered family processes u Altered nutrition: Less than body requirements u Anxiety u Fatigue u Fear u Impaired gas exchange u Ineffective breathing pattern u Knowledge deficit

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will consume a specific number of calories daily.
- u Family members will identify and contact available resources as needed.
- u The patient will express an understanding of the illness.
- u The patient will identify measures to prevent or reduce fatigue.

Nursing interventions

- u Provide supportive care, and help the patient adjust to lifestyle changes necessitated by chronic illness.
- u Be alert for changes in baseline respiratory function. Also watch for changes in sputum quality and quantity, restlessness, increased tachypnea, and changes in breath sounds. Report these immediately.
- u Perform chest physiotherapy, including postural drainage, chest percussion, and vibration for involved lobes, several times daily.
- u Weigh the patient three times weekly.
- u Provide high-calorie, high-protein foods. Offer small, frequent meals to conserve the patient's energy and prevent fatigue.
- u Make sure the patient receives adequate fluids to loosen secretions.
- u Schedule respiratory therapy at least 1 hour before or after meals. Provide mouth care after inhalation bronchodilator therapy.
- u Encourage daily activity, and provide diversions as appropriate. Help conserve the patient's energy and prevent fatigue by alternating rest and activity.
- u Administer medication as ordered, and note the patient's response.

PATHOPHYSIOLOGY

Understanding asbestosis

Asbestosis results when inhaled asbestos fibers travel down the airway and penetrate respiratory bronchioles and alveolar walls. They become encased in a brown, iron-rich, protein-like sheath (ferruginous bodies or asbestosis bodies) in sputum or lung tissue. Interstitial fibrosis may develop in lower lung zones, causing pathologic changes in lung parenchyma and pleurae. Raised hyaline plaques may form in the parietal pleura and the diaphragm and in pleura adjacent to the pericardium.

- u Watch for complications, such as pulmonary hypertension and cor pulmonale.

Patient teaching

- u Advise the patient to avoid crowds and people with known infections and to obtain influenza and pneumococcus immunizations.
- u If the patient receives home oxygen therapy, explain why he needs it and show him how to operate the equipment.
- u If the patient has a transtracheal catheter, teach him how to care for it. Review precautions for catheter use, and urge him to schedule appointments for follow-up care.
- u Teach the patient and family members how to perform chest physiotherapy.
- u Review the patient's medication regimen with him.
- u Encourage the patient to follow a high-calorie, high-protein diet to meet increased energy requirements. Tell him to drink plenty of fluids to prevent dehydration and to help loosen secretions.
- u If the patient smokes, encourage him to stop. Provide him with information or counseling, as appropriate.
- u Inform the public, as appropriate, about the health hazard from asbestos exposure and ways to prevent asbestosis.

BERYLLIOSIS

Berylliosis—a type of pneumoconiosis—is a systemic granulomatous disease that mainly affects the lungs. It occurs in two forms: acute nonspecific pneumonitis and chronic noncaseating granulomatous disease with interstitial fibrosis, which may cause death from respiratory failure and cor pulmonale. In about 10% of patients with acute berylliosis, chronic disease develops 10 to 15 years after exposure.

Most patients with chronic interstitial disease have only slight to moderate disability from impaired lung function and other symptoms. With each acute exacerbation, though, the prognosis worsens.

This occupational disease can affect workers in beryllium alloy, ceramics, foundry, grinder, cathode ray tube, gas mantle, missile, and nuclear reactor industries. It's associated with the milling and use of beryllium but not with beryl ore mining.

Berylliosis—also known as beryllium poisoning or beryllium disease—may also affect beryllium workers' families (from beryllium dust shaken off clothing) and others who live near beryllium alloy sites.

Causes

Inhaling beryllium dust, fumes, and mists causes berylliosis; the pattern of disease depends on the amount inhaled. Beryllium may also be absorbed through the skin. How the element exerts its toxic effect isn't known.

Complications

Berylliosis may progress to pulmonary scarring with pneumothorax, blebs, and respiratory failure. Pulmonary hypertension and cor pulmonale may also occur.

Assessment findings

The history reveals occupational, family, or neighborhood exposure to beryllium dust, fumes, or mists. The history may also include an itchy rash that has disappeared.

Depending on the amount of time between exposure and the patient's initial symptoms (usually 2 weeks from exposure), inspection may disclose a rash, caused by absorption of beryllium through broken skin, or a “beryllium ulcer,” caused when beryllium is accidentally implanted in the skin.

Inspection of the nasal mucosa may reveal swelling and ulceration, which can progress to septal perforation, tracheitis, and bronchitis (dry cough).

In acute disease, which develops rapidly (within 3 days) or a few weeks after exposure, the patient may report chest tightness and substernal pain. He may have a dry cough and tachycardia.

In chronic berylliosis, the history may disclose progressively worsening dyspnea. Patient complaints may include mild chest pain and a dry, unproductive cough. Tachypnea may accompany coarse crackles and decreased breath sounds.

Diagnostic tests

Chest X-rays in acute berylliosis suggest pulmonary edema, demonstrating an acute miliary process or a patchy acinous filling and diffuse infiltrates with prominent peribronchial markings. Findings in chronic berylliosis include reticulonodular infiltrates, hilar adenopathy, and large coalescent infiltrates in both lungs.

Pulmonary function studies demonstrate decreased vital capacity, forced vital capacity, residual volume to total lung capacity ratio, diffusing capacity for carbon monoxide, and compliance. These decreased values occur as fibrosis stiffens the lungs.

Arterial blood gas analysis indicates diminished partial pressure of arterial oxygen (Pa O₂) and partial pressure of arterial carbon dioxide.

In vitro lymphocyte transformation test, if positive, confirms the diagnosis. The test is also used to monitor workers' occupational exposure to beryllium.

Beryllium patch test, if positive, establishes a patient's hypersensitivity to beryllium but doesn't confirm the disease.

Tissue biopsy and spectrographic analysis, if positive, support but don't confirm the diagnosis.

Urinalysis may identify beryllium excreted in urine, indicating exposure to the metal. Differential diagnosis must rule out sarcoidosis and granulomatous infections.

Treatment

A beryllium ulcer requires excision or curettage. Acute berylliosis requires prompt corticosteroid therapy. If the patient has hypoxia, he may need oxygen delivered by nasal cannula or mask (usually 1 to 2 L/minute). If he has severe respiratory failure, he may need mechanical ventilation if the Pa O₂ falls below 40 mm Hg.

The patient with chronic berylliosis usually receives corticosteroid therapy to attempt to alter the disease's progression; maintenance therapy may be lifelong.

Respiratory symptoms may respond to bronchodilators, increased fluid intake (at least 3 L [3.2 qt] daily), and chest physiotherapy. Diuretic agents, digitalis preparations, and sodium restriction may help the patient with cor pulmonale.

Nursing diagnoses

- u Altered family processes
- u Altered nutrition: Less than body requirements
- u Anxiety
- u Fatigue
- u Fear
- u Impaired gas exchange
- u Ineffective breathing pattern
- u

Knowledge deficit

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will use support systems to assist with coping.
- u The patient will consume a specific number of calories daily.
- u The patient will identify measures to prevent or reduce fatigue.
- u The patient will express an understanding of the illness.

Nursing interventions

- u Help the patient adjust to lifestyle changes necessitated by chronic illness.
- u Provide high-calorie, high-protein foods. Offer small, frequent meals to conserve the patient's energy and prevent fatigue.
- u Make sure the patient receives adequate fluids to loosen and remove secretions.
- u Schedule respiratory therapy at least 1 hour before or after meals.
- u Perform chest physiotherapy several times daily.
- u Assist with endotracheal intubation if necessary.
- u Suction patient frequently to remove secretions.
- u Encourage daily activity. Provide diversional activities as appropriate. To conserve the patient's energy and prevent fatigue, alternate periods of rest and activity.
- u Administer medication as ordered. Note the patient's response, and monitor him for adverse reactions.
- u Watch for complications, such as pulmonary hypertension and cor pulmonale.

Patient teaching

- u Advise the patient to avoid crowds and people with known infections and to obtain influenza and pneumococcus immunizations.
- u If the patient receives home oxygen therapy, explain its purpose and teach him how to operate the equipment.
- u Teach the patient and family members how to perform chest physiotherapy with postural drainage and chest percussion. Advise the patient to maintain each position for about 10 minutes and then to perform percussion and cough. Also teach him coughing and deep-breathing techniques to promote good ventilation and to remove secretions.
- u Explain the medication regimen to the patient and family members. Discuss the dosage, adverse effects, and purposes of the prescribed drugs.
- u Encourage the patient to follow a high-calorie, protein-rich diet to promote health. Advise him to drink plenty of fluids to prevent dehydration and to help loosen secretions.
- u If the patient smokes, encourage him to stop. Provide him with further information or refer him for counseling.
- u Inform appropriate patient groups about the health risks posed by berylliosis. Discuss ways to prevent the disease and minimize exposure.

BRONCHIECTASIS

Bronchiectasis is a disorder characterized by chronic abnormal dilation of the bronchi and destruction of the bronchial walls. It can occur throughout the tracheobronchial tree, or it may be confined to one segment or lobe. It's usually bilateral and involves the basilar segments of the lower lobes.

The disease has three forms: cylindrical (fusiform), varicose, and saccular (cystic). It affects people of both sexes and all ages. With antibiotics available to treat acute respiratory tract infections, the incidence of bronchiectasis has dramatically decreased over the past 20 years. Its incidence is highest among Inuit populations in the northern hemisphere and the Maoris of New Zealand. Bronchiectasis is irreversible.

Causes and pathophysiology

Bronchiectasis results from conditions associated with repeated damage to bronchial walls and with abnormal mucociliary clearance, which causes a breakdown of supporting tissue adjacent to the airways. Such conditions include:

- u mucoviscidosis (cystic fibrosis)
- u immune disorders (agammaglobulinemia, for example)
- u recurrent, inadequately treated bacterial respiratory tract infections (such as tuberculosis)
- u complications of measles, pneumonia, pertussis, or influenza
- u obstruction (by a foreign body, tumor, or stenosis) with recurrent infection
- u inhalation of corrosive gas or repeated aspiration of gastric juices
- u congenital anomalies (rare), such as bronchomalacia, congenital bronchiectasis, and Kartagener's syndrome (bronchiectasis, sinusitis, and dextrocardia), and various rare disorders such as immotile cilia syndrome.

In bronchiectasis, hyperplastic squamous epithelium denuded of cilia replace ulcerated columnar epithelia. Abscess formation occurs, involving all layers of the bronchial walls. This produces inflammatory cells and fibrous tissues. The result is both dilation and narrowing of the airways. Sputum stagnates in the dilated bronchi and leads to secondary infection, characterized by inflammation and leukocytic accumulations. Additional debris collects in and occludes the bronchi. Building pressure from the retained secretions induces mucosal injury. Extensive vascular proliferation of bronchial circulation occurs and produces frequent hemoptysis.

Complications

Advanced bronchiectasis may produce chronic malnutrition and amyloidosis, right ventricular failure, and cor pulmonale.

Assessment findings

Patient complaints commonly include frequent bouts of pneumonia or a history of coughing up blood or blood-tinged sputum. The patient typically reports a chronic cough that produces copious, foul-smelling, mucopurulent secretions (up to several cups daily). He may also report dyspnea, weight loss, and malaise.

Inspection of the patient's sputum may show a cloudy top layer, a central layer of clear saliva, and a heavy, thick, purulent bottom layer. In advanced disease, the patient may have clubbed fingers and toes and cyanotic nail beds.

If the patient also has a complicating condition, such as pneumonia or atelectasis, percussion may detect dullness over lung fields. Auscultation may reveal coarse crackles during inspiration over involved lobes or segments and, occasionally, wheezes. With complicating atelectasis or pneumonia, you may hear diminished breath sounds during auscultation.

Diagnostic tests

Computed tomography scanning is the most useful test for diagnosis. It's sometimes used with high-resolution techniques to better determine anatomic changes.

Bronchography may be ordered for patients who are considering surgery or for those with recurrent or severe hemoptysis. In bronchography, a radiopaque contrast medium outlines the bronchial walls, allowing X-ray images to display the location and extent of disease.

Chest X-rays show peribronchial thickening, atelectatic areas, and scattered cystic changes that suggest bronchiectasis.

Bronchoscopy helps to identify the source of secretions or the bleeding site in hemoptysis.

Sputum culture and a Gram stain identify predominant pathogens.

Complete blood count can reveal anemia and leukocytosis.

Pulmonary function studies detect decreased vital capacity, expiratory flow, and hypoxemia; these tests also help evaluate disease severity, therapeutic effectiveness, and the patient's suitability for surgery.

Depending on the patient and his condition, additional tests may include urinalysis and electrocardiography. (Electrocardiography is normal unless cor pulmonale develops.) If the health care team suspects cystic fibrosis as the underlying cause of bronchiectasis, a sweat electrolyte test may be ordered.

Treatment

Antibiotic therapy (oral or I.V.) for 7 to 10 days—or until sputum production decreases—is the principal treatment. Bronchodilators and postural drainage and chest percussion help remove secretions if the patient has bronchospasm and thick, tenacious sputum. Occasionally, bronchoscopy may be used to remove secretions. Oxygen therapy may be used for hypoxia. Segmental resection, bronchial artery embolization, or lobectomy may be necessary if pulmonary function is poor.

The only cure for bronchiectasis is surgical removal of the affected lung portion. However, the patient with bronchiectasis affecting both lungs probably won't benefit from surgery.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Fatigue
- u Impaired gas exchange
- u Ineffective airway clearance
- u Ineffective breathing pattern

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will maintain adequate ventilation.
- u The patient will maintain respiratory rate at ±5 of baseline.
- u The patient will consume a specific number of calories daily.
- u The patient will identify measures to prevent or reduce fatigue.
- u The patient will use support systems to assist with coping.

Nursing interventions

- u Provide supportive care, and help the patient adjust to the lifestyle changes that irreversible lung damage necessitates.
- u Administer antibiotics as ordered, and record the patient's response to this medication.
- u Give oxygen as needed, and assess gas exchange by monitoring arterial blood gas values as ordered.
- u Perform chest physiotherapy, including postural drainage and chest percussion for involved lobes, several times a day, especially in the early morning and before bedtime.
- u Provide a warm, quiet, comfortable environment. Also, help the patient to alternate rest and activity periods.
- u Provide well-balanced, high-calorie meals for the patient. Offer small, frequent meals to prevent fatigue.
- u Make sure the patient receives adequate hydration to help thin secretions and promote easier removal.
- u Give frequent mouth care to remove foul-smelling sputum. Provide the patient with tissues and a waxed bag for disposal of the contaminated tissues.
- u Watch for developing complications, such as right ventricular failure and cor pulmonale.
- u After surgery, give meticulous postoperative care. Monitor vital signs, encourage deep breathing and position changes every 2 hours, and provide chest-tube care.

Patient teaching

- u Show family members how to perform postural drainage and percussion. Also teach the patient coughing and deep-breathing techniques to promote good ventilation and assist in secretion removal. Instruct him to maintain each postural drainage position for 10 minutes. Then direct the caregiver in performing percussion and instructing the patient to cough.
- u If appropriate, advise the patient to stop smoking because it stimulates secretions and irritates the airways. Refer the patient to a local smoking-cessation group.
- u Instruct the patient to avoid air pollutants and people with known upper respiratory tract infections.
- u Direct the patient to take medications (especially antibiotics) exactly as ordered. Make sure he knows the adverse effects associated with his medications. Instruct him to notify the doctor if any of these effects occur.

HOME CARE

Bronchiectasis care

Review the following home care points with the patient and the family regarding bronchiectasis:

- u Ensure that the patient is able to perform coughing and deep-breathing exercises prior to discharge.
- u The patient should be encouraged to rest as much as possible.
- u The patient should be encouraged to consume a balanced high-protein diet and plenty of fluids to promote healing and expectoration of secretions.
- u Postural drainage, percussion, and mouth care should be taught to the family to promote bronchial hygiene and prevention of infection.
- u Proper disposal of secretions should be discussed.
- u Review the importance of avoiding infection and situations where smoking is involved to promote health and well-being.

- u Teach the patient to dispose of all secretions properly to avoid spreading the infection to others. Advise him to wash his hands thoroughly after disposing of contaminated tissues.
- u Urge the patient to keep up-to-date in his immunization schedule to prevent childhood diseases.
- u Encourage the patient to rest as much as possible.
- u Discuss dietary measures. Encourage the patient to follow a balanced, high-protein diet. Suggest that he eat small, frequent meals. Explain that milk products may increase the viscosity of secretions. (See [Bronchiectasis care.](#))
- u Encourage the patient to drink plenty of fluids to thin secretions and to aid expectoration.
- u If the patient needs surgery, offer complete preoperative and postoperative instructions. Forewarn the patient if he is to have an I.V. line and chest tubes. Explain the reason for these procedures.

CHRONIC BRONCHITIS

Chronic bronchitis is a form of chronic obstructive pulmonary disease. It's marked by excessive production of tracheobronchial mucus that is sufficient to cause a

cough for at least 3 months each year for 2 consecutive years.

PATHOPHYSIOLOGY

What happens in chronic bronchitis

In chronic bronchitis, irritants inhaled for a prolonged period inflame the tracheobronchial tree. The inflammation leads to increased mucus production and a narrowed or blocked airway.

As inflammation continues, the mucus-producing goblet cells undergo hypertrophy, as do the ciliated epithelial cells that line the respiratory tract. Hypersecretion from the goblet cells blocks the free movement of the cilia, which normally sweep dust, irritants, and mucus from the airways. As a result, the airway stays blocked, and mucus and debris accumulate in the respiratory tract.

CROSS SECTION OF NORMAL BRONCHIAL TUBE

NARROWED BRONCHIAL TUBE IN CHRONIC BRONCHITIS

The severity of the disease is linked to the amount of cigarette smoke or other pollutants inhaled and the duration of the inhalation. A respiratory tract infection typically exacerbates the cough and related symptoms. However, few patients with chronic bronchitis develop significant airway obstruction. About 20% of men have chronic bronchitis.

Causes and pathophysiology

Cigarette smoking is the most common cause of chronic bronchitis. Some studies suggest a genetic predisposition to the disease as well.

The disease is directly correlated to heavy pollution and is more prevalent in people exposed to organic or inorganic dusts and noxious gases. Children of parents who smoke are at higher risk for respiratory tract infections that can lead to chronic bronchitis.

Chronic bronchitis results in hypertrophy and hyperplasia of the bronchial mucous glands, increased goblet cells, ciliary damage, squamous metaplasia of the columnar epithelium, and chronic leukocytic and lymphocytic infiltration of bronchial walls. Additional effects include widespread inflammation, airway narrowing, and mucus within the airways—all producing resistance in the small airways and, in turn, a severe ventilation-perfusion imbalance. (See [What happens in chronic bronchitis.](#))

Complications

Chronic bronchitis can lead to cor pulmonale, pulmonary hypertension, right ventricular hypertrophy, and acute respiratory failure.

Assessment findings

The patient's history typically reflects a long-time smoker who has frequent upper respiratory tract infections. Usually, the patient seeks treatment for a productive cough and exertional dyspnea. He may describe his cough as initially prevalent in the winter months but gradually becoming a year-round problem with increasingly severe episodes. He also typically reports progressively worsening dyspnea that takes increasingly longer to subside.

Inspection usually reveals a cough, producing copious gray, white, or yellow sputum. The patient may appear cyanotic, and he may use accessory respiratory muscles for breathing (a “blue bloater”). Vital signs usually include tachypnea; other typical findings include a substantial weight gain.

Palpation may disclose pedal edema and neck vein distention. Auscultation findings include wheezing, prolonged expiratory time, and rhonchi.

Diagnostic tests

Chest X-rays may show hyperinflation and increased bronchovascular markings.

Pulmonary function tests demonstrate increased residual volume, decreased vital capacity and forced expiratory flow, and normal static compliance and diffusing

capacity.

Arterial blood gas (ABG) analysis displays decreased partial pressure of arterial oxygen and normal or increased partial pressure of arterial carbon dioxide.

Sputum culture may reveal many microorganisms and neutrophils.

Electrocardiography may reveal atrial arrhythmias, peaked P waves in leads II, III, and aV_F and, occasionally, right ventricular hypertrophy.

Treatment

The most effective treatment is for the patient to stop smoking and to avoid air pollutants as much as possible. Antibiotics can be used to treat recurring infections. Bronchodilators may relieve bronchospasm and facilitate mucus clearance. Adequate fluid intake is essential, and chest physiotherapy may be needed to mobilize secretions. Ultrasonic or mechanical nebulizer treatments may help to loosen and mobilize secretions. Occasionally, a patient responds to corticosteroid therapy. Diuretics may be used to treat edema, and oxygen may be necessary to treat hypoxia.

Nursing diagnoses

⌞ Altered family processes ⌞ Altered nutrition: Less than body requirements ⌞ Anxiety ⌞ Fatigue ⌞ Fear ⌞ Impaired gas exchange ⌞ Ineffective breathing pattern ⌞ Knowledge deficit

Key outcomes

- ⌞ The patient will maintain adequate ventilation.
- ⌞ The patient will identify measures to prevent or reduce fatigue.
- ⌞ The patient will express an understanding of the illness.
- ⌞ Family members will identify and contact available support systems as needed.
- ⌞ The patient will express feelings of comfort and decreased fear and anxiety.

Nursing interventions

- ⌞ Answer the patient's questions, and encourage him and family members to express their concerns about the illness. Include the patient and family members in care decisions. Refer them to other support services as appropriate.
- ⌞ Assess for changes in baseline respiratory function. Evaluate sputum quality and quantity, restlessness, increased tachypnea, and altered breath sounds. Report changes immediately.
- ⌞ As needed, perform chest physiotherapy, including postural drainage and chest percussion and vibration for involved lobes, several times daily.
- ⌞ Weigh the patient three times weekly, and assess for edema.
- ⌞ Provide the patient with a high-calorie, protein-rich diet. Offer small, frequent meals to conserve the patient's energy and prevent fatigue.
- ⌞ Make sure the patient receives adequate fluids (at least 3 L [3.2 qt] a day) to loosen secretions.
- ⌞ Schedule respiratory therapy at least 1 hour before or after meals. Provide mouth care after bronchodilator inhalation therapy.
- ⌞ Encourage daily activity, and provide diversional activities as appropriate. To conserve the patient's energy and prevent fatigue, help him to alternate periods of rest and activity.
- ⌞ Administer medications as ordered, and note the patient's response to them.

Patient teaching

- ⌞ Advise the patient to avoid crowds and people with known infections and to obtain influenza and pneumococcus immunizations.
- ⌞ If the patient is receiving home oxygen therapy, explain the treatment rationale. Show him how to operate the equipment.
- ⌞ Teach the patient and family how to perform postural drainage and chest percussion. Instruct the patient to maintain each position for 10 minutes before a caregiver performs percussion and the patient coughs. Teach the patient coughing and deep-breathing techniques to promote good ventilation and to remove secretions.
- ⌞ Review all medications, including dosage, adverse effects, and purposes for the prescriptions. Teach the patient how to use an inhaler. Advise him to report any adverse reactions to the doctor immediately.
- ⌞ Encourage the patient to eat high-calorie, protein-rich meals and to drink plenty of fluids to prevent dehydration and help loosen secretions.
- ⌞ If the patient smokes, encourage him to stop. Provide him with smoking-cessation resources or counseling if necessary.
- ⌞ Urge the patient to avoid inhaled irritants, such as automobile exhaust fumes, aerosol sprays, and industrial pollutants.
- ⌞ Warn the patient that exposure to blasts of cold air may precipitate bronchospasm. Suggest that he avoid cold, windy weather or that he cover his mouth and nose with a scarf or mask if he must go outside.
- ⌞ If the patient takes methylxanthines such as theophylline, warn him that cigarette or marijuana smoking significantly increases plasma clearance of the medication. Also, patients who quit smoking should notify the doctor because they may experience the onset of adverse effects of higher blood levels of theophylline.
- ⌞ If appropriate, describe the signs and symptoms of peptic ulcer disease. Instruct the patient to check his stools every day for blood and to notify the doctor if he has persistent nausea, vomiting, heartburn, indigestion, constipation, diarrhea, or bloody stools.

COAL WORKER'S PNEUMOCONIOSIS

Coal worker's pneumoconiosis is a progressive, nodular pulmonary disease. It's also known as black lung, coal miner's disease, miner's asthma, anthracosis, and anthracosilicosis. The disease occurs in two forms: simple and complicated. With the simple form, the patient has characteristically limited lung capacity. In this patient, complicated coal worker's pneumoconiosis (also known as progressive massive fibrosis) may develop. In the complicated form, fibrous tissue masses form in the lungs.

A person's risk for coal worker's pneumoconiosis depends on various factors, including how long he has been exposed to coal dust (usually at least 15 years), the intensity of his exposure (dust count and size of inhaled particles), his proximity to the mine site, the silica content of the coal (anthracite has the highest silica content), and his susceptibility. The highest incidence of this disease is among anthracite miners in the eastern United States.

Causes and pathophysiology

Inhalation and prolonged retention of respirable coal dust particles (less than 5 microns wide) cause coal worker's pneumoconiosis. In the simple form, macules (coal dust–laden macrophages) form around terminal and respiratory bronchioles and are surrounded by a halo of dilated alveoli. At the same time, supporting tissues atrophy and harden, causing permanent small-airway dilation (focal emphysema). Simple coal worker's pneumoconiosis may progress to the complicated form—most likely if the disease begins after a relatively short exposure.

Complicated coal worker's pneumoconiosis may involve one or both lungs. Fibrous tissue masses enlarge and coalesce, grossly distorting pulmonary structures as the disease progressively destroys vessels, alveoli, and airways.

Complications

Pulmonary hypertension, cor pulmonale, and pulmonary tuberculosis can complicate coal worker's pneumoconiosis. In cigarette smokers, chronic bronchitis and emphysema can also complicate the disease.

Assessment findings

Whether the patient has simple or complicated coal worker's pneumoconiosis, the patient history discloses exposure to coal dust. In the simple form, the patient is

typically asymptomatic, especially if he's a nonsmoker.

If the patient has complicated coal worker's pneumoconiosis, the patient history may reveal exertional dyspnea and a cough. This patient may state that he occasionally coughs up inky-black sputum (from avascular necrosis and cavitation).

Additionally, the patient may report a productive cough with milky, gray, clear, or coal-flecked sputum or yellow, green, or thick sputum with recurrent bronchial and pulmonary infections.

Inspection may reveal a barrel chest. Percussion may uncover hyperresonant lungs with areas of dullness. On auscultation, you hear diminished breath sounds, crackles, rhonchi, and wheezes.

Diagnostic tests

Chest X-rays in simple coal worker's pneumoconiosis show small opacities (less than 10 mm in diameter). These opacities may inhabit all lung zones but appear more prominent in the upper lung zones. In complicated coal worker's pneumoconiosis, X-rays may show one or more large opacities (1 to 5 cm in diameter). Some may exhibit cavitation.

Pulmonary function studies indicate a vital capacity that is normal in simple coal worker's pneumoconiosis but decreased in the complicated form; decreased forced expiratory volume in 1 second (FEV₁) in the complicated form; and a normal ratio of FEV₁ to forced vital capacity. The ratio of residual volume to total lung capacity is normal in the simple form but decreased in the complicated form. Diffusing capacity for carbon monoxide—significantly below normal in the complicated form—reflects alveolar septal destruction and pulmonary capillary obliteration.

Arterial blood gas analysis typically shows normal partial pressure of arterial oxygen (Pa O₂) in simple coal worker's pneumoconiosis but decreased Pa O₂ in complicated disease. Partial pressure of arterial carbon dioxide is normal in the simple form (possibly decreasing in hyperventilation) but may increase if the patient is hypoxic and has severely impaired alveolar ventilation.

Treatment

The goal of treatment is to relieve respiratory symptoms, manage hypoxia and cor pulmonale, and avoid respiratory tract irritants and infections. Treatment also includes observation for developing tuberculosis.

Respiratory signs and symptoms may be relieved by bronchodilator therapy with theophylline or aminophylline (if bronchospasm is reversible), oral or inhaled sympathomimetics (such as metaproterenol), corticosteroids (such as oral prednisone or aerosolized beclomethasone), or inhalable cromolyn sodium. Chest physiotherapy may be used to mobilize and remove secretions.

Other measures include increased fluid intake (at least 3 L [3.2 qt] daily) and respiratory therapy with aerosolized preparations, inhaled mucolytics, and intermittent positive-pressure breathing or incentive spirometry. Diuretic agents, digitalis glycoside preparations, and sodium restriction may be ordered to treat cor pulmonale.

In serious illness, oxygen may be administered by cannula or mask (usually 1 to 2 L/minute) if the patient has chronic hypoxia, or by mechanical ventilation if Pa O₂ falls below 40 mm Hg.

Respiratory tract infections require prompt administration of antibiotics.

Nursing diagnoses

⌞ Altered family processes ⌞ Altered nutrition: Less than body requirements ⌞ Anxiety ⌞ Fatigue ⌞ Fear ⌞ Impaired gas exchange ⌞ Ineffective breathing pattern ⌞ Knowledge deficit

Key outcomes

- ⌞ The patient will maintain adequate ventilation.
- ⌞ The patient will use support systems to assist with coping.
- ⌞ Family members will identify and contact available resources as needed.
- ⌞ The patient will consume a specific number of calories daily.
- ⌞ The patient will identify measures to prevent or reduce fatigue.
- ⌞ The patient will express an understanding of the illness.

Nursing interventions

- ⌞ Help the patient adjust to lifestyle changes necessitated by chronic illness. Answer his questions, and encourage him to express his concerns. Include the patient and family members in care-related decisions.
- ⌞ Assess for changes in baseline respiratory function. Be alert for changes in sputum quality and quantity. Watch for restlessness, increased tachypnea, and changes in breath sounds. Report these changes immediately.
- ⌞ Provide the patient with high-calorie, high-protein foods, and offer small, frequent meals to conserve his energy and prevent fatigue.
- ⌞ Make sure the patient receives adequate fluids to loosen secretions.
- ⌞ Perform chest physiotherapy, including postural drainage and chest percussion and vibration, several times daily.
- ⌞ Schedule respiratory therapy at least 1 hour before or after meals. Provide mouth care after inhalation therapy.
- ⌞ If the patient requires incentive spirometry, assist him to a comfortable sitting or semi-Fowler's position to promote optimal lung expansion.
- ⌞ Encourage daily activity. Provide diversional activities as appropriate. To conserve the patient's energy and prevent fatigue, alternate periods of rest and activity.
- ⌞ Administer medications as ordered. Record the patient's response.
- ⌞ Watch for complications, such as pulmonary hypertension, cor pulmonale, and tuberculosis.

Patient teaching

- ⌞ Advise the patient to avoid crowds and people with known infections and to obtain influenza and pneumococcus immunizations.
- ⌞ If the patient receives home oxygen therapy, explain its purpose. Teach him how to use the equipment.
- ⌞ Teach the patient and family members how to perform chest physiotherapy with postural drainage and chest percussion. Advise the patient to maintain each position for about 10 minutes and then to perform percussion and coughing exercises. Teach him coughing and deep breathing techniques to promote good ventilation and to remove secretions.
- ⌞ Show the patient how to use an incentive spirometer properly, and tell him why he needs it.
- ⌞ Explain the patient's medication regimen to him and family members. Discuss the dosages, adverse effects, and purposes of prescribed drugs.
- ⌞ Encourage the patient to follow a high-calorie, high-protein diet and to drink plenty of fluids to prevent dehydration and help loosen secretions.
- ⌞ If the patient smokes, urge him to stop. Provide him with further information, or refer him for counseling.
- ⌞ As appropriate, provide information about coal worker's pneumoconiosis, including prevention. Educate workers and employers concerning the importance of wearing effective respirators in the workplace.

CYSTIC FIBROSIS

Cystic fibrosis is a chronic, progressive, inherited disease that affects the exocrine (mucus-secreting) glands. The disease is transmitted as an autosomal recessive

trait and is the most common fatal genetic disease of white children. When both parents are carriers of the recessive gene, they have a 25% chance of transmitting the disease with each pregnancy.

CULTURAL TIP The incidence of cystic fibrosis is highest in people of northern European ancestry. The disease is less common in Blacks, Native Americans, and people of Asian ancestry. It occurs with equal frequency in both sexes.

Cystic fibrosis is incurable, but medical research is being conducted to find better treatment. Life expectancy has greatly increased. Previously, patients with cystic fibrosis died by about age 16; today they live to age 28 or older.

Causes and pathophysiology

The gene responsible for cystic fibrosis encodes a protein that involves chloride transport across epithelial membranes. More than 100 specific mutations of the gene have been identified. The immediate causes of symptoms are increased viscosity of bronchial, pancreatic, and other mucous gland secretions and consequent destruction of glandular ducts. Cystic fibrosis accounts for almost all cases of pancreatic enzyme deficiency in children.

Complications

Cystic fibrosis can cause bronchiectasis, pneumonia, atelectasis, hemoptysis, dehydration, distal intestinal obstructive syndrome, malnutrition, a deficiency of fat-soluble vitamins, gastroesophageal reflux, nasal polyps, rectal prolapse, and cor pulmonale. Other, inevitable complications that occur as the disease progresses include hepatic disease, diabetes, pneumothorax, arthritis, pancreatitis, cholecystitis, hypochloremia, hyponatremia, clotting problems, retarded bone growth, and delayed sexual development.

Assessment findings

The clinical effects of cystic fibrosis may become apparent soon after birth or may take years to develop. They include major aberrations in sweat gland, respiratory, and GI functions.

Sweat gland dysfunction

In cystic fibrosis, sweat gland dysfunction is the most consistent abnormality. Increased concentrations of sodium and chloride in the sweat lead to hyponatremia and hypochloremia and can eventually induce fatal shock and arrhythmias, especially in hot weather.

Respiratory symptoms

Such symptoms reflect obstructive changes in the lungs: wheezy respirations; a dry, nonproductive, paroxysmal cough; dyspnea; and tachypnea. These changes stem from thick, tenacious secretions in the bronchioles and alveoli and eventually lead to severe atelectasis and emphysema.

Children with cystic fibrosis display a barrel chest, cyanosis, and clubbing of the fingers and toes. They suffer recurring bronchitis and pneumonia and associated nasal polyps and sinusitis. Death typically results from pneumonia, emphysema, or atelectasis.

GI symptoms

The GI effects of cystic fibrosis occur mainly in the intestines, pancreas, and liver. One early symptom is meconium ileus; the newborn with cystic fibrosis doesn't excrete meconium, a dark-green mucilaginous material found in the intestine at birth. He develops symptoms of intestinal obstruction, such as abdominal distention, vomiting, constipation, dehydration, and electrolyte imbalance.

Eventually, obstruction of the pancreatic ducts and resulting deficiency of trypsin, amylase, and lipase prevent the conversion and absorption of fat and protein in the intestinal tract. The undigested food is then excreted in frequent, bulky, foul-smelling, and pale stool with a high fat content.

This malabsorption induces poor weight gain, poor growth, ravenous appetite, distended abdomen, thin extremities, and sallow skin with poor turgor. The inability to absorb fats produces a deficiency of fat-soluble vitamins (A, D, E, and K), leading to clotting problems, retarded bone growth, and delayed sexual development. Males may experience azoospermia and sterility; females may experience secondary amenorrhea but can reproduce.

A common complication in infants and children is rectal prolapse. This stems from malnutrition and wasting of perirectal supporting tissues.

In the pancreas, fibrotic tissue, multiple cysts, thick mucus and, eventually, fat replace the acini (small saclike swellings normally found in this gland). This results in signs of pancreatic insufficiency; insufficient insulin production, abnormal glucose tolerance, and glycosuria.

About 15% of patients are pancreatic sufficient, having adequate pancreatic exocrine function for normal digestion. These patients have a better prognosis.

Biliary obstruction and fibrosis may prolong neonatal jaundice. In some patients, cirrhosis and portal hypertension may lead to esophageal varices, episodes of hematemesis and, occasionally, hepatomegaly.

Diagnostic tests

According to the Cystic Fibrosis Foundation, a definitive diagnosis requires:

Two clearly positive sweat tests, using pilocarpine solution (a sweat inducer), and the presence of an obstructive pulmonary disease, confirmed pancreatic insufficiency or failure to thrive, or a family history of cystic fibrosis.

Chest X-rays that show early signs of lung obstruction

Stool specimen analysis that shows the absence of trypsin, suggesting pancreatic insufficiency.

The following test results may support the diagnosis:

Deoxyribonucleic acid testing can now locate the presence of the Delta F 508 deletion (found in about 70% of cystic fibrosis patients, although the disease can cause more than 100 other indications). This test can also be used for carrier detection and prenatal diagnosis in families with a previously affected child.

If pulmonary exacerbation exists, pulmonary function tests can reveal decreased vital capacity, elevated residual volume due to air entrapments, and decreased forced expiratory volume in 1 second.

A liver enzyme test may reveal hepatic insufficiency; a sputum culture may reveal organisms that patients typically and chronically colonize, such as *Pseudomonas* and *Staphylococcus*.

A serum albumin level helps to assess nutritional status, and electrolyte analysis is used to assess for dehydration.

Treatment

Because cystic fibrosis has no cure, the goal of treatment is to help the patient lead as normal a life as possible. Specific treatments depend on the organ systems involved.

- u To combat electrolyte loss through sweat, the patient should generously salt his food and, during hot weather, take salt supplements.
- u Oral pancreatic enzymes taken with meals and snacks offsets pancreatic enzyme deficiencies. Such supplements improve absorption and digestion and help satisfy hunger on a reasonable caloric intake. The patient should also follow a diet that is high in fat, protein, and calories and includes vitamin A, D, E, and K supplements.
- u To manage pulmonary dysfunction, the patient should undergo chest physiotherapy, nebulization to loosen secretions followed by postural drainage, and breathing exercises several times daily to help remove lung secretions. But he shouldn't receive antihistamines, which dry mucous membranes, making mucus expectoration difficult.
- u Dornase alfa, a pulmonary enzyme given by aerosol nebulizer, helps to thin airway mucus, improving lung function and reducing the risk of pulmonary infection.
- u A patient with pulmonary infection needs to loosen and remove mucopurulent secretions by using intermittent nebulizer and postural drainage to relieve obstruction. Use of a cool-mist tent is controversial because mist particles may become trapped in the esophagus and stomach, never reaching the lungs.
- u Broad-spectrum antibiotics are used to control infection.
- u Oxygen therapy is used as needed.

HOME CARE

Managing cystic fibrosis

To help your patient manage cystic fibrosis at home, use the following as a guide:

- u Review breathing exercises and treatments with the patient and his family.
- u Evaluate the patient's and family's techniques for performing chest physiotherapy (CPT); reinstruct them if needed.
- u Encourage the use of CPT in the morning, before eating, after nebulization treatments, and before bedtime; recommend increasing CPT frequency whenever mucus becomes more abundant than usual.
- u Advise the patient not to eat for 1 hour prior to CPT.
- u Teach the patient to avoid tight or restrictive clothing around his chest, neck, or stomach. Suggest that he wear a nightshirt or gown to prevent friction during CPT.
- u Help the family find alternatives to cupped hands for CPT such as using a small, lightweight plastic bowl or cup.
- u Stress the importance of supplemental enzyme therapy; evaluate the patient's compliance, and suggest ways to improve it.
- u Emphasize the need for a well-balanced, high-calorie, high-protein diet; assist with meal planning and food selection as needed.
- u Help the patient and family obtain necessary equipment, supplies, and medications.
- u Provide referrals to local community agencies and the Cystic Fibrosis Foundation as needed.

- u Heart-lung transplantation may reduce the effects of the disease.
- u Since the discovery of the basic genetic defect of cystic fibrosis, new treatments have been explored. Experimental treatments include drugs such as amiloride and gene therapy. Researchers have targeted the lungs for gene therapy because the most serious pathology occurs there. They hope to insert corrected genetic material into lung stem cells, which produce new lung cells. Lung stem cells might be reached through an aerosolized delivery system currently under study.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fear u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Ineffective family coping: Disabling u Knowledge deficit

Key outcomes

- u The patient will maintain a patent airway and adequate ventilation.
- u The patient will maintain a breath rate at ± 5 from baseline.
- u The patient will consume adequate daily calories as required.
- u The patient will use support systems to assist with coping.
- u Family members will express their concerns about coping with the patient's illness.
- u The patient and family members will express an understanding of the illness.

Nursing interventions

- u Give medications as ordered. Administer pancreatic enzymes with meals and snacks.
- u Perform chest physiotherapy, including postural drainage and chest percussion designed for all lobes, several times a day as ordered.
- u Administer oxygen therapy as ordered. Check levels of arterial oxygen saturation using pulse oximetry.
- u Provide a well-balanced, high-calorie, high-protein diet. Include plenty of fats, which, though difficult for the patient to digest, are nutritionally necessary. Give him enzyme capsules to help combat most of the effects of fat malabsorption. Include vitamin A, D, E, and K supplements if laboratory analysis indicates any deficiencies.
- u Make sure the patient receives plenty of liquids to prevent dehydration, especially in warm weather.
- u Provide exercise and activity periods for the patient to promote health. Encourage him to perform breathing exercises to help improve his ventilation.
- u Provide the young child with play periods, and enlist the help of the physical therapy department. Some pediatric facilities have play therapists, who provide essential playtime for young patients.
- u Provide emotional support to the parents of children with cystic fibrosis. Because it's an inherited disease, the parents may feel enormous guilt. Encourage them to discuss their fears and concerns, and answer their questions as honestly as possible.
- u Be flexible with care and visiting hours during hospitalization to allow the child to continue schoolwork and friendships.
- u Include the family in all phases of the child's care. If the child is an adolescent, he may want to perform much of his own treatment protocol. Encourage him to do so. (See [Managing cystic fibrosis.](#))

Patient teaching

- u Inform the patient and family members about the disease, and thoroughly explain all treatment measures. Make sure they know about tests that can determine if family members carry the cystic fibrosis gene.
- u Teach the patient and family members about all the medications the patient may be receiving. Explain possible adverse reactions, and urge them to notify the doctor if these reactions occur.
- u Instruct the patient and family members about aerosol therapy, including intermittent nebulizer treatments before postural drainage. Tell them that these treatments help to loosen secretions and dilate the bronchi.
- u Instruct members of the patient's family in proper methods of chest physiotherapy.
- u If the doctor prescribes aerobic exercises, teach the patient how to do them, and review their importance in maintaining respiratory muscle and cardiopulmonary function and in improving activity tolerance.
- u Teach the patient and family members signs of infection and sudden changes in the patient's condition that they should report to the doctor. These include increased coughing, decreased appetite, sputum that thickens or contains blood, shortness of breath, and chest pain.
- u Advise the parents of a child with the disease not to be overly protective. Instead, help them explore ways to enhance their child's quality of life and to foster responsibility and independence in him from an early age. Stress the importance of good communication so that the child may express his fears and concerns.

u Encourage participation in local groups such as Cystic Fibrosis Foundation to help meet patient and family needs.

EMPHYSEMA

Emphysema is one of several diseases usually labeled collectively as chronic obstructive pulmonary disease (COPD). It's the most common cause of death from respiratory disease in the United States; approximately 2 million Americans are afflicted with the disease. Emphysema appears to be more prevalent in men than in women. Postmortem findings reveal few adult lungs without some degree of emphysema.

Causes

Emphysema may be caused by a genetic deficiency of alpha₁-antitrypsin (AAT) and by cigarette smoking. Genetically, one in 3,000 newborns are found with the disease, and 1% to 3% of all cases of emphysema are due to AAT deficiency. Cigarette smoking is thought to cause up to 20% of the cases. Other causative factors are unknown. Recurrent inflammation associated with the release of proteolytic enzymes from lung cells causes abnormal, irreversible enlargement of the air spaces distal to the terminal bronchioles. This leads to the destruction of alveolar walls, which results in a breakdown of elasticity. (See [What happens in emphysema.](#))

Complications

In emphysema, complications may include recurrent respiratory tract infections, cor pulmonale, and respiratory failure (see [Cor pulmonale](#)). Peptic ulcer disease strikes 20% to 25% of patients with COPD. Additionally, alveolar blebs and bullae may rupture, leading to spontaneous pneumothorax or pneumomediastinum.

Assessment findings

The patient history may reveal that the patient is a long-time smoker. The patient may report shortness of breath and a chronic cough. The history may also reveal anorexia with resultant weight loss and a general feeling of malaise.

Inspection may show a barrel-chested patient who breathes through pursed lips and also uses accessory muscles. You may notice peripheral cyanosis, clubbed fingers and toes, and tachypnea.

Palpation may reveal decreased tactile fremitus and decreased chest expansion. Percussion may detect hyperresonance. On auscultation, you may hear decreased breath sounds, crackles and wheezing during inspiration, a prolonged expiratory phase with grunting respirations, and distant heart sounds.

Diagnostic tests

Chest X-rays in advanced disease may show a flattened diaphragm, reduced vascular markings at the lung periphery, overaeration of the lungs, a vertical heart, enlarged anteroposterior chest diameter, and large retrosternal air space.

Pulmonary function tests typically indicate increased residual volume and total lung capacity, reduced diffusing capacity, and increased inspiratory flow.

PATHOPHYSIOLOGY

What happens in emphysema

In normal, healthy breathing, air moves in and out of the lungs to meet metabolic needs. Any change in airway size compromises the lungs' ability to circulate sufficient air.

In a patient with emphysema, recurrent pulmonary inflammation damages and eventually destroys the alveolar walls, creating large air spaces. This breakdown leaves the alveoli unable to recoil normally after expanding and results in bronchiolar collapse on expiration. This traps air within the lungs.

Associated pulmonary capillary destruction usually allows a patient with severe emphysema to match ventilation to perfusion and thus avoid cyanosis.

NORMAL ALVEOLI

ABNORMAL ALVEOLI

Arterial blood gas analysis usually shows reduced partial pressure of arterial oxygen and normal partial pressure of arterial carbon dioxide until late in the disease.

Electrocardiography may reveal tall, symmetrical P waves in leads II, III, and aV_F; vertical QRS axis; and signs of right ventricular hypertrophy late in the disease.

Red blood cell count usually demonstrates an increased hemoglobin level late in the disease when the patient has persistent severe hypoxia.

Treatment

Emphysema management usually includes bronchodilators such as aminophylline to promote mucociliary clearance; antibiotics to treat respiratory tract infection; and immunizations to prevent influenza and pneumococcal pneumonia.

Other treatment measures include adequate hydration and (in selected patients) chest physiotherapy to mobilize secretions.

Some patients may require oxygen therapy (at low settings) to correct hypoxia. They may also require transtracheal catheterization to receive oxygen at home. Counseling about avoiding smoking and air pollutants is necessary.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Anxiety u Fatigue u Fear u Impaired gas exchange u Ineffective airway clearance u Ineffective breathing pattern u Knowledge deficit

Key outcomes

- u The patient will maintain patent airway and adequate ventilation.
- u The patient will demonstrate skill in conserving energy while carrying out daily activities to tolerance level.
- u The patient will consume adequate daily calories as required.
- u The patient will express an understanding of the illness.
- u The patient will identify measures to prevent or reduce fatigue.
- u The patient will use support systems to assist with coping.

Nursing interventions

- u Provide supportive care, and help the patient adjust to lifestyle changes necessitated by a chronic illness.
- u Answer the patient's questions about his illness as honestly as possible. Encourage him to express his fears and concerns about his illness. Remain with him during periods of extreme stress and anxiety.
- u Include the patient and family members in care-related decisions. Refer the patient to appropriate support services as needed.
- u If ordered, perform chest physiotherapy, including postural drainage and chest percussion and vibration, several times daily.
- u Provide the patient with a high-calorie, protein-rich diet to promote health and healing. Give small, frequent meals to conserve energy and prevent fatigue.
- u Schedule respiratory treatments at least 1 hour before or after meals. Provide mouth care after bronchodilator therapy.
- u Make sure the patient receives adequate fluids (at least 3 L [3.2 qt] a day) to loosen secretions.
- u Encourage daily activity, and provide diversionary activities as appropriate. To conserve energy and prevent fatigue, assist the patient to alternate periods of rest and activity.
- u Administer medications as ordered. Record the patient's response to these medications.
- u Watch for complications, such as respiratory tract infections, cor pulmonale, spontaneous pneumothorax, respiratory failure, and peptic ulcer disease.

Patient teaching

- u For family members of patients with familial emphysema, recommend a blood test for AAT deficiency. If a deficiency is found, stress the importance of not smoking and avoiding areas (if possible) where smoking is permitted.
- u Advise the patient to avoid crowds and people with known infections and to obtain influenza and pneumococcus immunizations.
- u For the patient receiving home oxygen therapy, explain the rationales for oxygen therapy and proper use of equipment. If the patient requires a transtracheal catheter, instruct him about catheter care, precautions, and follow-up.
- u Teach the patient and family members how to perform postural drainage and chest percussion. Instruct them to maintain each position for about 10 minutes and then perform percussion and cough. Also teach the patient coughing and deep-breathing techniques to promote good ventilation and mobilize secretions.
- u Review the patient's medications and explain the rationale, dosage, and adverse effects related to the prescribed drug. Advise him to report adverse reactions to the doctor immediately. Show him how to use an inhaler correctly, if appropriate.

Cor pulmonale

Cor pulmonale (right ventricular hypertrophy) is most common in patients who smoke and have chronic obstructive pulmonary disease (COPD). Because it usually occurs late in irreversible disorders of the lungs or associated structures, the prognosis is poor.

In cor pulmonale, pulmonary hypertension increases the heart's workload and the right ventricle hypertrophies to force blood through the lungs. As this compensatory mechanism fails, the right ventricle dilates. Due to hypoxia, the bone marrow produces more red blood cells and blood viscosity increases, aggravating pulmonary hypertension and causing heart failure.

The underlying disorder may first cause a productive cough, exertional dyspnea, wheezing, fatigue, and weakness. Later, look for dyspnea at rest, tachypnea, orthopnea, edema, weakness, right upper quadrant discomfort, dependent edema and distended neck veins, altered consciousness, tachycardia, weak pulse, enlarged and tender liver, hepatojugular reflux, and a prominent parasternal or epigastric cardiac impulse. With COPD, note crackles, rhonchi, and diminished breath sounds.

The diagnosis is based on pulmonary artery catheterization that shows increased right-ventricular and pulmonary artery pressures, echocardiography or angiography showing ventricular enlargement, and evidence from chest x-rays, arterial blood gas analysis, electrocardiography, pulmonary function tests, and hematocrit and serum hepatic enzyme and bilirubin levels.

Treatment may include bed rest, digoxin, antibiotics, pulmonary artery vasodilators, angiotensin-converting enzyme inhibitors, calcium channel blockers, prostaglandins, oxygen administration or mechanical ventilation, and dietary and diuretic measures. Phlebotomy, tracheotomy, anticoagulation therapy, and corticosteroids may be used.

- u Encourage the patient to eat high-calorie, protein-rich foods. Urge him to drink plenty of fluids to prevent dehydration and to help loosen secretions.
- u If the patient smokes, encourage him to stop. Provide him with smoking cessation resources or counseling, if necessary.
- u Urge the patient to avoid respiratory irritants, such as automobile exhaust fumes, aerosol sprays, and industrial pollutants.
- u Warn the patient that exposure to blasts of cold air may precipitate bronchospasm. Suggest that he avoid cold, windy weather or that he cover his mouth and nose with a scarf or mask if he must go outside.
- u If appropriate, describe signs and symptoms of peptic ulcer disease. Instruct the patient to check his stools every day for blood and to notify the doctor if he has persistent nausea, vomiting, heartburn, indigestion, constipation, diarrhea, or bloody stools.
- u Inform the patient about signs and symptoms that suggest ruptured alveolar blebs and bullae. Explain the seriousness of possible spontaneous pneumothorax. Urge

him to notify the doctor if he feels sudden, sharp pleuritic pain that is exacerbated by chest movement, breathing, or coughing.

SILICOSIS

Silicosis is the most common form of pneumoconiosis. It's a progressive disease characterized by nodular lesions, which frequently progress to fibrosis. It's classified according to the severity of the pulmonary disease and the rapidity of its onset and progression, although it usually occurs as a simple asymptomatic illness.

Causes

Those who work around silica dust, such as foundry workers, boiler scalers, and stone cutters, have the highest incidence of the disease. Silica in its pure form occurs in the manufacture of ceramics (flint) and building materials (sandstone). It occurs in mixed form in the production of construction materials (cement). It's also found in powder form (silica flour) in paints, porcelain, scouring soaps, and wood fillers and in the mining of gold, lead, zinc, and iron.

Sand blasters, tunnel workers, and others exposed to high concentrations of respirable silica may develop acute silicosis after 1 to 3 years. Those exposed to lower concentrations of free silica can develop accelerated silicosis, usually after about 10 years of exposure.

The prognosis is good unless the disease progresses to the complicated fibrotic brain. (See [Understanding silicosis.](#))

Complications

Silicosis may progress to massive areas of pulmonary fibrosis, which may continue to grow even though the patient is no longer exposed to dust. Pulmonary fibrosis, in turn, may result in cor pulmonale, ventricular or respiratory failure, and pulmonary tuberculosis.

Assessment findings

The patient has a history of long-term industrial exposure to silica dust. He may complain of dyspnea on exertion, which he's likely to attribute to “being out of shape” or “slowing down.” If the disease has progressed to the chronic and complicated state, the patient may report a dry cough, especially in the morning.

When you inspect the patient, you may note decreased chest expansion and tachypnea. If he has advanced disease, he may also act lethargic and look confused. You may percuss areas of increased and decreased resonance. On auscultation, you may hear fine to medium crackles, diminished breath sounds, and an intensified ventricular gallop on inspiration—a hallmark of cor pulmonale.

Diagnostic tests

Chest X-rays in simple silicosis show small, discrete, nodular lesions distributed throughout both lung fields, although they typically concentrate in the upper lung zones. The lung nodes may appear enlarged and show eggshell calcification. In complicated silicosis, X-rays show one or more conglomerate masses of dense tissue.

Pulmonary function tests demonstrate reduced forced vital capacity (FVC) in complicated silicosis. If the patient has obstructive disease (emphysematous silicosis areas), forced expiratory volume in 1 second (FEV₁) is reduced. A patient with complicated silicosis also has reduced FEV₁ but has a normal or high ratio of FEV₁ to FVC. When fibrosis destroys alveolar walls and obliterates pulmonary capillaries or when it thickens the alveolocapillary membrane, the diffusing capacity for carbon monoxide falls below normal. Both restrictive and obstructive disease reduce maximal voluntary ventilation.

Arterial blood gas analysis reveals a normal partial pressure of arterial oxygen in simple silicosis, but it may drop significantly below normal in late stages or complicated disease. The patient has normal partial pressure of arterial carbon dioxide (Pac O₂) in the early stages of the disease, but hyperventilation may cause it to drop below normal. If restrictive lung disease develops—particularly if the patient is hypoxic and has severe alveolar ventilatory impairment—Paco₂ may increase above normal.

Treatment

The goal is to relieve respiratory symptoms, manage hypoxia and cor pulmonale, and prevent respiratory tract infections and irritations. Treatment includes careful observation for the development of tuberculosis.

Daily bronchodilation aerosols and increased fluid intake (at least 3 L [3.2 qt] daily) relieve respiratory signs and symptoms. Steam inhalation and chest physiotherapy (such as controlled coughing and segmental bronchial drainage) with chest percussion and vibration help clear secretions.

In severe cases, the patient may need oxygen by cannula, mask, or mechanical ventilation (if he can't maintain arterial oxygenation). Respiratory tract infection warrants prompt antibiotic administration.

Nursing diagnoses

u Altered family processes u Altered nutrition: Less than body requirements u Anxiety u Fatigue u Fear u Impaired gas exchange u Ineffective breathing pattern u Knowledge deficit

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will identify measures to prevent or reduce fatigue.
- u The patient and family members will identify and contact available resources as needed.
- u The patient will express an understanding of the illness.

Nursing interventions

- u Assess for changes in baseline respiratory functioning, including changes in sputum quality and quantity, restlessness, increased tachypnea, and changes in breath sounds. Report any changes to the doctor immediately.
- u Perform chest physiotherapy, including postural drainage and chest percussion and vibration designed for involved lobes, several times a day.
- u Provide the patient with a high-calorie, high-protein diet, preferably in small, frequent meals.
- u Schedule respiratory therapy at least 1 hour before or after meals. Provide mouth care after bronchodilator therapy.
- u Make sure the patient receives enough fluids to loosen secretions.
- u Encourage daily activity, and provide the patient with diversional activities as appropriate. To conserve his energy, alternate periods of rest and activity.
- u Administer medication as ordered. Monitor the patient for desired response and for adverse reactions.

PATHOPHYSIOLOGY

Understanding silicosis

Silicosis results when respirable crystalline silica dust, mostly from quartz, is inhaled and deposited in the pulmonary system. The risk depends on the concentration of dust in the atmosphere, the percentage of respirable free silica particles in the dust, and the duration of exposure. Although particles up to 10 microns in diameter can be inhaled, the disease-causing particles deposited in the alveolar space usually have a diameter of only 1 to 3 microns.

Nodules result when alveolar macrophages ingest the silica particles, which they can't process. As a result, the macrophages die and release proteolytic enzymes into surrounding tissue. The enzymes inflame the tissue, attracting other macrophages and fibroblasts. These produce fibrous tissue to wall off the reaction, resulting in a nodule that has an onionskin appearance.

These nodules develop adjacent to the terminal and respiratory bronchioles. The nodules are concentrated in the upper lung lobes but are frequently accompanied by bullous changes in both upper and lower lobes. If the disease doesn't progress, the patient may experience only minimal physiologic disturbances with no disability. Occasionally, however, the fibrotic response accelerates, engulfing and destroying a large area of the lung.

- u Watch for complications, such as pulmonary fibrosis, right ventricular hypertrophy, and cor pulmonale.
- u Help the patient adjust to the lifestyle changes associated with a chronic illness. Answer his questions, and encourage him to express his concerns about his illness.
- u Stay with him during periods of extreme stress and anxiety, and include the patient and family members in care decisions whenever possible.

Patient teaching

- u Advise the patient to avoid crowds and people with known infections. He should also receive influenza and pneumococcus immunizations.
- u Teach the patient receiving home oxygen therapy the reasons for treatment and the proper use of the equipment. If he needs a transtracheal catheter, teach him catheter care and precautions.
- u Show the patient and family members how to perform postural drainage and chest percussion. Also teach the patient coughing and deep-breathing techniques, explaining that they're done to help him breathe and remove secretions. Tell him to remain in each position for 10 minutes. Percussion and coughing should follow.
- u Thoroughly explain all medications.
- u Encourage the patient to follow a high-calorie, high-protein diet and to drink plenty of fluids to prevent dehydration and help loosen secretions.
- u If the patient smokes, encourage him to quit and, if necessary, refer him to resources that can help.
- u Warn the patient of the risk of tuberculosis and advise him to be tested as ordered.
- u Refer the patient and family members to other support services as appropriate.
- u If you have a patient at risk for silicosis, teach him the importance of wearing a mask and using other protective devices to reduce his risk.

TUBERCULOSIS

Tuberculosis (TB) is an acute or chronic infection characterized by pulmonary infiltrates and by the formation of granulomas with caseation, fibrosis, and cavitation. The American Lung Association estimates that active disease has increased by more than 20% in the past 5 years.

The disease is twice as common in men as in women and four times as common in nonwhites as in whites. Incidence is highest in people who live in crowded, poorly ventilated, unsanitary conditions, such as prisons, tenement houses, and homeless shelters. The typical newly diagnosed patient with TB is a single, homeless, nonwhite man. With proper treatment, the prognosis is usually excellent.

Causes

TB results from exposure to *Mycobacterium tuberculosis* and, sometimes, other strains of mycobacteria. Transmission occurs when an infected person coughs or sneezes, spreading infected droplets. (See [Understanding tuberculosis.](#))

The following are at-risk populations that incur a high incidence of TB with presenting symptoms:

- u Black and Hispanic men between ages 25 and 44
- u those in close contact with a newly diagnosed patient with TB
- u those who have had TB before
- u people with multiple sexual partners
- u recent immigrants from Africa, Asia, Mexico, and South America
- u gastrectomy patients
- u people affected with silicosis, diabetes, malnutrition, cancer, Hodgkin's disease, or leukemia
- u drug and alcohol abusers
- u patients in mental health facilities
- u nursing home residents, who are 10 times more likely to contract TB than anyone in the general population
- u those receiving treatment with immunosuppressants or corticosteroids
- u people with weak immune systems or diseases that affect the immune system, especially those with acquired immunodeficiency syndrome
- u prisoners
- u homeless persons.

Complications

TB can cause massive pulmonary tissue damage, with inflammation and tissue necrosis eventually leading to respiratory failure. Bronchopleural fistulas can develop from lung tissue damage, resulting in pneumothorax. The disease can also lead to hemorrhage, pleural effusion, and pneumonia. Small mycobacterial foci can infect other body organs, including the kidneys and the central nervous and skeletal systems. The patient also might develop complications such as liver involvement from drug therapy.

Assessment findings

The patient with a primary infection after an incubation period of 4 to 8 weeks is usually asymptomatic but may complain of weakness and fatigue, anorexia and weight loss, low-grade fever, and night sweats. The patient with reactivated TB may report chest pain and a cough that produces blood or mucopurulent or blood-tinged sputum. He may also have a low-grade fever.

When you percuss, you may note dullness over the affected area, a sign of consolidation or the presence of pleural fluid. On auscultation, you may hear crepitant crackles, bronchial breath sounds, wheezes, and whispered pectoriloquy.

Diagnostic tests

Several of the following tests may be necessary to distinguish TB from other diseases that may mimic it, such as lung carcinoma, lung abscess, pneumoconiosis, and bronchiectasis.

Chest X-rays show nodular lesions, patchy infiltrates (mainly in upper lobes), cavity formation, scar tissue, and calcium deposits. They may not help distinguish between active and inactive TB.

A tuberculin skin test reveals that the patient has been infected with TB at some point, but it doesn't indicate active disease. In this test, intermediate-strength purified protein derivative or 5 tuberculin units (0.1 ml) are injected intradermally on the forearm and read in 48 to 72 hours. A positive reaction (greater than or equal to a

10-mm induration) develops within 2 to 10 weeks after infection with the tubercle bacillus in both active and inactive TB.

Stains and cultures of sputum, cerebrospinal fluid, urine, drainage from abscess, or pleural fluid show heat-sensitive, nonmotile, aerobic, acid-fast bacilli.

Computed tomography scans or magnetic resonance imaging allow the evaluation of lung damage or confirm a difficult diagnosis.

Bronchoscopy may be performed if the patient can't produce an adequate sputum specimen.

Treatment

Antitubercular therapy with daily oral doses of isoniazid, rifampin, and pyrazinamide (with ethambutol added in some cases) for at least 6 months usually cures TB. After 2 to 4 weeks, the disease is no longer infectious and the patient can resume normal activities while continuing to take medication.

The patient with atypical mycobacterial disease or drug-resistant TB may require second-line drugs, such as capreomycin, streptomycin, paraaminosalicylic acid, pyrazinamide, and cycloserine.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Anxiety
- u Fear
- u Impaired gas exchange
- u Ineffective airway clearance
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient's airway will remain patent.
- u The patient will use support systems to assist with coping.
- u The patient will consume adequate daily calories as required.
- u The patient will identify measures to prevent or reduce fatigue.

PATHOPHYSIOLOGY

Understanding tuberculosis

When a person without immunity inhales droplets infected with *Mycobacterium tuberculosis*, the bacilli lodge in the alveoli, causing irritation. The immune system responds by sending leukocytes, lymphocytes, and macrophages to surround the bacilli, and the local lymph nodes swell and become inflamed.

If the encapsulated bacilli (tubercles) and the inflamed nodes rupture, the infection contaminates the surrounding tissue and may spread through the blood and lymphatic circulation to distant sites—a process called hematogenous dissemination. This same phagocytic cycle occurs whenever the bacilli spread. Sites of extrapulmonary tuberculosis include the pleura, meninges, joints, lymph nodes, peritoneum, and GI tract.

After exposure to *M. tuberculosis*, roughly 5% of infected people develop active tuberculosis within 1 year. In the remainder, microorganisms cause a latent infection. The host's immunologic defense system usually destroys the bacillus or walls it up in a tubercle. But the live, encapsulated bacilli may lie dormant within the tubercle for years, reactivating later to cause active infection. In this respect, the disease is an opportunistic infection.

- u The patient will express an understanding of the illness and comply with treatment modalities.

Nursing interventions

- u Administer ordered antibiotics and antitubercular agents.
- u Isolate the infectious patient in a quiet, properly ventilated room, as per guidelines from the Centers for Disease Control and Prevention, and maintain TB precautions. Provide diversional activities and check on him frequently. Make sure the call button is nearby.
- u Place a covered trash can nearby, or tape a waxed bag to the bedside for used tissues. Tell the patient to wear a mask when outside his room. Visitors and health care personnel should also take proper precautions while in the patient's room.
- u Make sure the patient gets plenty of rest. Provide for periods of rest and activity to promote health as well as conserve energy and reduce oxygen demand.
- u Provide the patient with well-balanced, high-calorie foods, preferably in small, frequent meals to conserve energy. (Small, frequent meals may also encourage the anorexic patient to eat more.) Record the patient's weight weekly. If he needs oral supplements, consult with the dietitian.

PREVENTION

Preventing tuberculosis

Explain respiratory and standard precautions to the hospitalized patient with tuberculosis. Before discharge, tell him that he must take precautions to prevent spreading the disease, such as wearing a mask around others, until his doctor tells him he's no longer contagious. He should tell all health care providers he sees, including his dentist and eye doctor, that he has tuberculosis so that they can institute infection-control precautions.

Teach the patient other specific precautions to avoid spreading the infection. Tell him to cough and sneeze into tissues and to dispose of the tissues properly. Stress the importance of washing his hands thoroughly in hot, soapy water after handling his own secretions. Also instruct him to wash his eating utensils separately in hot, soapy water.

- u Watch for adverse reactions to the medications.
- u Administer isoniazid with food. This drug can cause hepatitis or peripheral neuritis, so monitor levels of aspartate aminotransferase and alanine aminotransferase. To prevent or treat peripheral neuritis, give pyridoxine (vitamin B₆) as ordered.
- u If the patient receives ethambutol, watch for signs of optic neuritis; report them to the doctor, who's likely to discontinue the drug. Check the patient's vision monthly, and give this medication with food.
- u If the patient receives rifampin, watch for signs of hepatitis, purpura, and a flulike syndrome as well as other complications such as hemoptysis. Monitor liver and kidney function tests throughout therapy.
- u Perform chest physiotherapy, including postural drainage and chest percussion, several times a day.
- u Give the patient supportive care, and help him adjust to the changes he may have to make during his illness. Include the patient in care decisions, and let the family take part in the patient's care whenever possible.

Patient teaching

- u Show the patient and family members how to perform postural drainage and chest percussion. Also teach the patient coughing and deep-breathing techniques.

Instruct him to maintain each position for 10 minutes and then to perform percussion and cough.

- u Teach the patient the adverse effects of his medication, and tell him to report them immediately. Emphasize the importance of regular follow-up examinations, and instruct the patient and family members concerning the signs and symptoms of recurring TB. Stress the importance of faithfully following long-term treatment
- u Advise anyone exposed to an infected patient to receive tuberculin tests and, if a positive reaction occurs, chest X-rays and prophylactic isoniazid. (See [Preventing tuberculosis.](#))
- u Warn the patient taking rifampin that the drug temporarily makes body secretions appear orange; reassure him that this effect is harmless. If the patient is a woman, warn her that oral contraceptives may be less effective while she's taking rifampin.
- u Teach the patient the signs and symptoms that require medical assessment: increased cough, hemoptysis, unexplained weight loss, fever, and night sweats.
- u Stress the importance of eating high-calorie, high-protein, balanced meals.
- u Emphasize the importance of scheduling and keeping follow-up appointments.
- u Refer the patient to such support groups as the American Lung Association.

INTRODUCTION

The nervous system—the body's communications network—coordinates and organizes the functions of all other body systems. This intricate network has three main divisions:

- u the central nervous system (CNS), the control center, made up of the brain and the spinal cord
- u the peripheral nervous system, which includes nerves that connect the CNS to remote body parts and which relays and receives messages from these parts
- u the autonomic nervous system, which regulates the involuntary function of the internal organs.

Fundamental unit

The neuron is the fundamental unit of the nervous system. A neuron is a highly specialized conductor cell that receives and transmits electrochemical nerve impulses. It has a special, distinguishing structure. Delicate, threadlike nerve fibers extend from the central cell body and transmit signals: Axons carry impulses away from the cell body; dendrites carry impulses to it. Most neurons have multiple dendrites but only one axon.

Sensory (afferent) neurons transmit impulses from special receptors to the spinal cord or the brain. Motor (efferent) neurons transmit impulses from the CNS to regulate activity of muscles or glands. And interneurons (connecting or association neurons) shuttle signals through complex pathways between sensory and motor neurons. Interneurons account for 99% of all the neurons in the nervous system and include most of the neurons in the brain itself. (See [Structure of the neuron.](#))

Intricate control system

This intricate network of interlocking receptors and transmitters, with the brain and spinal cord, forms a dynamic control system—a “living computer”—that controls and regulates every mental and physical function. From birth to death, the nervous system efficiently organizes the body's affairs—controlling the smallest action, thought, or feeling; monitoring communication and the instinct for survival; and allowing introspection, wonder, and abstract thought. The brain, the center of this central system, is a large, soft mass of nervous tissue that is housed within the cranium and protected and supported by the meninges.

Structure of the neuron

A neuron consists of nerve fibers, dendrites, and axons. The neuron receives and transmits electrochemical nerve impulses.

The fragile brain and spinal cord are protected by bone (the skull and vertebrae), which cushions cerebrospinal fluid (CSF), and three membranes:

- u the *dura mater*, or outer sheath, made of tough, white fibrous tissue
- u the *arachnoid membrane*, the delicate and lacelike middle layer

u the *pia mater*, the inner meningeal layer, consisting of fine blood vessels held together by connective tissue. This membrane is thin and transparent and clings to the brain and spinal cord surfaces, carrying branches of the cerebral arteries deep into the brain's fissures and sulci.

Between the dura mater and the arachnoid membrane is the *subdural space*; between the pia mater and the arachnoid membrane is the *subarachnoid space*. Within the subarachnoid space and the brain's four ventricles is *CSF*, a liquid comprising water and traces of organic materials (especially protein), glucose, and minerals.

CSF is formed from blood in capillary networks called *choroid plexi*, which are located primarily in the brain's lateral ventricles. CSF is eventually reabsorbed into the venous blood through the *arachnoid villi*, in dural sinuses on the brain's surface.

The *cerebrum*, the largest portion of the brain, houses the nerve center that controls sensory and motor activities and intelligence. The outer layer of the cerebrum, the *cerebral cortex*, consists of neuron cell bodies, or gray matter; the inner layers consist of axons, or white matter, plus basal ganglia, which control motor coordination and steadiness. The cerebral surface is deeply convoluted, furrowed with elevations (gyri) and depressions (sulci).

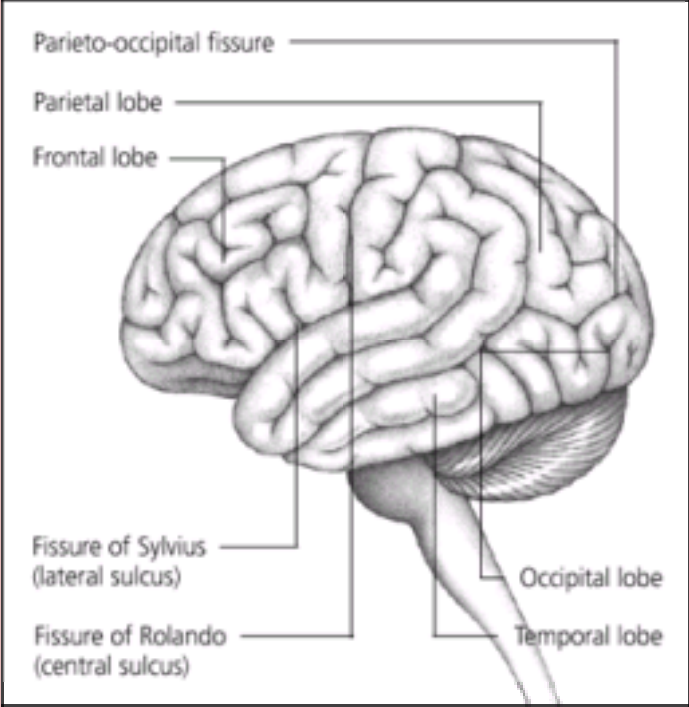

A look at the lobes

Several fissures divide the cerebrum into hemispheres and lobes; each lobe has a specific function. The *fissure of Sylvius* (lateral sulcus) separates the temporal lobe from the frontal and parietal lobes. The *fissure of Rolando* (central sulcus) separates the frontal lobes from the parietal lobe. The parieto-occipital fissure separates the occipital lobe from the two parietal lobes.

Lobes and their functions

The *frontal lobe* controls voluntary muscle movements and contains motor areas (including the motor area for speech, or Broca's area). It's the center for personality, behavioral, and intellectual functions, such as judgment, memory, and problem solving; for autonomic functions; and for cardiac and emotional responses.

The *temporal lobe* is the center for taste, hearing, and smell and, in the brain's dominant hemisphere, interprets spoken language. The *parietal lobe* coordinates and interprets sensory information from the opposite side of the body. The *occipital lobe* interprets visual stimuli.

The diagram illustrates the lateral view of the human brain, highlighting the four lobes and the major fissures that divide them. Labels on the left side point to the Parieto-occipital fissure, Parietal lobe, Frontal lobe, Fissure of Sylvius (lateral sulcus), and Fissure of Rolando (central sulcus). Labels on the right side point to the Occipital lobe and Temporal lobe. The brain is shown with its characteristic convoluted surface, with the cerebellum and brainstem visible at the base.

The *longitudinal fissure* divides the cerebrum into two hemispheres connected by a wide band of nerve fibers called the *corpus callosum*, which allows the hemispheres to share learning and intellect. These two hemispheres don't share equally; one always dominates, giving one side control over the other. Because motor impulses descending from the brain through the pyramidal tract cross in the medulla, the right hemisphere controls the left side of the body; the left hemisphere, the right side' of the body. Several fissures divide the cerebrum into lobes, each of which is associated with specific functions. (See [A look at the lobes.](#))

The *thalamus*, a relay center below the corpus callosum, further organizes cerebral function by transmitting impulses to and from appropriate areas of the cerebrum. Besides its primary relay function, the thalamus is responsible for primitive emotional response such as fear and for distinguishing pleasant stimuli from unpleasant ones.

The *hypothalamus*, which lies beneath the thalamus, is an autonomic center that has connections with the brain, spinal cord, autonomic nervous system, and pituitary gland. It regulates temperature, appetite, blood pressure, breathing, sleep patterns, and peripheral nerve discharges that occur with behavioral and emotional expression. It also partially controls pituitary gland secretion and stress reaction.

Base of the brain

Beneath the cerebrum, at the base of the brain, is the *cerebellum*. It's responsible for coordinating muscle movements with sensory impulses and maintaining muscle tone and equilibrium.

The *brain stem* houses cell bodies for most of the cranial nerves and includes the *midbrain*, the *pons*, and the *medulla oblongata*. With the thalamus and the hypothalamus, the brain stem makes up a nerve network called the *reticular formation*, which acts as an arousal mechanism. It also relays nerve impulses between the spinal cord and other parts of the brain. The midbrain is the reflex center for the third and fourth cranial nerves and mediates pupillary reflexes and eye movements. The pons helps regulate respirations. It's also the reflex center for the fifth through eighth cranial nerves and mediates chewing, taste, saliva secretion, hearing, and equilibrium. The medulla oblongata influences cardiac, respiratory, and vasomotor functions.

Blood flow to the brain

Four major arteries—two *vertebral* and two **carotid**—supply the brain with oxygenated blood. These arteries originate in or near the aortic arch. The two vertebral arteries (branches of the subclavians) converge to become the basilar artery, which supplies the posterior brain. The common carotids, which supply 85% to 90% of the brain's blood supply, branch into the two internal carotids, which divide further to supply the anterior brain and the middle brain. These arteries interconnect through the *circle of Willis* at the base of the brain. This anastomosis ensures continual circulation to the brain despite interruption of any of the brain's major vessels.

Inside the spinal cord

A cross section of the spinal cord shows an internal H-shaped mass of gray matter divided into horns, which consist primarily of neuron cell bodies. Cell bodies in the *posterior*, or *dorsal*, horn primarily relay sensations; those in the anterior, or ventral, horn are needed for voluntary or reflex motor activity. The illustration shows the major components of the spinal cord.

Spinal cord: Conductor pathway

The *spinal cord* extends downward from the brain, through the vertebrae, to the second lumbar vertebra. The spinal cord is a two-way conductor pathway between the brain stem and the peripheral nervous system. The spinal cord is also the reflex center for activities that don't require brain control, such as a knee-jerk reaction to a reflex hammer.

The spinal cord contains a mass of gray matter divided into horns that are made up mostly of neuron cell bodies, which relay sensations and are needed for voluntary or reflex motor activity. The white matter surrounding the outer part of these horns consists of myelinated nerve fibers grouped functionally in vertical columns called tracts. (See [Inside the spinal cord](#).)

The *sensory*, or *ascending, tracts* carry sensory impulses up the spinal cord to the brain, while *motor*, or *descending, tracts* carry motor impulses down the spinal cord. The brain's motor impulses reach a descending tract and continue through the peripheral nervous system by *upper motor neurons*. These neurons originate in the brain and form two major systems:

- u The *pyramidal system* (corticospinal tract) is responsible for fine, skilled movements of skeletal muscle. An impulse in this system originates in the frontal lobe's motor cortex and travels downward to the pyramids of the medulla, where it crosses to the opposite side of the spinal cord.
- u The *extrapyramidal system* (extracorticospinal tract) controls gross motor movements. An impulse traveling in this system originates in the frontal lobe's motor cortex and is mediated by basal ganglia, the thalamus, cerebellum, and reticular formation before descending to the spinal cord.

Reaching outlying areas

Messages transmitted through the spinal cord reach outlying areas through the peripheral nervous system, which originates in 31 pairs of segmentally arranged spinal nerves attached to the spinal cord. Spinal nerves are numbered according to their point of origin in the cord:

- u 8 cervical—C1 to C8
- u 12 thoracic—T1 to T12
- u 5 lumbar—L1 to L5
- u 5 sacral—S1 to S5
- u 1 coccygeal.

On the cross section of the spinal cord, you'll see that these spinal nerves are attached to the spinal cord by two roots:

- u the *anterior*, or *ventral, root*, which consists of motor fibers that relay impulses from the cord to glands and muscles
- u the *posterior*, or *dorsal, root*, which consists of sensory fibers that relay sensory information from receptors to the cord. The posterior root has a swelling on it—the posterior root ganglion—which is made up of sensory neuron cell bodies.

After leaving the vertebral column, each spinal nerve separates into rami (branches), which distribute peripherally with extensive but organized overlapping. This overlapping reduces the chance of lost sensory or motor function from interruption of a single spinal nerve.

Two functional systems

The *somatic (voluntary) nervous system* is activated by will but can also function independently. It's responsible for all conscious and higher mental processes and for subconscious and reflex actions such as shivering.

The *autonomic (involuntary) nervous system* regulates functions of the unconscious level to control involuntary body functions, such as digestion, respiration, and cardiovascular function. It's usually divided into two antagonistic systems. The *sympathetic nervous system* controls energy expenditure, especially in stressful situations, by releasing the adrenergic catecholamine norepinephrine. The *parasympathetic nervous system* helps conserve energy by releasing the cholinergic neurohormone acetylcholine. These antagonistic systems balance each other to support homeostasis.

Assessing neurologic function

A complete neurologic assessment helps confirm a suspected neurologic disorder. It establishes a clinical baseline and can offer lifesaving clues to rapid deterioration. Neurologic assessment includes:

- u *Patient history*. In addition to the usual information, try to elicit the patient and family members' perception of the disorder. Use the interview to make observations that help evaluate mental status and behavior.
- u *Physical examination*. Pay particular attention to obvious abnormalities that may signal serious neurologic problems, for example, fluid draining from the nose or ears.
- u *Neurologic examination*. Determine cerebral, cerebellar, motor, sensory, and cranial nerve function.

Obviously, time doesn't always allow for a complete neurologic examination during bedside assessment. Therefore, you'll need to set priorities. For example, typical ongoing bedside assessment focuses on level of consciousness (LOC), pupillary response, motor function, reflexes, and vital signs. When time permits, a complete neurologic examination can provide valuable information regarding total neurologic function.

ASSESSMENT TIP If the patient's history suggests a neurologic problem, the focus of your assessment can be based on the history. This saves you valuable time and effort.

Mental status, intellect, and behavior

Mental status and behavior are good indicators of cerebral function. Note the patient's appearance, mannerisms, posture, facial expression, grooming, and tone of

voice. Check for orientation to time, place, and person and for memory of recent and past events. To test intellect, ask the patient to count backward from 100 by 7's, read aloud, or interpret a common proverb, and see how well he understands and follows commands. If you make such checks frequently, vary your questions to avoid a programmed response.

CULTURAL TIP An interpreter or family member who's bilingual may assist you in eliciting responses if you don't speak the patient's language. Also, many individuals are illiterate, so you need to determine the appropriateness of testing for reading skills. Pictures may be used to aid communication.

Using the Glasgow Coma Scale		
To quickly assess a patient's level of consciousness (LOC) and to uncover baseline changes, use the Glasgow Coma Scale. This assessment tool grades consciousness in relation to eye opening and motor and verbal responses. A decreased reaction score in one or more categories warns of impending neurologic crisis. A score of 15 for all 3 categories indicates normal LOC. A patient who scores 7 or less is comatose and probably has severe neurologic damage. If the score is 3, it indicates probable brain death.		
If the patient has an endotracheal tube or a tracheostomy tube and is unable to respond verbally, use the abbreviation "T" to score this patient. For example, if the patient scores a 5 for best verbal response but he has a tracheostomy tube in place, this score is noted as 5T.		
TEST	PATIENT'S REACTION	SCORE
Eye opening response	Opens spontaneously	4
	Opens to verbal command	3
	Opens to pain	2
	No response	1
Best motor response	Obeys verbal command	6
	Localizes painful stimuli	5
	Flexion-withdrawal	4
	Flexion-abnormal (decorticate rigidity)	3
	Extension (decerebrate rigidity)	2
	No response	1
Best verbal response	Oriented and converses	5
	Disoriented and converses	4
	Inappropriate words	3
	Incomprehensible sounds	2
	No response	1
Total	3 to 15	

Level of consciousness

The single most valuable indicator of neurologic function, LOC can vary from alertness (response to verbal stimulus) to coma (failure to respond even to painful stimulus). It's best to document the patient's exact response to the stimulus: "patient pulled away in response to nail bed pressure" rather than just to write "stuporous."

The Glasgow Coma Scale (GCS) is used to assess eye opening as well as verbal and motor responses. This test doesn't help you detect early changes in LOC, but it can alert you to life-threatening changes. Although the scale doesn't indicate a patient's exact LOC, it does provide an easy way to describe his overall neurologic status and to detect and interpret changes from the baseline. (See [Using the Glasgow Coma Scale.](#))

In this test, each response receives a numerical value. For instance, if the patient readily responds verbally and is oriented to time, place, and person, he scores a 5; if he's totally unable to respond verbally, he scores a 1. If the patient is intubated or has a tracheostomy, assess and score appropriately, such as 5T (T meaning tracheostomy).

ASSESSMENT TIP When testing for motor response, remember to score the best response in the best extremity. Remember to document observation and assessment accurately in your notes, particularly if the patient doesn't respond adequately.

A score of 15 for all three parts is normal; 7 or less indicates a coma; 3—the lowest score possible—usually points to brain death. Although the GCS is useful, it isn't a substitute for a complete neurologic assessment.

Assessing motor function

The patient's inability to perform the following simple tests, or demonstration of tics, tremors, or other abnormalities during such testing, suggests cerebellar dysfunction.

- u Ask the patient to touch his nose with each index finger, alternating hands. Repeat this test with his eyes closed.
- u Instruct the patient to tap the index finger and thumb of each hand together rapidly.
- u Have the patient draw a figure eight in the air with his foot.
- u To test tandem walk, ask the patient to walk heel-to-toe in a straight line.
- u To test balance, perform the Romberg test: Ask the patient to stand with his feet together, eyes closed, and arms at his sides without losing balance.

Motor function is a good indicator of LOC and can also point to central or peripheral nervous system damage. During all tests of motor function, watch for differences between right- and left-side functions.

- u To check gait, ask the patient to walk while you observe posture, balance, and coordination of leg movement and arm swing.
- u To check muscle tone, palpate muscles at rest and in response to passive flexion. Look for flaccidity, spasticity, and rigidity. Measure muscle size, and look for involuntary movements, such as rapid jerks, a tremor, or contractions.
- u To evaluate muscle strength, have the patient grip your hands and squeeze. Then ask him to push against your palm with his foot. Compare muscle strength on each side, using a 5-point scale (5 is normal strength, 0 is complete paralysis). Test the patient's ability to extend and flex the neck, elbows, wrists, fingers, toes, hips, and knees; extend the spine; contract and relax the abdominal muscles; and rotate the shoulders.
- u Rate reflexes on a 4-point scale (4 is hyperactive reflex, 0 is absent reflex). Before testing reflexes, see that the patient is comfortable and relaxed. Then, to test superficial reflexes, stroke the skin of the abdominal, gluteal, plantar, and scrotal regions with a moderately sharp object that won't puncture the skin. A normal reflex is flexion in response to this stimulus. To test deep reflexes, use a reflex hammer to briskly tap the biceps, triceps, and brachioradialis, patellar, and Achilles tendon regions. Normal response is rapid muscle extension and contraction.

Assessing sensory function

Impaired or absent sensation in the trunk or extremities can point to brain, spinal cord, or peripheral nerve damage. Be sure to determine the extent of sensory dysfunction because this helps locate neurologic damage. For instance, localized dysfunction indicates local peripheral nerve damage; dysfunction over a single dermatome (an area served by 1 of the 31 pairs of spinal nerves) indicates damage to the nerve's dorsal root; and dysfunction extending over more than one dermatome suggests brain or spinal cord damage.

In assessing sensory function, always test both sides of symmetrical areas; for instance, test both arms, not just one. Reassure the patient that the test won't be painful.

- u *Superficial pain perception*: Lightly press the point of an open safety pin against the patient's skin. Don't press hard enough to scratch or puncture the skin.
- u *Thermal sensitivity*: Ask the patient to tell you what he feels when you place a test tube filled with hot water and one filled with cold water against his skin.
- u *Tactile sensitivity*: Ask the patient to close his eyes and tell you what he feels when touched lightly on the hands, wrists, arms, thighs, lower legs, feet, and trunk with a wisp of cotton.
- u *Sensitivity to vibration*: Place the base of a vibrating tuning fork against the patient's wrists, elbows, knees, or other bony prominences. Hold it in place, and ask the patient to tell you when it stops vibrating.
- u *Position sense*: Move the patient's toes or fingers up, down, and to the side. Ask the patient to tell you the direction of movement.
- u *Discriminatory sensation*: Ask the patient to close his eyes and identify familiar textures (velvet, burlap) or objects placed in his hand or numbers and letters traced on his palm.
- u *Two-point discrimination*: Using calipers or other sharp objects, touch the patient in two places simultaneously. Ask if he can feel one or two points.

Localizing cranial nerve function

By using the simple tests that follow, you can reliably localize cranial nerve dysfunction:

- u *Olfactory nerve (I)*: Have the patient close his eyes and, using each nostril separately, try to identify common nonirritating smells, such as cinnamon, coffee, and peppermint.
- u *Optic nerve (II)*: Examine the patient's eyes with an ophthalmoscope if you've been trained to do so, and have him read a Snellen eye chart or a newspaper. To test peripheral vision, ask him to cover one eye and fix his other eye on a point directly in front of him. Then, ask if he can see you wiggle your finger to his far right or left.
- u *Oculomotor nerve (III)*: Compare the size and shape of the patient's pupils and the equality of pupillary response to a small light in a darkened room.
- u *Trochlear nerve (IV)* and *abducens nerve (VI)*: To assess for conjugate and lateral eye movement, ask the patient to follow your finger with his eyes as you slowly move it from his far left to his far right.
- u *Trigeminal nerve (V)*: To test facial sensory response, stroke the patient's jaws, cheeks, and forehead with a cotton applicator, the point of a pin, or test tubes filled with hot or cold water.

ALERT Corneal response is generally only tested in a comatose patient. It isn't commonly done on an alert patient.

Because testing for a blink reflex is irritating to the patient, it isn't commonly done. If you must test for this response (it may be decreased in patients who wear contact lenses), touch the cornea lightly with a wisp of cotton or tissue, and avoid repeating the test if possible. To test for jaw jerk, ask the patient to hold his mouth slightly open and then tap the middle of his chin with a reflex hammer. The jaw should jerk closed.

- u *Facial nerve (VII)*: To test upper and lower facial motor function, ask the patient to raise his eyebrows, wrinkle his forehead, or show his teeth. To test sense of taste, ask him to identify the taste of well-known salty, sour, sweet, and bitter substances that you place on his tongue.
- u *Acoustic nerve (VIII)*: Ask the patient to identify common sounds such as a ticking clock. With a tuning fork, test for air and bone conduction if you've been taught how to perform this procedure.
- u *Glossopharyngeal nerve (IX)*: To test the gag reflex, touch a tongue blade to each side of the patient's pharynx.
- u *Vagus nerve (X)*: Observe the ability to swallow, and watch for symmetrical movements of the soft palate when the patient says, "Ah."
- u *Spinal accessory nerve (XI)*: To test shoulder muscle strength, palpate the patient's shoulders and ask him to shrug against a resistance.
- u *Hypoglossal nerve (XII)*: To test tongue movement, ask the patient to stick out his tongue. Inspect it for a tremor, atrophy, and lateral deviation. To test for strength, ask the patient to move his tongue from side to side while you hold a tongue blade against it.

Testing for a definitive diagnosis

A firm diagnosis of many neurologic disorders can require a wide range of diagnostic tests. If possible, noninvasive tests are done first and may include the following:

- u *Skull X-rays*: This test identifies skull malformations, fractures, erosion, or thickening that may indicate tumors.
- u *Computed tomography (CT) scan*: This series of X-rays of slices of the brain produces a three-dimensional effect. It's used to identify intracranial tumors, hemorrhage, arteriovenous malformation, and cerebral atrophy, calcification, edema, and infarction. If a contrast medium is used, this is an invasive procedure.
- u *Magnetic resonance imaging (MRI)*: Because it shows the CNS in greater detail than a CT scan, MRI is far better for detecting lesions of the brain stem, posterior fossa, and spinal cord. MRI is the diagnostic test of choice for early detection of cerebral infarction and brain tumors because it can demonstrate demyelination disorders, such as multiple sclerosis, intraluminal clots and blood flow in arteriovenous malformations, and aneurysms. It's contraindicated for patients with metal implants, rods, screws, prosthetic devices, or pacemakers.
- u *Magnetic resonance angiography (MRA)*: This noninvasive test evaluates cerebral vessels. It maximizes the signals in vessels that have flow. When performed with a contrast medium (gadolinium-DPTA), this test allows better differentiation of structures than MRI and provides clearer views of areas of abnormal contrast.
- u *Electroencephalogram (EEG)*: This test records electrical activity in the brain. Abnormalities may result from a seizure, psychological or metabolic disorder, tumor, drug overdose, or mental retardation.
- u *Visual evoked potentials*: This test exposes the eyes to alternating patterned and unpatterned stimuli, stimulating the visual pathways to the brain. It helps evaluate optic neuropathies and optic nerve lesions.
- u *Brain stem auditory evoked potentials*: Using such auditory stimuli as clicks, this test stimulates the brain's auditory pathways, which can help diagnose posterior fossa tumors, demyelinating disease, and conductive hearing loss. It can be used on alert or comatose patients.
- u *Somatosensory evoked potentials*: In this test, a peripheral nerve receives an electrical stimulus to evaluate impulse transmission from the nerve to the cerebral cortex.

Invasive tests may include:

- u *Lumbar puncture*: In this test, a needle is inserted into the subarachnoid space of the spinal cord, usually between L3 and L4 (or L4 and L5), allowing measurement of CSF pressure and aspiration of CSF for analysis. This specimen is used to detect infection or hemorrhage, determine cell count, and determine glucose, protein, and globulin levels. Lumbar puncture is usually contraindicated in patients with hydrocephalus or known increased intracranial pressure (ICP) because a rapid reduction in pressure may cause brain herniation.
- u *Myelography*: After a lumbar puncture and CSF removal, a radiopaque dye is instilled. X-rays show spinal abnormalities and determine spinal cord or nerve root compression related to back pain or extremity weakness.
- u *Arteriography (cerebral angiography)*: A catheter is inserted into the femoral or another artery and is indirectly threaded to the carotid artery. Then a radiopaque dye is injected, allowing X-ray visualization of cerebral vessels. Sometimes the catheter is threaded directly into the brachial or carotid artery. This test can reveal cerebrovascular abnormalities and spasms plus arterial changes due to tumor, arteriosclerosis, hemorrhage, aneurysm, or blockage from a cerebrovascular accident.
- u *Ventriculography*: Air is introduced into the lateral ventricle through an opening in the skull. X-rays are taken and used to identify tumors or anomalies that affect the ventricular system.
- u *Brain scan*: A scanner measures gamma rays produced by a radioisotope-injected I.V. isotope uptake, and distribution in the brain can reveal masses or vascular lesions.
- u *Position emission tomography (PET) scan*: This test provides colorimetric information about the brain's metabolic activity by detecting how quickly tissues consume radioactive isotopes. It can help detect cerebral dysfunction caused by tumors, seizures, transient ischemic attacks, head trauma, some mental illnesses, Alzheimer's disease, Parkinson's disease, and multiple sclerosis.
- u *ICP monitoring*: Continuous ICP monitoring is common in intensive care units with patients at risk for increased ICP. A pressure sensor can be placed in the

ventricles (intraventricular catheter), subarachnoid space (subarachnoid bolt), epidural space (epidural sensor), or brain parenchyma (intraparenchymal monitor). The sensor transmits ICP changes to a transducer, which converts the impulse to electrical or light signals. A recording device converts the signals to visible tracings that can be seen on an oscilloscope or transferred to graph paper.

⌞ *Electromyography*. A needle inserted into selected muscles at rest and during voluntary contraction picks up nerve impulses and measures nerve conduction time. This test is used to detect lower motor neuron disorders and nerve damage.

Congenital disorders

Neurologic disorders present at birth can stem from a variety of maternal or fetal causes. A weakness in the arterial wall may cause cerebral aneurysm. Some, such as cerebral palsy, result from prenatal, perinatal, or postnatal central nervous system damage. Others, such as hydrocephalus, result from cerebrospinal fluid dysfunction. Embryonic neural tube defects during the first trimester of pregnancy can lead to spinal cord malformations.

Cerebral aneurysm

Cerebral aneurysm is a localized dilation of a cerebral artery that results from a weakness in the arterial wall. The most common form is the saccular (berry) aneurysm, a saclike outpouching in a cerebral artery. (See [Comparing types of aneurysms](#).)

Cerebral aneurysms commonly rupture, causing subarachnoid hemorrhage. Sometimes bleeding also spills into the brain tissue and subsequently forms a clot. This may result in potentially fatal increased intracranial pressure (ICP) and brain tissue damage.

Most cerebral aneurysms occur at bifurcations of major arteries in the circle of Willis and its branches. An aneurysm can produce neurologic symptoms by exerting pressure on the surrounding structures such as the cranial nerves. (See [Common sites of cerebral aneurysm](#).)

Cerebral aneurysms are much more common in adults than in children. Incidence is slightly higher in women than in men, especially women in their late 40s or early to middle 50s, but cerebral aneurysm may occur at any age. In about 20% of patients, multiple aneurysms occur.

The prognosis is usually guarded but depends on the patient's age and neurologic condition, other diseases, and the extent and location of the aneurysm. About half the patients who suffer subarachnoid hemorrhages die immediately. With new and better treatment, the prognosis is improving.

Causes

Cerebral aneurysm results from a congenital defect of the vessel wall, head trauma, hypertensive vascular disease, advancing age, infection, or atherosclerosis, which can weaken the vessel wall.

Complications

Potentially fatal complications after rupture of an aneurysm include subarachnoid hemorrhage and brain tissue infarction. Cerebral vasospasm, probably the most common cause of death after rupture, occurs in about 40% of all patients after subarachnoid hemorrhage occurs.

Other possible complications include rebleeding, which usually occurs within the first 7 days but can occur anytime within the first 6 months; meningeal irritation from blood in the subarachnoid space; and hydrocephalus, which can occur weeks or even months after rupture if blood obstructs the fourth ventricle.

Assessment findings

Most cerebral aneurysms produce no symptoms until rupture occurs. History information may have to be obtained from a family member if the patient is unconscious or severely neurologically impaired.

Usually, the patient history reveals the sudden onset of an unusually severe headache that is accompanied by nausea, vomiting and, commonly, loss of consciousness. The patient or family member may report that the rupture was preceded by a period of activity, such as exercise, labor and delivery, or sexual intercourse. The patient also may have a history of hypertension, infection, or head injury.

Other findings vary with the location of the aneurysm and the extent and severity of hemorrhage. Bleeding causes meningeal irritation, which can result in nuchal rigidity, back and leg pain, fever, restlessness, irritability, occasional seizures, and blurred vision. If the aneurysm is adjacent to the oculomotor nerve, ptosis and vision disturbances, such as diplopia and vision loss, may occur. If the bleeding extends into the brain tissue, hemiparesis, unilateral sensory deficits, dysphagia, visual defects, and altered consciousness may occur. Additional findings may result from complications. (See [What to watch for after a ruptured aneurysm](#).)

To better describe the condition of patients with ruptured cerebral aneurysm, the following grading system has been developed:

⌞ *grade I (minimal bleeding)*. The patient is alert, with no neurologic deficit; he may have a slight headache and nuchal rigidity.

Comparing types of aneurysms

Saccular (berry) aneurysm

- u Most common type
- u Secondary to congenital weakness of media
- u Usually occurs at major vessel bifurcations
- u Occurs at the circle of Willis
- u Has a neck or stem
- u Has a sac that may be partly filled with a blood clot

Fusiform (spindle-shaped) aneurysm

- u Occurs with atherosclerotic disease
- u Characterized by irregular vessel dilation
- u Develops on internal carotid or basilar arteries
- u Rarely ruptures
- u Produces brain and cranial nerve compression or cerebrospinal fluid obstruction

Mycotic aneurysm

- u Rare
- u Associated with septic emboli that occur secondary to bacterial endocarditis
- u Develops when emboli lodge in arterial lumen, causing arteritis; the arterial wall weakens and dilates

Dissecting aneurysm

- u Caused by arteriosclerosis, head injury, syphilis, or trauma during angiography
- u Develops when blood is forced between layers of arterial walls, stripping intima from the underlying muscle layer

Traumatic aneurysm

- u Develops in the carotid system
- u Associated with fractures and intimal damage
- u May thrombose spontaneously

Giant aneurysm

- u Similar to saccular aneurysm, but larger—1 1/8"(3 cm) or more in diameter
- u Behaves like a space-occupying lesion, producing cerebral tissue compression and cranial nerve damage
- u Associated with hypertension

Charcot-Bouchard aneurysm

- u Microscopic
- u Associated with hypertension
- u Involves basal ganglia or brain stem

Common sites of cerebral aneurysm

Cerebral aneurysms usually arise at arterial bifurcations in the circle of Willis and its branches. The illustration below shows the most common aneurysm sites around this circle.

- u *grade II (mild bleeding)*. The patient is alert, with a mild to severe headache, nuchal rigidity and, possibly, third-nerve palsy.
- u *grade III (moderate bleeding)*. The patient is confused or drowsy, with nuchal rigidity and, possibly, a mild focal deficit.
- u *grade IV (severe bleeding)*. The patient is stuporous, with nuchal rigidity and, possibly, mild to severe hemiparesis.
- u *grade V (moribund [often fatal])*. If not fatal, the patient is in a deep coma or decerebrate.

Diagnostic tests

The following tests help establish a diagnosis, which usually follows aneurysmal rupture:

Angiography confirms the aneurysm's location and displays the vessels' condition.

Lumbar puncture can be used to detect blood in the cerebrospinal fluid (CSF), but this procedure is contraindicated if the patient shows signs of increased ICP.

Computed tomography scanning is used to locate the clot and identify hydrocephalus, areas of infarction, and the extent of blood spillage in the cisterns around the

brain.

Magnetic resonance imaging and magnetic resonance angiography show the extent of bleeding and the vessels' condition.

Treatment

If indicated, initial emergency treatment includes oxygenation and ventilation. Then, to reduce the risk of rebleeding, the doctor may attempt to repair the aneurysm. Usually, surgical repair (by clipping, ligating, or wrapping the aneurysm neck with muscle) takes place as soon as the patient's condition allows after the initial bleeding.

After surgical repair, the patient's condition depends on the extent of damage from the initial bleeding and the degree of success in treating the resulting complications. Surgery can't improve the patient's neurologic condition unless it removes a hematoma or reduces the compression effect.

When surgical correction poses too much risk (in very elderly patients and those with heart, lung, or other serious diseases), when the aneurysm is in a particularly dangerous location, or when vasospasm necessitates a delay in surgery, the patient may receive conservative treatment, including:

- bed rest in a quiet, darkened room (may last for 4 to 6 weeks) if immediate surgery isn't possible
- avoidance of coffee, other stimulants, and aspirin
- codeine or another analgesic as needed
- hydralazine or another antihypertensive if needed
- a vasoconstrictor to maintain blood pressure at the optimum level (20 to 40 mm Hg above normal) if needed
- corticosteroids to reduce meningeal irritation
- phenobarbital or another sedative to relax the patient
- nimodipine, a calcium channel blocker, to decrease cerebral vessel vasospasm
- albumin for volume expansion, to decrease vasospasm.

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Altered thought processes
- Altered tissue perfusion (cerebral)
- Anxiety
- Impaired gas exchange
- Impaired physical mobility
- Ineffective breathing pattern
- Knowledge deficit
- Pain
- Risk for impaired skin integrity
- Risk for injury

WARNING

<div></div> <div>What to watch for after a ruptured aneurysm</div>				
If your patient survives a ruptured cerebral aneurysm, monitor him closely for rebleeding, cerebral vasospasm, and acute hydrocephalus, which are life-threatening complications. The table below lists the signs and symptoms of each complication and tells when it's most likely to occur and how it should be treated.				
COMPLICATION	SIGNS AND SYMPTOMS		ONSET	TREATMENT
Rebleeding	Deterioration of neurologic status, decrease in level of consciousness (LOC), intensifying headache		7 to 10 days after rupture	<ul style="list-style-type: none">▫ Sedation, rest▫ Avoidance of Valsalva's maneuver
Cerebral vasospasm	Decrease in LOC, motor weakness or paralysis, visual deficits, changes in vital signs (particularly respiratory patterns)		Several hours to days after rupture	<ul style="list-style-type: none">▫ Intravascular volume expanders▫ Induced hypertensive therapy▫ Calcium channel blockers
Hydrocephalus	Mental changes, gait disturbances, general mental and physical deterioration	Can occur several hours to days later as a result	<ul style="list-style-type: none">▫ Cerebrospinal fluid drainage via intraventricular catheter	

Key outcomes

- The patient will maintain adequate ventilation.
- The patient will maintain a baseline of ±5 breaths/minute.
- The patient will consume adequate daily calories as required.
- The patient will maintain an improved level of consciousness (LOC).

Nursing interventions

During initial treatment after hemorrhage:

- Maintain a patent airway because the patient may need supplementary oxygen. Position the patient to promote pulmonary drainage and prevent upper airway obstruction. Following facility policy, suction the airway as needed to remove secretions and to prevent hypoxia and vasodilation from carbon dioxide accumulation. Suction in less than 20 seconds to avoid increased ICP.
- Provide frequent nose and mouth care.

If surgery is delayed:

- Impose aneurysm precautions to minimize the risk of rebleeding and to avoid increased ICP. Such precautions include bed rest in a dark, quiet room (with head of the bed flat or elevated less than 30 degrees as ordered); limited visitors; avoidance of such stimulants as coffee; avoidance of Valsalva's maneuver and other strenuous activity; and restricted fluid intake.
- Watch for these danger signs of rebleeding, intracranial clot, vasospasm, or other complications: decreased LOC, unilateral enlarged pupil, onset or worsening of hemiparesis or motor deficit, increased blood pressure, slowed pulse rate, worsening or sudden onset of a headache, renewed or persistent vomiting, and renewed or worsening nuchal rigidity. Intermittent signs, such as restlessness, extremity weakness, and speech alterations, can also indicate increasing ICP.
- Administer hydralazine or another antihypertensive agent as ordered, and carefully monitor blood pressure.
- Report any significant change in blood pressure, but especially note a rise in systolic pressure. If this occurs, notify the doctor immediately.

For preoperative and postoperative interventions and conservative treatment:

- u Provide emotional support to the patient and family members. To minimize stress, encourage the patient to use relaxation techniques. Encourage him to express his concerns if he's able.
- u Turn the patient often. Encourage deep breathing and leg movement. Assist with active range-of-motion exercises; if the patient is paralyzed, perform passive range-of-motion exercises.
- u Monitor arterial blood gas levels, LOC, and vital signs often, and accurately measure intake and output. Avoid taking temperature rectally because vagus nerve stimulation may cause cardiac arrest.
- u Give fluids as ordered, and monitor I.V. infusions. Maintain fluid volume to decrease risk of vasospasm.
- u If the patient has facial weakness, assist him during meals; assess his gag reflex, and place the food in the unaffected side of his mouth.
- u If the patient can't swallow, insert a nasogastric tube as ordered, and give all tube feedings slowly. Prevent skin breakdown by taping the tube so it doesn't press against the nostril.
- u If the patient can eat, provide a high-fiber diet (including such foods as bran, salads, and fruit) to prevent straining during defecation, which can increase ICP. Obtain an order for a stool softener or a mild laxative, and administer it as ordered. Implement a bowel elimination program based on previous habits. If the patient is receiving steroids, check the stool for blood.
- u If the patient has third or facial nerve palsy, administer artificial tears to the affected eye, and tape the eye shut at night to prevent corneal damage.
- u Raise the bed's side rails to protect the patient from injury. If possible, avoid using restraints because these can cause agitation and raise ICP.
- u If appropriate, perform postoperative craniotomy care: Inspect the patient's head dressing for bleeding and CSF drainage; position the patient so that the neck is in a straight line to prevent interference with cerebral drainage by neck flexion; monitor ICP as ordered; and maintain adequate respiratory function and brain oxygenation using supplementary oxygen and mechanical ventilation as ordered.
- u Monitor the patient for postoperative complications, including sudden hemiplegia, psychological problems (disorientation, amnesia, Korsakoff's syndrome, personality impairment), fluid and electrolyte disturbances, and GI bleeding.

Patient teaching

- u Teach the patient, if possible, and family members about his condition. Encourage family members to adopt a realistic attitude, but don't discourage hope. Answer questions honestly.
- u Explain all tests, neurologic examinations, treatments, and procedures to the patient even if he's unconscious.
- u Warn the patient who's being treated conservatively to avoid all unnecessary physical activity.
- u If surgery is to be performed, provide preoperative teaching if the patient's condition permits. Be sure the patient, if possible, and family members understand the surgery and its possible complications. Reinforce the doctor's explanations as necessary.
- u Before discharge, make a referral to a home health care nurse or a rehabilitation center when necessary.
- u Teach family members to recognize and immediately report signs of rebleeding, such as headache, nausea, vomiting, and changes in LOC (irritability, restlessness).

CEREBRAL PALSY

Cerebral palsy—the most common crippling disease in children—comprises several neuromuscular disorders resulting from prenatal, perinatal, or postnatal central nervous system damage. Although nonprogressive, these disorders may become more obvious as an affected infant grows older.

The three major types of cerebral palsy—spastic (affecting about 70% of children with cerebral palsy), athetoid (affecting about 20%), and ataxic (affecting about 10%)—sometimes occur in mixed forms. Motor impairment may be minimal (sometimes apparent only during physical activities such as running) or severely disabling. Associated defects, such as seizures, speech disorders, and mental retardation, are common. The prognosis varies. In mild impairment, proper treatment may make a near-normal life possible.

Incidence of cerebral palsy is highest in premature infants and in those who are small for gestational age. Cerebral palsy is slightly more common in boys than in girls and occurs more often in whites.

Causes

Cerebral palsy usually stems from conditions that result in cerebral anoxia, hemorrhage, or other damage. Conditions that cause these problems can occur before, during, or after birth.

Prenatal causes include Rhesus (Rh) factor or ABO blood type incompatibility, maternal infection (especially rubella in the first trimester), maternal diabetes, irradiation, anoxia, toxemia, malnutrition, abnormal placental attachment, and isoimmunization.

During parturition, conditions that can cause cerebral palsy include trauma during delivery, depressed maternal vital signs from general or spinal anesthesia, asphyxia from the cord wrapping around the neck, prematurity, prolonged or unusually rapid labor, and multiple births (infants born last in a multiple birth have an especially high rate of cerebral palsy). Postnatal causes include infections, such as meningitis and encephalitis, head trauma, poisoning, and any condition that results in cerebral thrombus or embolus.

Complications

Cerebral palsy may produce complicating conditions, including seizure disorders (in about 25% of patients); speech, vision, and hearing problems; language and perceptual deficits; mental retardation (in up to 40% of patients); dental problems; and respiratory difficulties, such as poor swallowing and gag reflexes.

Assessment findings

Maternal or patient history often reveals the possible cause of cerebral palsy. Patients who have mixed forms of the disorder may display a combination of clinical findings. (See [When to suspect cerebral palsy.](#))

Generally, inspection reveals a child with retarded growth and development. If you observe the patient eating, you may notice that he has difficulty chewing and swallowing. Other findings vary depending on the type of cerebral palsy.

In *spastic cerebral palsy*, inspection may reveal underdevelopment of affected limbs and the characteristic scissors gait: Typically, the child walks on his toes, crossing one foot in front of the other. Neurologic examination may reveal hyperactive deep tendon reflexes and increased stretch reflexes, rapid alternating muscle contraction and relaxation, and weakness. Muscle contraction in response to manipulation with a tendency toward contractures also occurs.

In *athetoid cerebral palsy*, inspection may disclose involuntary movements, such as grimacing, wormlike writhing, dystonia, and sharp jerks that impair voluntary movement. Usually, the arms are affected more severely than the legs; involuntary facial movements may make speech difficult. These characteristic athetoid movements may become more severe during stress, decrease with relaxation, and disappear during sleep.

The history of a patient with *ataxic cerebral palsy* chronicles a lack of leg movement during infancy and a wide gait noticed when the child began to walk. Neurologic examination may reveal disturbed balance, incoordination (especially of the arms), hypoactive reflexes, nystagmus, weakness, and tremors. Ataxia makes sudden or fine movements almost impossible.

The patient's history and physical examination findings, including results of the neurologic assessment, confirm the diagnosis of cerebral palsy.

When to suspect cerebral palsy

Early detection is essential for effective treatment and requires careful clinical observation during infancy and precise neurologic assessment. Suspect cerebral palsy whenever an infant:

- u has difficulty sucking or keeping the nipple or food in his mouth
- u seldom moves voluntarily or has arm or leg tremors with voluntary movement
- u crosses his legs when lifted from behind rather than pulling them up or bicycling like a normal infant
- u has legs that are hard to separate, making diaper changing difficult
- u persistently uses only one hand or, as he gets older, uses his hands well but not his legs.

Diagnostic tests

Appropriate tests are performed to diagnose conditions associated with cerebral palsy and to determine the degree of visual, auditory, and mental impairment. For example, an EEG may be performed to identify the source of seizure activity.

Treatment

Cerebral palsy can't be cured, but proper treatment can help affected children reach their full potential within the limits set by this disorder. Such treatment requires a comprehensive and cooperative effort involving doctors, nurses, teachers, psychologists, the child's family, and occupational, physical, and speech therapists. Home care is often possible. Children with milder forms of cerebral palsy should attend a regular school; severely afflicted children may need special education classes.

Treatment usually includes:

- u braces or splints and special appliances, such as adapted eating utensils and a low toilet seat with arms to help these children perform activities independently
- u range-of-motion exercises to minimize contractures
- u phenytoin, phenobarbital, or another anticonvulsant to control seizures
- u sometimes muscle relaxants or neurosurgery to decrease spasticity
- u orthopedic surgery to correct contractures (most often part of the treatment in spastic cerebral palsy). Children with this form are especially prone to developing equinus deformity because the heel cord shortens. Achilles tendon lengthening is commonly performed to improve foot function. Muscle transfer procedures are performed to improve function of the wrist or other joints.

Nursing diagnoses

- u Altered growth and development
- u Altered nutrition: Less than body requirements
- u Altered thought processes
- u Body image disturbance
- u Impaired physical mobility
- u Knowledge deficit
- u Risk for altered family processes
- u Risk for altered parenting
- u Risk for impaired skin integrity
- u Self-esteem disturbance
- u Sensory or perceptual alterations

Key outcomes

- u The patient will consume adequate daily calories as required.
- u The patient will express positive feelings about himself.
- u The patient will maintain joint mobility and range of motion.
- u The patient and family members will develop adequate coping mechanisms.
- u The patient and family members will demonstrate knowledge of the condition.

Nursing interventions

- u Because a child with cerebral palsy may be hospitalized for orthopedic surgery and treatment of other complications, provide emotional support to the child and family members. Answer their questions and be available to them during periods of adjustment.
- u To help the child deal with activities of daily living, speak slowly and distinctly. Encourage the child to ask for things he wants. Listen patiently and don't rush him.
- u Give all care in an unhurried manner to avoid increasing muscle spasticity.
- u Allow the child and family members to participate in care decisions as much as possible. This improves the child's self-esteem and body image and also helps family members continue the plan of care at home.
- u Plan an adequate diet to meet the child's high energy needs. During meals, maintain a quiet, unhurried atmosphere with as few distractions as possible. The child may need special utensils and a chair with a solid footrest. Stroking the throat may aid swallowing.
- u Give frequent mouth care and dental care.
- u Reduce muscle spasms that increase postoperative pain by moving and turning the child carefully after surgery. Give analgesics as ordered, and monitor for response.
- u If the child wears a brace, help him apply it as needed. Every day, inspect the skin for areas of pallor or redness that indicate prolonged pressure. Provide meticulous skin care and daily massage for the area under the brace. Allow the patient to wear a T-shirt (provided it doesn't ride up under the brace) to help maintain skin integrity and promote comfort.
- u Administer ordered medications as required, and perform prescribed exercises to maintain muscle tone.
- u Care for associated hearing and visual disturbances as necessary.

Patient teaching

- u Determine how much the child and his parents already know about the disorder and any associated conditions. Reinforce the doctor's explanation, and clear up any misconceptions they have.
- u Teach parents and, if appropriate, the child about any prescribed medications. Provide written information about potential adverse reactions and when to notify the doctor.
- u Instruct parents to inspect the skin daily for pressure areas from braces. Explain the need to massage skin areas under the brace.
- u Teach the child to place food far back in his mouth to facilitate swallowing. Explain the need to chew food thoroughly, drink through a straw, and suck lollipops to develop the muscle control needed to minimize drooling.
- u Explain the importance of good nutrition for patients with this disorder. If possible, arrange for the dietitian to instruct the parents and the child.
- u As appropriate, teach parents how to perform prescribed exercises to maintain muscle tone and joint function.
- u Emphasize to parents the importance of giving the child opportunities for learning. If appropriate, tell parents about summer camps for handicapped children and the Special Olympics. Explain that these activities can help the child realize that he isn't the only person with this handicap. Refer family members to community support groups such as the local chapter of the United Cerebral Palsy Association.

HYDROCEPHALUS

Hydrocephalus is an excessive accumulation of cerebrospinal fluid (CSF) in the ventricular spaces of the brain. It's most common in neonates but can also occur in adults as a result of injury or disease. In infants, hydrocephalus enlarges the head; in both infants and adults, resulting compression can damage brain tissue. With early detection and surgical intervention, the prognosis improves but remains guarded.

Causes

Hydrocephalus results from an obstruction in CSF flow (noncommunicating hydrocephalus) or from faulty absorption of CSF (communicating hydrocephalus).

In noncommunicating hydrocephalus, the obstruction occurs most frequently between the third and fourth ventricles and at the aqueduct of Sylvius. It can also occur at the outlets of the fourth ventricle (foramina of Luschka and Magendie) or, rarely, at the foramen of Monro. This obstruction may result from faulty fetal development (myelomeningocele, congenital arachnoid cysts), infection (syphilis, granulomatous diseases, meningitis), tumor, cerebral aneurysm, or a blood clot.

In communicating hydrocephalus, faulty reabsorption of CSF may result from surgery to repair a myelomeningocele, adhesions between meninges at the base of the brain, or meningeal hemorrhage.

Complications

Potential complications of hydrocephalus include mental retardation, impaired motor function, and vision loss. Death may result from increased intracranial pressure (ICP) in people of all ages; infants may also die of infection and malnutrition.

Assessment findings

The patient's history may disclose the cause of hydrocephalus. In an infant, inspection may reveal an enlarged head that is clearly disproportionate to the infant's growth, an unmistakable sign of hydrocephalus. If an assessment of the infant occurs immediately after the start of hydrocephalus, the head may appear normal in size with bulging fontanel.

Other characteristic findings noted on inspection include distended scalp veins; thin, fragile, and shiny scalp skin; and underdeveloped neck muscles. (See [The infant with hydrocephalus.](#))

In severe hydrocephalus, the infant's parents may report a high-pitched, shrill cry; irritability; anorexia; and episodes of projectile vomiting. Inspection may reveal depression of the roof of the eye orbit, displacement of the eyes downward, and prominent sclera (sunset sign). Neurologic examination may demonstrate abnormal muscle tone of the legs.

In adults and older children with a fused cranium, the patient history may uncover signs of increased ICP, including frontal headaches, nausea, and vomiting that may be projectile. If the patient or parents report that these symptoms cause waking or occur on awakening, hydrocephalus should be suspected. The patient may also report diplopia and restlessness. Neurologic examination may detect a decreased level of consciousness, ataxia, and impaired intellect. Neurologic impairment may also cause incontinence.

The infant with hydrocephalus

Characteristic changes of hydrocephalus in infants include marked head enlargement; distended scalp veins; thin, shiny, and fragile-looking scalp skin; and underdeveloped neck muscles.

Diagnostic tests

Skull X-rays show thinning of the skull with separation of sutures and widening of the fontanel in infants.

Angiography, computed tomography scanning, and magnetic resonance imaging differentiate between hydrocephalus and intracranial lesions and can also demonstrate Arnold-Chiari syndrome, which occurs with hydrocephalus. (See [Arnold-Chiari syndrome.](#))

Treatment

Surgical correction is the only treatment for hydrocephalus. Surgery is performed either to remove an obstruction to CSF flow or to implant a shunt to divert CSF flow. Usually, such surgery involves insertion of a ventriculoperitoneal shunt, which drains excess CSF fluid from the brain's lateral ventricle into the peritoneal cavity.

ADVANCED PRACTICE

Arnold-Chiari syndrome

Hydrocephalus is frequently accompanied by the Arnold-Chiari syndrome, especially when a myelo-meningocele is also present. In this condition, which may exist apart from hydrocephalus, an elongation or tonguelike downward projection of the cerebellum and medulla extends through the foramen magnum into the cervical portion of the spinal canal, impairing cerebrospinal fluid drainage from the fourth ventricle.

In addition to signs and symptoms of hydrocephalus, infants with this syndrome may have nuchal rigidity, noisy respirations, irritability, vomiting, weak sucking reflex, and a preference for hyperextension of the neck.

Treatment requires surgery to insert a shunt like that used in hydrocephalus. Surgical decompression of the cerebellar tonsils at the foramen magnum is sometimes indicated.

If a concurrent abdominal problem exists, the doctor may use a ventriculoatrial shunt, which drains fluid from the brain's lateral ventricle into the right atrium of the heart, where the fluid makes its way into the venous circulation.

Nursing diagnoses

u Altered cerebral tissue perfusion u Altered family processes u Altered growth and development u Altered nutrition: Less than body requirements u Anxiety u Body

image disturbance u Impaired skin integrity u Pain u Risk for ineffective airway clearance u Risk for infection

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will maintain adequate ventilation.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain and improve current level of consciousness.
- u The patient will perform activities of daily living with maximum level of mobility and independence.

Nursing interventions

- u Provide emotional support, and encourage the patient (if appropriate) and family to express their concerns. An older child about to undergo shunt surgery may focus on associated hair loss and the visibility of a mechanical device. To help him deal with this change in body image, introduce him to other children with similar problems.
- u Encourage maternal-infant bonding when possible. When caring for the infant yourself, hold him on your lap for feeding, stroke and cuddle him, and speak soothingly.
- u Check fontanel for tension or fullness, and measure and record head circumference. On the patient's chart, draw a picture showing where to measure the head so that other staff members measure it in the same place, or mark the forehead with ink.
- u Elevate the head of the bed to 30 degrees to help alleviate increasing ICP.
- u Administer oxygen as ordered. Have suction equipment at the bedside, and suction as necessary.

Before surgery to insert a shunt:

- u Provide small, frequent feedings, if necessary, to ensure adequate nutrition. To help lessen vomiting, decrease movement during and immediately after meals.
- u Feed the infant slowly. To lessen strain from the weight of the infant's head on your arm while holding him during feeding, place his head, neck, and shoulders on a pillow.
- u To prevent aspiration after feeding and hypostatic pneumonia, place the infant on his side and reposition every 2 hours, or prop him up in an infant seat.
- u To prevent skin breakdown, make sure the infant's earlobe is flat, and place a foam rubber pad under his head.
- u When turning the infant, move his head, neck, and shoulders with his body to reduce strain on his neck.
- u Monitor the infant closely for signs of neurologic complications, such as change in level of consciousness (LOC), vomiting, seizure activity, irregular respirations, and bradycardia. Notify the doctor of these changes.
- u Check the infant's growth and development periodically.

After shunt surgery:

- u Place the infant on the side opposite the operative site, with his head level with his body unless the doctor's orders specify otherwise.
- u Monitor intake and output, and administer I.V. fluids as ordered.
- u Check temperature, pulse rate, blood pressure, and LOC. Also check fontanel for fullness daily. Watch for vomiting, which may be an early sign of increased ICP and shunt malfunction.
- u Watch for signs of infection, especially meningitis: fever, stiff neck, irritability, or tense fontanel. Also watch for redness, swelling, and other signs of local infection over the shunt tract. Check dressing often for drainage. Use strict aseptic technique when changing dressing.

ALERT Be alert for other postoperative complications, including shunt failure, adhesions, paralytic ileus, migration, peritonitis, and intestinal perforation (with peritoneal shunt).

- u Carefully titrate analgesics to provide pain relief but still permit adequate neurologic assessment.

Patient teaching

- u Determine how much the patient (if appropriate) and family members know about the disorder, its treatment, and possible complications. Reinforce the doctor's explanation as needed.
- u Help parents set goals consistent with the patient's ability and potential. Teach them to focus on their child's strengths, not his weaknesses.
- u Provide preoperative teaching as appropriate. Be sure the patient (if appropriate) and his parents understand the surgical procedure and the desired outcome. Teach them about postoperative care measures.
- u Discuss special education programs with the parents, and emphasize the infant's needs for sensory stimulation appropriate for his age.
- u Instruct them to watch for signs of shunt malfunction, infection, and paralytic ileus.
- u Tell them that shunt insertion requires periodic surgery to lengthen the shunt as the child grows older and that surgery may also be required to correct malfunction or to treat infection.

SPINAL CORD DEFECTS

Spinal cord defects are caused by defective embryonic neural tube closure during the first trimester of pregnancy. These defects usually occur in the lumbosacral area, but they're occasionally found in the sacral, thoracic, and cervical areas. The meninges and brain tissue can protrude if the skull doesn't fuse properly. (See [Understanding encephalocele.](#))

Spina bifida occulta is an incomplete closure of one or more vertebrae without protrusion of the spinal cord or meninges. It's the most common and least severe spinal cord defect. In more severe forms of spina bifida such as *spina bifida cystica*, incomplete closure of one or more vertebrae causes protrusion of the spinal contents in an external sac or a cystic lesion.

ADVANCED PRACTICE

Understanding encephalocele

An encephalocele is a congenital saclike protrusion of the meninges and brain through a defective opening in the skull. It's usually in the occipital area, but it may occur in the parietal, nasopharyngeal, or frontal area.

Clinical effects

Various clinical effects of encephalocele depend on the defect's location and the degree of tissue involvement. Visual defects may occur because optic tracks are stretched or absent. Often, paralysis and hydrocephalus accompany encephalocele.

Treatment

Surgery is performed during infancy to place protruding tissues back in the skull, excise the sac, and correct associated craniofacial abnormalities.

Always handle an infant with encephalocele carefully, and avoid pressure on the sac. Both before and after surgery, watch for signs of increased intracranial pressure (bulging fontanels). As the child grows older, teach his parents to watch for developmental deficiencies that may signal mental retardation.

Spina bifida cystica has two classifications: myelomeningocele (meningomyelocele) and meningocele. In myelomeningocele, the external sac contains meninges, cerebrospinal fluid (CSF), and a portion of the spinal cord or nerve roots distal to the conus medullaris. When the spinal nerve roots end at the sac, motor and sensory functions below the sac are terminated. In meningocele, less severe than myelo-meningocele, the sac contains only meninges and CSF. Meningocele may produce no neurologic symptoms. (See [Types of spinal cord defects.](#))

Spina bifida is relatively common: Each year, in the United States, about 12,000 infants are born with some form of spina bifida. Incidence is highest in people of Welsh or Irish ancestry.

The prognosis varies with the degree of accompanying neurologic defect. It's worst in patients with large open lesions, neurogenic bladders (which predispose to infection and renal failure), or total paralysis of the legs. Because such features are usually absent in spina bifida occulta and meningocele, the prognosis is much better for these patients, and many of them can lead normal lives.

Types of spinal cord defects

There are three major types of spinal cord defects. Spina bifida occulta is characterized by a depression or raised area and a tuft of hair over the defect. In myelomeningocele, an external sac contains meninges, cerebrospinal fluid, and a portion of the spinal cord or nerve roots. In meningocele, an external sac contains only meninges and cerebrospinal fluid.

SPINA BIFIDA OCCULTA

MYELOMENINGOCELE

MENINGOCELE

Causes and pathophysiology

The exact cause of spinal cord defects isn't known. Viruses, radiation, and other environmental factors may be responsible for such defects. Spinal cord defects occur in offspring of women who have previously had children with similar defects, so genetic factors may also be responsible.

Normally, about 20 days after conception, the embryo develops a neural groove in the dorsal ectoderm. This groove rapidly deepens as the two edges fuse to form the neural tube. By about day 23, this tube is completely closed except for an opening at each end. Theoretically, if the posterior portion of the neural tube fails to close by the 4th week of gestation, or if it closes and then splits open from a cause such as an abnormal increase in CSF later in the first trimester, a spinal cord defect results.

Complications

Spinal cord defects can lead to infection, paralysis, hydrocephalus and, if the disorder remains untreated, death.

Assessment findings

The history of the infant's mother may reveal environmental factors that could have placed the infant at risk for development of spinal cord defects.

Inspection of the neonate with spina bifida occulta often reveals a depression or dimple; a tuft of hair; soft, fatty deposits; port wine nevi; or a combination of these abnormalities over the spinal defect. Palpation may reveal a depression or raised area along the spine over the defect. In many cases, neurologic status is normal because spina bifida occulta doesn't always cause neurologic dysfunction.

In spina bifida cystica, inspection reveals a saclike protrusion over the spinal cord. Transillumination of the protruding sac can sometimes distinguish between meningocele (light typically crosses through the sac) and myelomeningocele (light doesn't cross the sac). Depending on the defect's location, effects of myelo-meningocele may include permanent neurologic dysfunction. Neurologic examination may reveal flaccid or spastic paralysis and bowel and bladder incontinence.

Other assessment findings are often related to associated disorders. These findings may include trophic skin disturbances (ulcerations, cyanosis), clubfoot, knee contractures, hydrocephalus (in about 90% of patients) and, possibly, mental retardation, Arnold-Chiari syndrome (in which part of the brain protrudes into the spinal canal), and curvature of the spine.

Diagnostic tests

Spinal X-rays show the bone defect in spina bifida and can also demonstrate associated hydrocephalus in meningocele and myelomeningocele.

Myelography differentiates spina bifida from other spinal abnormalities, especially spinal cord tumors.

Cephalic measurements and computed tomography scanning demonstrate associated hydrocephalus in meningocele and myelomeningocele.

Urinalysis and urine cultures may also be done.

Treatment

Care of the patient with a severe spinal defect requires a team approach, including the neurosurgeon, orthopedist, urologist, pediatrician, nurse, social worker, occupational and physical therapists, and family members. Specific measures depend on the severity of the neurologic deficit.

Spina bifida occulta requires little or no treatment. If indicated, surgery is performed soon after birth to release the tethered spinal cord and prevent further neurologic deterioration.

Initial treatment for spina bifida cystica includes surgical closure of the defect as soon as possible after birth, if possible within 48 hours. Then the child's growth and development are continually assessed throughout life. If the protruding sac is large, plastic surgery is required for skin grafting over the lesion. Surgery doesn't reverse the neurologic deficit. Usually, a shunt is necessary to relieve associated hydrocephalus. If hydrocephalus isn't apparent at the time of the initial surgery, the child must be frequently reassessed for its occurrence because hydrocephalus occurs in about 80% of children with myelomeningocele.

After surgery, supportive measures are required to promote independence and prevent further complications. Orthopedic, rehabilitation, and urologic consultations help determine the extent of the child's disabilities. Rehabilitation measures, which may be necessary throughout the child's life, may include:

- u waist supports, leg braces, walkers, crutches, and other orthopedic appliances
- u diet and bowel training to manage fecal incontinence
- u neurogenic bladder management to reduce urinary stasis, possibly intermittent catheterization, and antispasmodics, such as bethanechol or propantheline.

Nursing diagnoses

- u Altered growth and development
- u Altered parenting
- u Altered tissue perfusion (peripheral)
- u Altered urinary elimination
- u Impaired physical mobility
- u Impaired skin integrity
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient will maintain adequate skin integrity.
- u The patient will maintain joint mobility and range of motion.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will perform activities of daily living with maximum level of mobility and independence.
- u The patient will maintain balance in intake and output.

Nursing interventions

- u Provide psychological support, and encourage a positive attitude. Help parents work through their feelings of guilt, anger, and helplessness.

Before surgery:

- u Prevent infection by cleaning the defect gently with sterile normal saline solution or other solutions as ordered. Inspect the defect often for signs of infection, and keep it covered with sterile dressings moistened with sterile normal saline solution. Don't use ointments on the defect because they may cause skin maceration. Administer prophylactic antibiotic as ordered. Prevent skin breakdown by placing sheepskin or a foam pad under the infant and positioning the child in the prone position for the first days after surgery. Keep the skin clean, and apply lotion to knees, elbows, chin, and other pressure areas. Give antibiotics as ordered.
- u Position the child on his abdomen with the head of the bed slightly elevated to prevent contamination of the sac with urine or feces. If necessary, use pediatric fecal-incontinence bags to protect skin integrity.
- u Observe the child for signs of meningitis, including irritability, fever, feeding intolerance, and seizures. Notify the doctor if any of these signs occurs.
- u Hold and cuddle the infant, but avoid placing pressure on the sac. When holding him on your lap, position him on his abdomen.
- u Provide adequate time for parent-infant bonding.
- u Measure head circumference daily, and watch for signs of hydrocephalus and meningeal irritation, such as fever and nuchal rigidity. Be sure to mark the place where you measure the patient's head so that you get accurate readings.
- u Minimize contractures with passive range-of-motion exercises and casting. To prevent hip dislocation, moderately abduct the hips with a pad between the knees or with sandbags and ankle rolls.
- u Monitor intake and output. Watch for signs of decreased skin turgor, dryness, or other signs of dehydration. Provide meticulous perineal care to prevent infection.
- u Ensure adequate nutrition.

After surgery:

- u Monitor the patient's vital signs often. Watch for signs of shock (decreased blood pressure, tachycardia, lethargy), infection (malaise, elevated temperature, alteration in feeding pattern), and increased intracranial pressure (projectile vomiting). Frequently assess the infant's fontanels. Remember that before age 2, infants don't show typical signs of increased intracranial pressure because suture lines aren't fully closed. In infants, the most telling sign is bulging fontanels.
- u Use aseptic technique when caring for the wound. Change the dressing regularly as ordered or whenever it becomes soiled with urine or stool. Report any signs of drainage, wound rupture, and infection.
- u If a muscle flap has been used to close the defect site, place the patient in a prone position during the first 48 hours after surgery.
- u Usually, the child can't wear a diaper or a shirt until after the surgical correction because it would irritate the sac; so keep him warm in an infant Isolette.
- u Watch for hydrocephalus, which often follows such surgery. Measure the child's head circumference, and monitor the infant's fontanel size and sutures.
- u If a shunt is in place to decrease hydrocephalus, observe the site for redness or swelling. Stay alert for fever and neurologic changes.
- u If leg casts have been applied to treat deformities, look for signs that the child is outgrowing the cast. Check distal pulses to ensure adequate circulation. Petal the cast edges with plastic to prevent softening and skin irritation. Use a cool-air blow dryer to dry skin under the cast. Periodically check for foul odor and other indications of skin breakdown.

Patient teaching

- u Teach parents how to recognize early signs of complications, such as hydrocephalus, pressure ulcers, and urinary tract infection.
- u To help maintain adequate bladder function, teach parents Credé's maneuver, intermittent catheterization and, if necessary, conduit hygiene. Stress the importance of increased fluid intake to help prevent frequent urinary tract infections and, possibly, renal failure. Encourage parents to begin a bladder training routine with their child by age 3.
- u To help prevent constipation and bowel obstruction, stress the need for increased fluid intake, a high-fiber diet, exercise, and use of a stool softener as ordered. If possible, teach parents to help empty their child's bowel by telling him to bear down and giving a glycerin suppository as needed. Explain the problems associated with incomplete bowel elimination, especially for children with myelomeningocele, and encourage parents to begin a bowel-training program when the child is a toddler.
- u Teach parents to recognize developmental lags early (a possible result of hydrocephalus). If present, stress the importance of follow-up IQ assessment to help plan realistic educational goals. The child may need to attend a school with special facilities. Stress the need for stimulation to ensure maximum mental development. Help parents plan activities appropriate to their child's abilities.

u Refer parents for genetic counseling, and suggest that amniocentesis be performed in future pregnancies. For more information and names of support groups, refer parents to the Spina Bifida Association of America.

Paroxysmal disorders

Paroxysmal disorders are characterized by a marked, usually episodic increase in symptoms that affect the neurologic system. Epilepsy and headache are two of these disorders.

EPILEPSY

Epilepsy is a condition of the brain characterized by a susceptibility to recurrent seizures. It's also known as seizure disorder. Seizures are paroxysmal events associated with abnormal electrical discharges of neurons in the brain. In most patients, this conditiondoesn't affect intelligence. Epilepsy usually occurs in patients under age 20. About 80% of patients have good seizure control with strict adherence to prescribed treatment.

Causes

About half the cases of epilepsy are idiopathic. No specific cause can be found, and the patient has no other neurologic abnormality. Nonidiopathic epilepsy may be caused by:

- u genetic abnormalities, such as tuberous sclerosis and phenylketonuria (PKU)
- u perinatal injuries
- u metabolic abnormalities, such as hypocalcemia, hypoglycemia, and pyridoxine deficiency
- u brain tumors or other space-occupying lesions
- u infections, such as meningitis, encephalitis, or brain abscess
- u traumatic injury, especially if the dura mater was penetrated
- u ingestion of toxins, such as mercury, lead, or carbon monoxide
- u cerebrovascular accident.

Researchers also have detected hereditary EEG abnormalities in some families, and certain seizure disorders appear to have a familial incidence.

CULTURAL TIP Some ethnic groups have genetic or multifunctional disorders such as PKU in relatively high frequency. Asian, Polish, Swedish, and Scottish individuals have a higher than average existence of PKU. Be aware that many cultural groups have a stigma against this condition and believe it's caused by things such as evil spirits. Helping the patient to understand the disorder is essential to ensure proper treatment.

Complications

Associated complications can occur during a seizure. These include anoxia from airway occlusion by the tongue or vomitus and traumatic injury. Such traumatic injury could result from a fall at the onset of a generalized tonic-clonic seizure; from the rapid, jerking movements that occur during or after a generalized tonic-clonic seizure; or from a fall or sudden movement sustained while the patient is confused or has an altered level of consciousness.

Assessment findings

Depending on the type and cause of the seizure, signs and symptoms vary. (See [Differentiating seizures.](#)) Physical findings may be normal if the assessment is performed when the patient isn't having a seizure and the cause is idiopathic. If the seizure is associated with an underlying problem, the patient's history and physical examination should reveal signs and symptoms of that problem unless the seizure was caused by a brain tumor, which may produce no other symptoms.

WARNING

Understanding status epilepticus

Status epilepticus—which can occur in all seizure types—is a continuous seizure state unless interrupted by emergency interventions. The most life-threatening example is *generalized tonic-clonic status epilepticus*, a continuous generalized tonic-clonic seizure without an intervening return of consciousness.

Status epilepticus, always an emergency, is accompanied by respiratory distress. It can result from abrupt withdrawal of antiepileptic medications, hypoxic or metabolic encephalopathy, acute head trauma, or septicemia secondary to encephalitis or meningitis.

Emergency treatment for status epilepticus usually consists of diazepam, phenytoin, or phenobarbital; dextrose 50% I.V. (when seizures are secondary to hypoglycemia); and thiamine I.V. (in the presence of chronic alcoholism or withdrawal).

In many cases, the patient's history reveals that seizure occurrence is unpredictable and unrelated to activities. Occasionally, a patient may report precipitating factors or events—for example, that the seizures always take place at a particular time, such as during sleep, or after a particular circumstance, such as lack of sleep or emotional stress. The patient may also report nonspecific changes, such as headache, mood changes, lethargy, and myoclonic jerking, occurring up to several hours before the onset of a seizure.

Patients who experience a generalized seizure may describe an aura, which represents the beginning of abnormal electrical discharges within a focal area of the brain. Typical auras may include a pungent smell, GI distress (nausea or indigestion), a rising or sinking feeling in the stomach, a dreamy feeling, an unusual taste, or a visual disturbance such as a flashing light that precedes seizure onset by a few seconds or minutes.

The patient may describe the effect the seizures have on his lifestyle, activities of daily living, and coping mechanisms. The patient may also have a history of status epilepticus. (See [Understanding status epilepticus.](#))

If you observe the patient during a seizure, be sure to note the type of seizure he's experiencing. Otherwise, details of what occurs during a seizure—obtained from a family member or friend, if necessary—may help to identify the seizure type.

ADVANCED PRACTICE

Differentiating seizures

The hallmark of epilepsy is recurring seizures, which can be classified as partial or generalized. Some patients may be affected by more than one type.

Partial seizures

Partial seizures arise from a localized area in the brain and cause specific symptoms. In some patients, partial seizure activity spreads to the entire brain, causing a generalized seizure. Partial seizures include simple partial (Jacksonian motor-type and sensory-type), complex partial (psychomotor or temporal lobe), and secondarily generalized partial seizures.

Simple partial (jacksonian motor-type) seizure

This type begins as a localized motor seizure, which is characterized by a spread of abnormal activity to adjacent areas of the brain. Typically, the patient experiences a stiffening or jerking in one extremity, accompanied by a tingling sensation in the same area. For example, the seizure may start in the thumb and spread to the entire hand and arm. The patient seldom loses consciousness, although the seizure may secondarily progress to a generalized tonic-clonic seizure.

Simple partial (sensory-type) seizure

Perception is distorted in this type of seizure. Symptoms can include hallucinations, flashing lights, tingling sensations, a foul odor, vertigo, or déjà vu (the feeling of having experienced something before).

Complex partial seizure

Symptoms of complex partial seizure vary but usually include purposeless behavior. The patient may experience an aura and exhibit overt signs, including a glassy stare, picking at his clothes, aimless wandering, lip-smacking or chewing motions, and unintelligible speech. A seizure may last for a few seconds or as long as 20 minutes. Afterward, mental confusion may last for several minutes; as a result, an observer may mistakenly suspect psychosis or intoxication with alcohol or drugs. The patient has no memory of his actions during the seizure.

Secondarily generalized partial seizure

This type of seizure can be either simple or complex and can progress to generalized seizures. An aura may precede the progression. Loss of consciousness occurs immediately or within 1 or 2 minutes of the start of the progression.

Generalized seizures

As the term suggests, these seizures cause a generalized electrical abnormality in the brain. They include several distinct types.

Absence (petit mal) seizure

This type occurs most often in children but also may affect adults. It usually begins with a brief change in level of consciousness, indicated by blinking or rolling of the eyes, a blank stare, and slight mouth movements. The patient retains his posture and continues preseizure activity without difficulty. Typically, a seizure lasts from 1 to 10 seconds. The impairment is so brief that the patient is sometimes unaware of it. If not properly treated, these seizures can recur as often as 100 times a day. An absence seizure can progress to a generalized tonic-clonic seizure.

Myoclonic seizure

Myoclonic seizure — also called bilateral massive epileptic myoclonus — is marked by brief, involuntary muscular jerks of the body or extremities, which may occur in a rhythmic manner, and a brief loss of consciousness.

Generalized tonic-clonic (grand mal) seizure

Typically, this seizure begins with a loud cry, precipitated by air rushing from the lungs through the vocal cords. The patient falls to the ground, losing consciousness. The body stiffens (tonic phase) and then alternates between episodes of muscle spasm and relaxation (clonic phase). Tongue biting, incontinence, labored breathing, apnea, and subsequent cyanosis may also occur. The seizure stops in 2 to 5 minutes, when abnormal electrical conduction of the neurons is completed. The patient then regains consciousness but is somewhat confused and may have difficulty talking. If he can talk, he may complain of drowsiness, fatigue, headache, muscle soreness, and arm or leg weakness. He may fall into a deep sleep after the seizure.

Akinetic seizure

Akinetic seizure is characterized by a general loss of postural tone and a temporary loss of consciousness. This type of seizure occurs in young children. Sometimes it's called a drop attack because it causes the child to fall.

Diagnostic tests

EEG can be used to identify paroxysmal abnormalities which may confirm the diagnosis of epilepsy by providing evidence of the continuing tendency to have seizures. A negative EEG doesn't rule out epilepsy because the paroxysmal abnormalities occur intermittently. The EEG also helps guide the prognosis and can help to classify the disorder.

Computed tomography scanning and magnetic resonance imaging provide density readings of the brain and may indicate abnormalities in internal structures.

Other helpful tests include serum glucose and calcium studies, skull X-rays, lumbar puncture, brain scan, and cerebral angiography.

Treatment

Typically, treatment for epilepsy consists of drug therapy specific to the type of seizure. The most commonly prescribed drugs include phenytoin, carbamazepine, phenobarbital, and primidone administered individually for generalized tonic-clonic seizures and complex partial seizures. Valproic acid, clonazepam, and ethosuximide are commonly prescribed for absence (petit mal) seizures. Lamotrigine is also prescribed as adjunct therapy for partial seizures. Fosphenytoin is a new I.V. preparation that is effective in treatment.

If drug therapy fails, treatment may include surgical removal of a demonstrated focal lesion to attempt to bring an end to seizures. Surgery is also performed when epilepsy results from an underlying problem, such as intracranial tumors, a brain abscess or cyst, and vascular abnormalities.

Vagal nerve stimulation may be attempted. A pacemaker with a stimulator lead is placed on the vagus nerve. The nerve is stimulated for approximately 30 seconds every 5 minutes. This is useful in refractory epilepsy, decreasing seizure frequency and intensity. It has also diminished the need for more medication and increased the quality of life for some individuals. (See [Vagal nerve stimulation.](#))

Nursing diagnoses

- u Anxiety
- u Fear
- u Ineffective individual coping
- u Knowledge deficit
- u Risk for injury
- u Social isolation

Vagal nerve stimulation

The vagal nerve stimulator is a new Food and Drug Administration—approved method to treat epilepsy. The device is implanted surgically and consists of a pacemaker-like generator and a lead. A small incision is placed in the chest, and the device is implanted in the chest and neck area.

The vagal nerve stimulator stimulates the vagus nerve for 30 seconds every 5 minutes to prevent seizure occurrence. A magnet over the area can activate the device to give extra, on-demand stimulation if a seizure is felt coming on. Adverse effects are voice change, throat discomfort, shortness of breath, and coughing and are usually only felt when the device is “on.”

Key outcomes

- u The patient will remain free from injury.
- u The patient will communicate an understanding of the condition and treatment regimen.
- u The patient and family members will use support systems and develop adequate coping.
- u The patient and family members will express feelings of decreased anxiety and fear.
- u The patient will resume active participation in social situations and activities.

Nursing interventions

- u Provide emotional support. Encourage the patient and family to express their fears and concerns. Suggest counseling to help them cope.
- u If the patient is taking anticonvulsants, constantly monitor him for signs and symptoms of toxicity, such as slurred speech, ataxia, lethargy, dizziness, drowsiness, nystagmus, irritability, nausea, and vomiting.
- u When administering phenytoin I.V., use a large vein, administer at a slow rate (not to exceed 50 mg/minute), and monitor the patient frequently.
- u Prepare the patient for surgery.
- u If necessary, provide preoperative and postoperative care appropriate for the type of surgery the patient is to undergo.

Patient teaching

- u Provide adequate patient support by developing an understanding of epilepsy and the myths and misconceptions that surround it. Answer any questions the patient and family members have about the condition. Help them to cope by dispelling myths. For example, assure them that epilepsy isn't contagious and is controllable for most patients who follow a prescribed regimen of medication. Provide assurance that most patients maintain a normal lifestyle.

PREVENTION

**Preventing seizures**

Teach the patient the following measures to help him control and decrease the occurrence of seizures:

- u Make the exact dose of medication at the times prescribed. Missing doses, doubling doses, or taking extra doses can cause a seizure.
- u Eat balanced, regular meals. Low blood glucose levels (hypoglycemia) and inadequate vitamin intake can lead to seizures.
- u Be alert for odors that may trigger an attack. Advise the patient and his family to inform the doctor of any strong odors they notice at the time of a seizure.
- u Limit alcohol intake. In fact, the patient should check with the doctor to find out whether he should drink any alcoholic beverages.
- u Get enough sleep. Excessive fatigue can precipitate a seizure.
- u Treat a fever early during an illness. If the patient can't reduce a fever, he should notify the doctor.
- u Learn to control stress. If appropriate, suggest learning relaxation techniques such as deep-breathing exercises.
- u Avoid trigger factors, such as flashing lights, hyperventilation, loud noises, heavy musical beats, video games, and television.

- u Explain to the patient and family the need for compliance with the prescribed drug schedule. Assure the patient that anticonvulsant drugs are safe when taken as ordered. Reinforce dosage instructions, and find methods to help the patient remember to take medications. Stress the importance of taking the medication regularly at a scheduled time. Caution the patient to monitor the amount of medication left so that he doesn't run out of it.
- u Teach the patient about the medication's possible adverse effects—drowsiness, lethargy, hyperactivity, confusion, visual and sleep disturbances—all of which indicate the need for dosage adjustment. Tell him that phenytoin therapy may lead to hyperplasia of the gums, which may be relieved by conscientious oral hygiene. Instruct the patient to report adverse reactions immediately.
- u Explain the importance of having anticonvulsant blood levels checked at regular intervals even if the seizures are under control.
- u Instruct the patient to eat regular meals and to check with his doctor before dieting. Explain that maintaining adequate glucose levels provides the necessary energy for central nervous system neurons to work normally. (See [Preventing seizures.](#))
- u If the patient is a candidate for surgery, provide appropriate preoperative teaching. Explain the care that the patient can expect postoperatively.
- u Know which social agencies in your community can help epileptic patients. Refer the patient to the Epilepsy Foundation of America for general information and to the state motor vehicle department for information about a driver's license.

Finally, teach the patient's family how to care for the patient during a seizure. This is especially important if the patient experiences generalized tonic-clonic seizures, which may necessitate first aid. Instruct family members to do the following:

- u Avoid restraining the patient during a seizure.
- u Help the patient to a lying position, loosen any tight clothing, and place something flat and soft, such as a pillow, jacket, or hand, under his head.
- u Clear the area of hard objects.
- u Avoid forcing anything into the patient's mouth if his teeth are clenched—a tongue blade or spoon could lacerate mouth and lips or displace teeth, precipitating respiratory distress.
- u Protect the patient's tongue, if his mouth is open, by placing a soft object (such as folded cloth) between his teeth.
- u Turn his head to the side to provide an open airway.
- u Reassure the patient after the seizure subsides by telling him that he's all right, orienting him to time and place, and informing him that he's had a seizure.

HEADACHE

Headache is the most common patient complaint. It usually occurs as a symptom of an underlying disorder. Unless the underlying disorder is serious, headache rarely necessitates hospitalization.

About 90% of all headaches are classified as vascular, muscle contraction, or a combination of the two; 10% are caused by underlying intracranial, systemic, or psychological disorders. Migraine headaches, probably the most intensively studied, are throbbing, vascular headaches that usually begin to appear in childhood or adolescence and recur throughout adulthood. Migraine headaches affect up to 10% of Americans, are more common in females than in males, and have a strong

familial incidence. The patient with a migraine headache usually needs to be hospitalized only if nausea and vomiting are severe enough to lead to dehydration and possible shock.

Causes

Most chronic headaches result from tension—muscle contraction—which may be caused by emotional stress, fatigue, menstruation, or environmental stimuli (noise, crowds, bright lights). Other possible causes include glaucoma; inflammation of the eyes or mucosa of the nasal or paranasal sinuses; diseases of the scalp, teeth, extracranial arteries, or external or middle ear; and muscle spasms of the face, neck, or shoulders.

Headaches also may be caused by vasodilators (nitrates, alcohol, histamine), systemic disease, hypoxia, hypertension, head trauma and tumors, intracranial bleeding, abscess, or aneurysm.

Although the cause is unknown, migraine headaches are believed to be associated with constriction and dilation of intracranial and extracranial arteries. Certain biochemical abnormalities are thought to occur during a migraine attack. These include local leakage of a vasodilator polypeptide through the dilated arteries and a decrease in the plasma level of serotonin.

Headache pain can emanate from the pain-sensitive structures of the skin, scalp, muscles, arteries, veins; cranial nerves V, VII, IX, and X; and cervical nerves 1, 2, and 3. Intracranial mechanisms of headache include traction or displacement of arteries, venous sinuses, or venous tributaries and inflammation or direct pressure on the cranial nerves with afferent pain fibers.

Complications

Potential complications of headache include worsening of already existing hypertension, phonophobia, emotional lability, and motor weakness.

Assessment findings

The patient's history pinpoints the headache's location, characteristics, onset, and duration. Typically, findings indicate whether the headache is bilateral or unilateral; how often it occurs; how it feels (for example, dull, aching, steady, burning, or penetrating pain); whether it's continuous or intermittent; and how long the patient has been experiencing this type of headache.

The patient's history also may reveal precipitating factors (such as tension, menstruation, loud noises, menopause, or alcohol) and aggravating factors (for example, coughing, sneezing, or sunlight). In addition, the history may indicate whether the headache interferes with daily activities; if the patient has any associated symptoms, such as nausea, vomiting, weakness, facial pain, and scotomas; and if the patient has allergies, takes headache-inducing medications, or has a family history of headaches.

During physical examination of the head and neck, inspection may reveal signs of infection; palpation may detect defects, crepitus, or tender spots (especially after trauma); and auscultation may detect bruits. If the patient has no underlying problem, physical, neurologic, and ophthalmoscopic examination findings should be normal.

The history of a patient with a *migraine headache* usually reveals that the headache began with a unilateral, pulsating pain that gradually became more generalized. The patient—usually female, with a compulsive or perfectionist personality—may report that the headache was preceded by a scintillating scotoma, hemianopia, unilateral paresthesia, or speech disorders. (This aura is thought to result from vasoconstriction and ischemia in the cerebral cortex and, possibly, in the retina.)

Most migraine headaches last from 2 hours to several days and are accompanied by irritability, anorexia, nausea, vomiting, and photophobia. About 90% of patients report a family history of migraine headaches.

During a migraine attack, the patient may appear pale. (See [Clinical features of migraine headaches.](#))

The patient with *muscle-contraction* or *traction-inflammatory vascular headache* may complain of a dull, persistent ache; tender spots on the head and neck; and a feeling of tightness around the head—with a characteristic “hatband” distribution—that begins in the forehead, temple, or back of the neck. The patient may describe the pain as severe and unrelenting.

If the headache results from intracranial bleeding, neurologic examination may reveal neurologic deficits, such as paresthesia and muscle weakness. If the patient with intracranial bleeding has received treatment for the headache before your assessment, he may report that narcotics failed to relieve the pain. If the patient reports that the pain is most severe when he awakens and decreases somewhat when he lifts his head to an upright position, the pain may be caused by a tumor. Either of these symptoms indicates the need for further testing.

ADVANCED PRACTICE

 Clinical features of migraine headaches	
Migraine headaches occur in four basic types: common, classic, hemiplegic and ophthalmoplegic, and basilar artery The following chart compares the signs and symptoms that characterize each migraine type.	
TYPE	SIGNS AND SYMPTOMS
Common migraine (most prevalent; affects 85% of patients) Usually occurs on weekends and holidays	<ul style="list-style-type: none">▫ Prodromal symptoms (fatigue, nausea and vomiting, and fluid imbalance) precede headache by about a day.▫ Most prominent feature is sensitivity to light and noise.▫ Headache pain (unilateral or bilateral, aching or throbbing) lasts longer than in classic migraine.
Classic migraine (affects 10% of patients) Usually occurs in compulsive personalities and within families	<ul style="list-style-type: none">▫ Prodromal symptoms include visual disturbances, such as zigzag lines and bright lights (most common), sensory disturbances (tingling of the face, lips, and hands), or motor disturbances (staggering gait).▫ Headaches are recurrent and periodic.
Hemiplegic and ophthalmoplegic migraine (rare) Usually occurs in young adults	<ul style="list-style-type: none">▫ Pain is severe and unilateral.▫ Extraocular muscle palsies (involving third cranial nerve) and ptosis occur.▫ With repeated headaches, permanent third cranial nerve injury is possible.▫ In hemiplegic migraine, neurologic deficits (hemiparesis, hemiplegia) may persist after headache subsides.

Basilar artery migraine Occurs in young women before their menstrual periods	<ul style="list-style-type: none">Prodomal symptoms usually include partial vision loss followed by vertigo, ataxia, dysarthria, tinnitus and, sometimes, tingling of the fingers and toes, lasting from several minutes to almost an hour.Headache pain characterized by severe occipital throbbing and vomiting may occur.
--	---

Diagnostic tests

The doctor's initial impression of the patient's condition is used to determine which diagnostic tests to perform. Such tests may include skull X-rays (including cervical, spine, and sinus), EEG, computed tomography scan, and lumbar puncture.

Treatment

Depending on the type of headache, analgesics—ranging from aspirin to codeine or meperidine—may provide relief. A tranquilizer such as diazepam may help during acute attacks.

Other treatment measures include identification and elimination of causative factors and, possibly, psychotherapy for headaches caused by emotional stress. Chronic tension headaches may also require muscle relaxants.

For migraine headache, ergotamine preparations (taken alone or with caffeine) and other drugs, such as metoclopramide or naproxen, work best when taken early in the course of an attack. For acute migraine attacks or cluster headaches, 5HT₁ receptor agonists such as sumatriptan or rizatriptan are most effective.

If nausea and vomiting make oral administration impossible, many of these drugs may be given as rectal suppositories. If migraine headaches occur more than two or three times a month, the doctor may order preventive drugs, such as propranolol and cyproheptadine.

CULTURAL TIP The patient and family members may be open to various culturally influenced therapies, which can be very therapeutic, such as yoga, mediation, or other relaxation type therapies. Herbal remedies should be investigated before use because their composition can impede rather than help with the healing process.

Nursing diagnoses

- Altered family processes
- Altered health maintenance
- Anxiety
- Energy field disturbance
- Fatigue
- Hopelessness
- Knowledge deficit
- Pain

Key outcomes

- The patient will express feelings of comfort and relief of pain.
- The patient will feel increasingly relaxed.
- The patient will continue to receive treatments that help him to relax and promote inner well-being.
- The patient will express an increased sense of well-being.
- The patient and family members will use support systems to assist with coping.

Nursing interventions

- Encourage the patient to discuss his problems. Listen to him and provide emotional support, especially during periods of physical and emotional stress. Have the patient perform relaxation techniques to prevent or ease headache. If possible, provide him with a warm bath to promote relaxation.
- To decrease the severity of the pain, keep the patient's room dark and quiet. Place ice packs on the patient's forehead, or a cold cloth over his eyes. Administer ordered medications as required to relieve pain or to prevent a migraine headache. Administer medications, such as antidepressants, barbiturates, and tranquilizers, as ordered, to help the patient cope with stress and anxiety.

Patient teaching

- Refer patients who experience migraine headaches to the National Headache Foundation. This organization provides a list of doctors and clinics in the United States that specialize in the care of patients with headache.
- Encourage the patient to keep a diary of headache occurrence, noting severity, relief, and length of attack. (See [Preventing headaches.](#))

PREVENTION

Preventing headaches

- Using the history as a guide, help the patient understand what precipitates his headaches so he can avoid exacerbating factors. These factors include hunger, lack of exercise, and erratic sleep schedules.
- Teach the patient how to perform relaxation techniques. Explain that education in relaxation techniques and biofeedback may help him to change his attitude toward stress and can help him decrease the frequency of vascular and muscle-contraction headaches.
- Encourage the patient to exercise regularly. Explain that regular exercise promotes relaxation.
- If the patient experiences migraine headaches, instruct him to take the prescribed medication at the onset of migraine symptoms. Also advise him to prevent dehydration by drinking plenty of fluids after nausea and vomiting subside, avoid long intervals between meals, and awaken at the same time every day (in some patients a disruption in normal sleeping patterns can precipitate a headache).
- Encourage the patient who experiences migraine headaches to keep a record of activities and events that take place just before an attack; this can help identify a pattern that precedes the onset of a migraine.

Brain and spinal cord disorders

Impaired cerebral circulation, inflammation, and infection are among the many causes of brain and spinal cord disorders that can lead to neurologic dysfunction.

ALZHEIMER'S DISEASE

Alzheimer's disease is a progressive degenerative disorder of the cerebral cortex (especially the frontal lobe) that accounts for more than half of all cases of dementia. An estimated 5% of people over age 65 have a severe form of this disease, and 12% suffer from mild to moderate dementia. Because this is a primary progressive dementia, the prognosis for a patient with this disease is poor.

Causes

The cause of Alzheimer's disease is unknown, but several factors are thought to be closely connected to this disease. These include neurochemical factors, such as deficiencies of the neurotransmitters acetylcholine, somatostatin, substance P, and norepinephrine; environmental factors, such as aluminum and manganese;

trauma; genetic factors; and viral factors such as slow-growing central nervous system viruses.

Researchers believe that up to 70% of Alzheimer's cases stem from a genetic abnormality. Recently, they located the abnormality on chromosome 21. They've also isolated a genetic substance (amyloid) that causes brain damage typical of Alzheimer's disease. The brain tissue of patients with this dementia has three distinguishing features: neurofibrillary tangles, neuritic plaques, and granulovascular degeneration.

Complications

Complications of Alzheimer's disease include injury from the patient's own violent behavior or from wandering or unsupervised activity; pneumonia and other infections, especially if the patient doesn't receive enough exercise; malnutrition and dehydration if the patient refuses or forgets to eat; and aspiration.

Assessment findings

As you assess this patient, keep in mind that the onset of this disorder is insidious and that initial changes are almost imperceptible but gradually progress to serious problems. The patient history is almost always obtained from a family member or caregiver.

Typically, the patient history shows initial onset of very small changes, such as forgetfulness and subtle memory loss without loss of social skills and behavior patterns. It also reveals that over time the patient began experiencing recent memory loss and had difficulty learning and remembering new information. The history also may reveal a general deterioration in personal hygiene and appearance and an inability to concentrate.

Depending on the severity of the disease, the patient history may reveal that the patient experiences several of the following problems: Difficulty with abstract thinking and activities that require judgment; progressive difficulty in communicating; and a severe deterioration of memory, language, and motor function that in the more severe cases finally results in coordination loss and an inability to speak or write. He may also perform repetitive actions and experience restlessness; negative personality changes, such as irritability, depression, paranoia, hostility, and combativeness; nocturnal awakening; and disorientation.

The person giving the history may explain that the patient is suspicious and fearful of imaginary people and situations, misperceives his environment, misidentifies objects and people, and complains of stolen or misplaced objects.

He also may report that the patient seems overdependent on caregivers and has difficulty using correct words and may often substitute meaningless words. He may report that conversations with the patient drift off into nonsensical phrases. The patient's emotions may be described as labile. Also, the patient may laugh or cry inappropriately and have mood swings, sudden angry outbursts, and sleep disturbances.

Neurologic examination confirms many of the problems revealed during the history. In addition, it often reveals an impaired sense of smell (usually an early symptom), impaired stereognosis (inability to recognize and understand the form and nature of objects by touching them), gait disorders, tremors, and loss of recent memory. The patient's susceptibility to infection and accidents (due to the loss of the cough reflex) and to pulmonary disease (such as pneumonia) may result in death. The patient with Alzheimer's disease also has a positive snout reflex.

ASSESSMENT TIP The snout test involves tapping or stroking the patient's lips or the area just under the nose. Grimacing or puckering the lips is a positive sign for Alzheimer's disease in an adult. A positive result in early infancy is normal. When results are positive in an adult, the snout reflex test suggests organic brain disease.

If the patient is in the final stages, he typically has urinary or fecal incontinence and may twitch and have seizures. (See [Stages of Alzheimer's disease.](#))

Diagnostic tests

Alzheimer's disease is diagnosed by exclusion. Various tests such as those described below are performed to rule out other disorders. The diagnosis can't be confirmed until death, when pathologic findings come to light at autopsy.

Position emission tomography measures the metabolic activity of the cerebral cortex and may help confirm early diagnosis.

Computed tomography scanning in some patients shows progressive brain atrophy in excess of that which occurs in normal aging. Magnetic resonance imaging may permit evaluation of the condition of the brain and rule out intracranial lesions as the source of dementia.

EEG allows evaluation of the brain's electrical activity and may show slowing of the brain waves in the late stages of the disease. This diagnostic test also helps identify tumors, abscesses, and other intracranial lesions that might cause the patient's symptoms.

Cerebrospinal fluid analysis may help determine if the patient's signs and symptoms stem from a chronic neurologic infection. Cerebral blood flow studies may detect abnormalities in blood flow to the brain.

Neuropsychology testing is a battery of tests designed to assess cognitive ability and reasoning. They can help differentiate Alzheimer's disease from other types of dementia.

Treatment

No cure or definitive treatment exists for Alzheimer's disease. Therapy consists of cerebral vasodilators, such as ergoloid mesylates, isoxsuprine, and cyclandelate to enhance the brain's circulation; hyperbaric oxygen to increase oxygenation to the brain; psychostimulators such as methylphenidate to enhance the patient's mood; and antidepressants if depression seems to exacerbate the patient's dementia.

Most other drug therapies being tried are experimental. These include choline salts, lecithin, physostigmine, enkephalins, and naloxone, which may slow the disease process. Drugs commonly given to enhance cognition include thiorine hydrochloride with aricept-donepezil hydrochloride (Cognex).

Nursing diagnoses

u Altered family process u Altered nutrition: Less than body requirements u Altered thought processes u Constipation u Impaired verbal communication u Ineffective family coping: Disabling u Ineffective individual coping u Knowledge deficit u Risk for infection u Risk for injury u Self-care deficit: Bathing or hygiene u Self-care deficit: Dressing or grooming u Self-care deficit: Feeding u Self-care deficit: Toileting

Key outcomes

- u The patient will perform activities of daily living within confines of the disease process.
- u The patient will consume daily calorie requirements.
- u The patient will remain free from signs and symptoms of infection.

ADVANCED PRACTICE

Stages of Alzheimer's disease

Alzheimer's disease progresses in three stages. The symptoms of each are outlined below.

FUNCTIONS

SYMPTOMS

Early stage

Language	Anomia, empty speech
Memory	Defective
Visuospatial skills	Impaired
Calculation	Impaired
Personality	Indifferent, occasional irritability
Klüver-Bucy syndrome	Absent
Motor system	Normal
EEG	Normal
CT scan/MRI	Normal

Middle stage

Language	Fluent aphasia
Memory	Severely impaired
Visuospatial skills	Severely impaired
Personality	Indifferent or irritable
Motor system	Restless, pacing
EEG	Slowing of background rhythms
CT scan/MRI	Atrophy

Late stage

Intellectual function	Severely impaired
Language	Palilalia, echolalia, or mutism
Motor system	Limb rigidity
Sphincter control	Incontinence
EEG	Diffuse slowing
CT scan/MRI	Diffuse atrophy

HOME CARE

Teaching patients about Alzheimer's disease

Counsel family members to expect progressive deterioration in the patient with Alzheimer's disease. To help them plan future patient care, discuss the stages of this relentless and inevitably progressive disease.

Bear in mind that family members may refuse to believe that the disease is advancing. Be sensitive to their concerns and, if necessary, review the information again when they're more receptive.

Forgetfulness

The patient becomes forgetful, especially of recent events. He frequently loses everyday objects such as keys. Aware of his loss of function, he may compensate by relinquishing tasks that might reveal his forgetfulness. Because his behavior isn't disruptive and may be attributed to stress, fatigue, or normal aging, he usually doesn't consult a doctor at this stage.

Confusion

The patient has increasing difficulty at activities that require planning, decision making, and judgment, such as managing personal finances, driving a car, and performing his job. He does retain skills such as personal grooming. Social withdrawal occurs when the patient feels overwhelmed by a changing environment and his inability to cope with multiple stimuli. Travel is difficult and tiring. As he becomes aware of his progressive loss of function, he may become severely depressed.

Safety becomes a concern when the patient forgets to turn off appliances or to recognize unsafe situations such as boiling water. At this point, the family may need to consider day care or a supervised residential facility.

Decline in activities of daily living

The patient at this stage loses his ability to perform daily activities, such as eating or washing, without direct supervision. Weight loss may occur. He withdraws from the family and increasingly depends on the primary caregiver. Communication becomes difficult as his understanding of written and spoken language declines. Agitation, wandering, pacing, and nighttime awakening are linked to his inability to cope with a multisensory environment. He may mistake his mirror image for a real person (pseudohallucination). Caregivers must be constantly vigilant, which may lead to physical and emotional exhaustion. They may also be angry and feel a sense of loss.

Total deterioration

In the final stage of Alzheimer's disease, the patient no longer recognizes himself, his body parts, or other family members. He becomes bedridden, and his activity consists of small, purposeless movements. Verbal communication stops, although he may scream spontaneously. Complications of immobility may include pressure ulcers, urinary tract infections, pneumonia, and contractures.

- u The patient will perform self-care needs within the confines of the disease process.
- u The patient and family members will use support systems and develop adequate coping behaviors.

Nursing interventions

- u Establish an effective communication system with the patient and family members to help them adjust to the patient's altered cognitive abilities.
- u Provide emotional support to the patient and family members. Encourage them to talk about their concerns. Listen carefully to them, and answer their questions

- honestly and completely.
- u Because the patient may misperceive his environment, use a soft tone and a slow, calm manner when speaking to him.
 - u Allow the patient sufficient time to answer your questions because his thought processes are slow, impairing his ability to communicate verbally.
 - u Administer ordered medications to the patient and note their effects.
 - u If the patient has trouble swallowing, check with a pharmacist to see if tablets can be crushed or capsules can be opened and mixed with a semisoft food.
 - u Protect the patient from injury by providing a safe, structured environment. Provide rest periods between activities because these patients tire easily.
 - u Encourage the patient to exercise, as ordered, to help maintain mobility.
 - u Encourage patient independence, and allow ample time for the patient to perform tasks.
 - u Encourage sufficient fluid intake and adequate nutrition. Provide assistance with menu selection, and allow the patient to feed himself as much as he can. Provide a well-balanced diet with adequate fiber. Avoid stimulants, such as coffee, tea, cola, and chocolate. Give the patient semisolid foods if he has dysphagia. Insert and care for a nasogastric tube or a gastrostomy tube for feeding as ordered.
 - u Because the patient may be disoriented or neuromuscular functioning may be impaired, take the patient to the bathroom at least every 2 hours, and make sure he knows the location of the bathroom.
 - u Assist the patient with hygiene and dressing as necessary. Many patients with Alzheimer's disease are incapable of performing these tasks.

Patient teaching

- u Teach the patient's family about the disease. Explain that the cause of the disease is unknown. Review the signs and symptoms of the disease with them. Be sure to explain that the disease progresses but at an unpredictable rate and that patients eventually suffer complete memory loss and total physical deterioration. (See [Teaching patients about Alzheimer's disease.](#))
- u Review the diagnostic tests that are to be performed and treatment the patient requires.
- u Advise family members to provide the patient with exercise. Suggest physical activities, such as walking or light housework, that occupy and satisfy the patient.
- u Stress the importance of diet. Instruct family members to limit the number of foods on the patient's plate so he doesn't have to make decisions. If the patient has coordination problems, tell family members to cut his food and to provide finger foods, such as fruit and sandwiches. Suggest using plates with rim guards, built-up utensils, and cups with lids and spouts.
- u Encourage family members to allow the patient as much independence as possible while ensuring his and others' safety. Tell them to create a routine for all the patient's activities, which helps them avoid confusion. If the patient becomes belligerent, advise family members to remain calm and try to distract him.
- u Refer family members to support groups such as the Alzheimer's Association. Set up an appointment with the social service department to help family members assess their needs.

CEREBROVASCULAR ACCIDENT

Also known as stroke, cerebrovascular accident (CVA) is a sudden impairment of cerebral circulation in one or more of the blood vessels supplying the brain. CVA interrupts or diminishes oxygen supply and commonly causes serious damage or necrosis in brain tissues. The sooner circulation returns to normal after CVA, the better chances are for complete recovery. About half of those who survive CVA remain permanently disabled and experience a recurrence within weeks, months, or years.

CVA is the third most common cause of death in the United States today and the most common cause of neurologic disability. It afflicts 500,000 persons each year; half of them die as a result. Although it mostly affects older adults, it can occur in people of any age and is most common in men, especially blacks.

CVAs are classified according to their course of progression. The least severe is the transient ischemic attack (TIA), which results from a temporary interruption of blood flow, most often in the carotid and vertebrobasilar arteries. (See [Transient ischemic attack: A warning sign of CVA.](#))

A progressive stroke, or stroke-in-evolution(thrombus-in-evolution), begins with a slight neurologic deficit and worsens in a day or 2. In a completed stroke, neurologic deficits are at the maximum at the onset.

Causes

Major causes of CVA include cerebral thrombosis, embolism, and hemorrhage.

Thrombosis is the most common cause of CVA in middle-aged and elderly people. CVA results from obstruction of a blood vessel. Typically, the main site of the obstruction is the extracerebral vessels, but sometimes it's intracerebral.

Embolism, the second most common cause of CVA, can occur at any age, especially among patients with a history of rheumatic heart disease, endocarditis, posttraumatic valvular disease, myocardial fibrillation and other cardiac arrhythmias, or after open-heart surgery. It usually develops rapidly—in 10 to 20 seconds—and without warning. Most often, the left middle cerebral artery is the embolus site.

Hemorrhage, the third most common cause of CVA, may also occur suddenly at any age. Such hemorrhage results from chronic hypertension or aneurysms, which cause sudden rupture of a cerebral artery.

Factors that increase the risk of CVA include a history of TIAs, heart disease, atherosclerosis, hypertension, arrhythmias, electrocardiogram changes, rheumatic heart disease, diabetes mellitus, gout, postural hypotension, cardiac enlargement, high serum triglyceride levels, lack of exercise, use of oral contraceptives, smoking, and a family history of cerebrovascular disease. Genetic risk factors include apolipoprotein E4, homocysteines, and factor V mutation.

ADVANCED PRACTICE

Transient ischemic attack: A warning sign of CVA

A transient ischemic attack (TIA) is a recurrent episode of neurologic deficit lasting less than 1 hour without permanent neurologic defects. It's usually considered a warning sign of an impending thrombotic cerebrovascular accident (CVA); TIAs are reported in 50% to 80% of patients who had a cerebral infarction from such thrombosis. The age of onset varies. Incidence increases dramatically after age 50 and is highest among blacks and men.

In TIA, microemboli released from a thrombus may temporarily interrupt blood flow, especially in the small distal branches of the brain's arterial tree. Small spasms in those arterioles may impair blood flow and also precede TIA. Predisposing factors are the same as for thrombotic CVAs.

Clinical features

The most distinctive characteristics of TIA are the transient duration of neurologic deficits and the complete return of normal function. The signs and symptoms of TIA correlate with the location of the affected artery. They include double vision, speech deficits (slurring or thickness), unilateral blindness, staggering or uncoordinated gait, unilateral weakness or numbness, falling because of weakness in the legs, and dizziness.

Treatment

During an active TIA, treatment aims to prevent a completed stroke and consists of aspirin, antiplatelet drugs, or anticoagulants to minimize the risk of thrombosis. After or between attacks, preventive treatment includes carotid endarterectomy or cerebral microvascular bypass.

Complications

Among the many possible complications of CVA are unstable blood pressure from loss of vasomotor control, fluid imbalances, malnutrition, infections such as pneumonia, and sensory impairment, including vision problems. Altered level of consciousness (LOC), aspiration, contractures, and pulmonary emboli also may occur.

Assessment findings

Clinical features of CVA vary with the artery affected (and, consequently, the portion of the brain it supplies), the severity of the damage, and the extent of collateral circulation that develops to help the brain compensate for a decreased blood supply.

ASSESSMENT TIP When assessing a patient who may have experienced a CVA, remember this: If the CVA occurs in the left hemisphere, it produces signs and symptoms on the right side. If it occurs in the right hemisphere, signs and symptoms appear on the left side. A CVA that causes cranial nerve damage produces signs of cranial nerve dysfunction on the same side as the hemorrhage.

The patient's history obtained from a family member or friend, if necessary, may uncover one or more risk factors for CVA. The history may also reveal either a sudden onset of hemiparesis or hemiplegia or a gradual onset of dizziness, mental disturbances, or seizures. The patient or a family member may also report that the patient lost consciousness or suddenly developed aphasia. Speaking with the patient during the history may reveal communication problems, such as dysarthria, dysphasia or aphasia, and apraxia.

Neurologic examination identifies most of the physical findings associated with CVA. These may include unconsciousness or changes in LOC, such as a decreased attention span, difficulties with comprehension, forgetfulness, and a lack of motivation. If conscious, the patient may exhibit anxiety along with communication and mobility difficulties. Inspection may reveal related urinary incontinence.

Motor function tests and muscle strength tests often show a loss of voluntary muscle control and hemiparesis or hemiplegia on one side of the body. In the initial phase, flaccid paralysis with decreased deep tendon reflexes may occur. These reflexes return to normal after the initial phase, along with an increase in muscle tone and, in some cases, muscle spasticity on the affected side.

Vision testing often reveals hemianopia on the affected side of the body and, in patients with left-sided hemiplegia, problems with visuospatial relations.

Sensory assessment may reveal sensory losses, ranging from slight impairment of touch to the inability to perceive the position and motion of body parts. The patient also may have difficulty interpreting visual, tactile, and auditory stimuli. (See [Understanding neurologic deficits in CVA.](#))

Diagnostic tests

Magnetic resonance imaging (MRI) and magnetic resonance angiography allow evaluation of the lesion's location and size without exposing the patient to radiation. MRI doesn't distinguish hemorrhage, tumor, and infarction as well as computed tomography (CT) scanning, but it provides superior images of the cerebellum and the brain stem.

Cerebral angiography details disruption or displacement of the cerebral circulation by occlusion or hemorrhage. It's the test of choice for examining the entire cerebral artery.

Digital subtraction angiography is used to evaluate the patency of the cerebral vessels and identify their position in the head and neck. It's also used to detect and evaluate lesions and vascular abnormalities.

CT scanning detects structural abnormalities, edema, and lesions, such as nonhemorrhagic infarction and aneurysms. Thus, it differentiates CVA from imitative disorders, such as primary metastatic tumor and subdural, intracerebral, or epidural hematoma. Patients with TIA commonly have a normal CT scan.

Positron emission tomography provides data on cerebral metabolism and cerebral blood flow changes, especially in ischemic stroke. Single-photon emission tomography identifies cerebral blood flow and helps diagnose cerebral infarction.

Transcranial Doppler studies evaluate the velocity of blood flow through major intracranial vessels, which can indicate the vessels' diameter. Carotid Doppler studies measure flow through the carotid arteries. It can provide information on etiology of stroke.

2-D echocardiogram evaluates the heart for dysfunction and provides information on etiology of a stroke.

Cerebral blood flow studies measure blood flow to the brain and help detect abnormalities.

Ophthalmoscopy may show signs of hypertension and atherosclerotic changes in the retinal arteries.

EEG may show reduced electrical activity in an area of cortical infarction. This test is especially useful when CT scan results are inconclusive. It can also differentiate seizure activity from CVA.

Oculoplethysmography indirectly measures ophthalmic blood flow and carotid artery blood flow.

Appropriate baseline laboratory studies include urinalysis, coagulation studies, complete blood count, serum osmolality, and tests for electrolyte, glucose, triglyceride, creatinine, and blood urea nitrogen levels.

Treatment

Treatment should include careful blood pressure management. Labetalol is the pressor of choice to regulate blood pressure. Blood pressure that is too low increases ischemia; blood pressure that is too high increases risk of hemorrhage. Tissue plasminogen activator may be used in emergency care of the patient within 3 hours of onset of the symptoms. Thrombolytic agents are a consideration if there is a sign of hemorrhage on CT, if there are no other contraindications, and if it is begun in a timely fashion.

PATHOPHYSIOLOGY

Understanding neurologic deficits in CVA

A cerebrovascular accident (CVA) can leave one patient with midhand weakness and another with complete unilateral paralysis. In both patients, the functional loss reflects damage to the brain area normally perfused by the occluded or ruptured artery. But the damage doesn't stop there. Resulting hypoxia and ischemia produce edema that affects distal parts of the brain, causing further neurologic deficits.

Most CVAs occur in the anterior cerebral circulation and cause symptoms from damage in the middle cerebral artery, internal carotid artery, or anterior cerebral artery. CVAs can also occur in the posterior circulation. These originate in the vertebral arteries and result in signs and symptoms caused by damage to the vertebral or basilar artery and posterior cerebral artery, resulting in higher mortality. Described below are the signs and symptoms that accompany CVA at the following sites.

Middle cerebral artery

The patient may experience aphasia, dysphasia, reading difficulty (dyslexia), writing inability (dysgraphia), visual field cuts, and hemiparesis on the affected side (more severe in the face and arm than in the leg).

Internal carotid artery

The patient may complain of headaches. Expect to find weakness, paralysis, numbness, sensory changes, and visual disturbances, such as blurring on the affected side. You may also detect altered level of consciousness, bruits over the carotid artery, aphasia, dysphasia, and ptosis.

Anterior cerebral artery

You may note confusion, weakness, and numbness (especially of the arm) on the affected side, paralysis of the contralateral foot and leg with accompanying footdrop, incontinence, loss of coordination, impaired motor and sensory functions, and personality changes (flat affect, distractibility).

Vertebral or basilar artery

The patient may complain of numbness around the lips and mouth and dizziness. You may note weakness on the affected side; visual deficits, such as color blindness, lack of depth perception, and diplopia; poor coordination; dysphagia; slurred speech; amnesia; and ataxia.

Posterior cerebral artery

The patient may experience visual field cuts, sensory impairment, dyslexia, coma, and cortical blindness from ischemia in the occipital area. Usually, paralysis is absent.

Medical management of CVA commonly includes physical rehabilitation, dietary and drug regimens to help decrease risk factors, possibly surgery, and care measures to help the patient adapt to specific deficits, such as speech impairment and paralysis.

Depending on the cause and extent of the CVA, the patient may undergo a craniotomy to remove a hematoma, endarterectomy to remove atherosclerotic plaques from the inner arterial wall, or extracranial-intracranial bypass to circumvent an artery that is blocked by occlusion or stenosis. Ventricular shunts may be necessary to drain cerebrospinal fluid.

Medications useful in CVA include:

- u anticonvulsants, such as phenytoin or phenobarbital, to treat or prevent seizures
- u stool softeners to avoid straining, which increases intracranial pressure (ICP)
- u anticoagulants, such as heparin, warfarin, Plavix, and ticlopidine, to reduce the risk of thrombotic stroke
- u analgesics such as codeine to relieve headache that may follow hemorrhagic CVA. Usually, aspirin is contraindicated in hemorrhagic CVA because it increases bleeding tendencies, but it may be useful in preventing TIAs.

Nursing diagnoses

- u Altered tissue perfusion (cerebral)
- u Anxiety
- u Impaired gas exchange
- u Impaired physical mobility
- u Impaired verbal communication
- u Ineffective airway clearance
- u Powerlessness
- u Risk for aspiration
- u Risk for impaired skin integrity
- u Risk for infection
- u Risk for injury
- u Self-care deficit: Bathing or hygiene
- u Self-care deficit: Dressing or grooming
- u Self-care deficit: Toileting
- u Self-esteem disturbance
- u Sensory or perceptual alterations
- u Total incontinence

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will maintain adequate ventilation.
- u The patient will remain free from injury.
- u The patient will achieve as maximal independence as possible within conditions.
- u The patient will maintain joint mobility and range of motion.

Nursing interventions

- u During the acute phase, provide continuing neurologic assessment, respiratory support, continuous monitoring of vital signs, careful positioning to prevent aspiration and contractures, management of GI problems, and careful monitoring of fluid, electrolyte, and nutritional intake. Patient care must also prevent complications such as infection.
- u Maintain a patent airway and oxygenation. Loosen constricting clothes. Watch for ballooning of the cheek with respiration. The side that balloons is the side affected by the stroke. If the patient is unconscious, he could aspirate saliva, so keep him in a lateral position to allow secretions to drain naturally or suction secretions as needed. Insert an artificial airway, and start mechanical ventilation or supplemental oxygen, if necessary.
- u Check vital signs and neurologic status as ordered, record observations, and report any significant changes to the doctor. Monitor blood pressure, LOC, pupillary changes, motor function (voluntary and involuntary movements), sensory function, speech, skin color, temperature, signs of increased ICP, and nuchal rigidity or flaccidity. Remember, if CVA is impending, blood pressure rises suddenly, pulse rate is rapid and bounding, and the patient may complain of headache.
- u Watch for signs of pulmonary emboli, such as chest pains, shortness of breath, dusky color, tachycardia, fever, and changed sensorium. If the patient is unresponsive, monitor his arterial blood gas levels often and alert the doctor to increased partial pressure of carbon dioxide or decreased partial pressure of oxygen.
- u Maintain fluid and electrolyte balance. If the patient can take liquids orally, offer them as often as fluid limitations permit. Administer I.V. fluids as ordered; never give too much too fast because this can increase ICP.
- u Offer the urinal or bedpan every 2 hours. If the patient is incontinent, he may need an indwelling urinary catheter, but this should be avoided if possible because of the risk of infection.
- u Ensure adequate nutrition. Check for gag reflex before offering small oral feedings of semisolid foods. Place the food tray within the patient's visual field. Have the patient sit upright and tilt his head slightly forward when eating. If the patient has dysphagia or one-sided facial weakness, provide him with semisoft foods and tell him to chew on the unaffected side of his mouth. If oral feedings aren't possible, insert a nasogastric tube for tube feedings as ordered.
- u Manage GI problems. Be alert for signs that the patient is straining during defecation because this increases ICP. Modify the patient's diet, administer stool softeners as ordered, and give laxatives if necessary. If the patient vomits (usually during the first few days), keep him positioned on his side to prevent aspiration.
- u Provide careful mouth care. Clean and irrigate the patient's mouth to remove food particles. Care for his dentures as needed.
- u Provide meticulous eye care. Remove secretions with a cotton ball and normal saline solution. Instill eyedrops as ordered. Patch the patient's affected eye if he can't close his eyelid.
- u Position the patient and align his extremities correctly. Use high-topped sneakers to prevent footdrop and contracture, and use convoluted foam, flotation, or

pulsating mattress to prevent pressure ulcers. To decrease the possibility of pneumonia, turn the patient at least every 2 hours. Elevate the affected hand to control dependent edema, and place it in a functional position.

- u Assist the patient with exercise. Perform range-of-motion exercises for both the affected and unaffected sides. Teach and encourage the patient to use his unaffected side to exercise his affected side.
- u Give medications as ordered, and watch for and report adverse reactions.
- u Establish and maintain communication with the patient. If he's aphasic, set up a simple method of communicating basic needs. Then remember to phrase your questions so he'll be able to answer using this system. Repeat yourself quietly and calmly (remember, he isn't deaf), and use gestures if necessary to help him understand. Even the unresponsive patient can hear, so don't say anything in his presence you wouldn't want him to hear.
- u Provide psychological support and establish rapport with the patient. Set realistic short-term goals. Spend time with him, involve family members in his care when possible, and explain his deficits and strengths. Remember that building rapport may be difficult because of the mood changes that may result from brain damage or as a reaction to being dependent.
- u Protect the patient from injury. For example, keep the bed's side rails up at all times; pad the rails if the patient tends to bang them with his feet or arms.
- u If surgery is necessary, provide preoperative and postoperative care. Monitor vital signs, fluid and electrolyte balance, and intake and output. Care for the operative area, provide pain relief, and watch for complications from the surgery.

HOME CARE

Recovering from a CVA

For a patient with a cerebrovascular accident (CVA), follow these guidelines to promote his recovery at home:

- u Assess the patient's self-care ability, and determine the availability of capable support people.
- u Refer the patient for physical, occupational, and speech therapy as needed. Reinforce the therapist's instructions about exercise, mobility, and activities of daily living.
- u Obtain appropriate assistive devices. If the patient has difficulty speaking, suggest a talking board or a pad and pencil.
- u Reinforce caregiver teaching about rehabilitation, and encourage the patient to be as independent as possible.
- u Review all medication information with caregivers; instruct them to call the doctor if adverse reactions occur.
- u Teach caregivers to recognize signs of an impending CVA.
- u Suggest options for caregiver support and help. Refer the patient and family to local support groups and national organizations for more information.
- u Review emergency measures with the patient and caregivers.
- u Emphasize the need to attend all follow-up visits.

Patient teaching

- u Teach the patient and family members about the disorder. Explain the diagnostic tests, treatments, and rehabilitation the patient is to undergo.
- u If surgery is scheduled, provide preoperative teaching. Be sure the patient and family understand the surgery and its possible effects.
- u If necessary, teach the patient to comb his hair, dress, and wash. With the aid of a physical and an occupational therapist, obtain appliances, such as hand bars by the toilet and ramps, as needed. If speech therapy is indicated, encourage the patient to begin as soon as possible. To reinforce teaching, involve the patient's family in all aspects of rehabilitation. With their cooperation and support, devise a realistic discharge plan, and let them help decide when the patient can return home.
- u Prepare the patient and family for home care. (See [Recovering from a CVA](#), and [Preventing CVA](#).)
- u If a special diet such as a weight loss diet for an obese patient is prescribed, have the dietitian teach the patient about the diet. Reinforce the explanations as needed.

PREVENTION

Preventing CVA

To decrease the risk of another cerebrovascular accident (CVA), teach the patient and family about the need to correct risk factors. For example, if the patient smokes, refer him to a smoking cessation program. Teach the importance of maintaining an ideal weight and the need to control such diseases as diabetes and hypertension. Teach all patients the importance of following a low-cholesterol, low-salt diet; increasing activity; avoiding prolonged bed rest; and minimizing stress. Early recognition of signs and symptoms of complications or impending stroke is imperative, as is seeking prompt treatment because stroke is a brain attack.

- u Teach the patient and, if needed, a family member about the schedule, dosage, actions, and adverse effects of prescribed drugs. Make sure the patient taking aspirin realizes that he can't substitute acetaminophen for aspirin.

ENCEPHALITIS

Encephalitis is a severe inflammation of the brain characterized by intense lymphocytic infiltration of brain tissues and the leptomeninges. This causes cerebral edema, degeneration of the brain's ganglion cells, and diffuse nerve cell destruction.

Encephalitis is usually caused by a mosquito-borne or, in some areas, a tick-borne virus. Transmission by means other than arthropod bites may occur through ingestion of infected goat's milk and accidental injection or inhalation of the virus.

CULTURAL TIP Eastern equine encephalitis can produce permanent neurologic damage and is often fatal. It occurs in the eastern regions of North, Central, and South America. Western equine encephalitis occurs throughout the western hemisphere; California encephalitis, throughout the United States; St. Louis encephalitis, in Florida and in the western and southern United States; and Venezuelan encephalitis, in South America.

Causes

Encephalitis usually results from infection with arboviruses specific to rural areas. In urban areas, encephalitis is most frequently caused by enteroviruses (coxsackievirus, poliovirus, and echovirus). Other causes include herpesvirus, mumps virus, adenoviruses, and demyelinating diseases after measles, varicella, rubella, or vaccination.

Complications

Potential complications associated with viral encephalitis include bronchial pneumonia, urine retention, urinary tract infection, pressure ulcers, and coma. Epilepsy, parkinsonism, and mental deterioration may also occur.

Assessment findings

Depending on the severity of the disease, all forms of viral encephalitis have similar clinical features. The severity of arbovirus encephalitis may range from subclinical

to rapidly fatal necrotizing disease. Herpes encephalitis also produces signs and symptoms that vary from subclinical to acute and often fatal fulminating disease.

If encephalitis is the primary illness, the patient may be acutely ill when he seeks treatment because the nonspecific symptoms that occur before the onset of acute neurologic symptoms aren't recognized as signs of encephalitis. Thus, patient history may include reports of systemic symptoms, such as headache, muscle stiffness, malaise, sore throat, and upper respiratory tract symptoms that existed for several days before the onset of neurologic symptoms.

After neurologic symptoms occur, patient history may reveal the sudden onset of altered levels of consciousness (LOC), from lethargy or drowsiness to stupor. The patient or a family member may also report the occurrence of seizures, which may be the only presenting sign of encephalitis.

On neurologic examination, the patient may be confused, disoriented, or hallucinating. He may demonstrate tremors, cranial nerve palsies, exaggerated deep tendon reflexes, absent superficial reflexes, and paresis or paralysis of the extremities. The patient may complain of a stiff neck when the head is bent forward.

Vital signs usually reveal fever. The patient may also be nauseated and vomiting.

If the cerebral hemispheres are involved, assessment findings may include aphasia, involuntary movements identified on inspection, ataxia, sensory defects such as disturbances of taste and smell, and poor memory retention.

Diagnostic tests

During an encephalitis epidemic, diagnosis is readily made from clinical findings and patient history. Sporadic cases are difficult to distinguish from other febrile illnesses, such as gastroenteritis or meningitis. The following tests help establish a diagnosis:

Blood analysis or, rarely, cerebrospinal fluid (CSF) analysis identifies the virus and confirms the diagnosis. The common viruses that also cause herpes, measles, and mumps are easier to identify than arboviruses. Inoculating young mice with a specimen taken from the patient can isolate arboviruses and herpesviruses.

Serologic studies in herpes encephalitis may show rising titers of complement-fixing antibodies. In some types of encephalitis, serologic tests of blood may be diagnostic.

Lumbar puncture discloses CSF pressure elevated in all forms of encephalitis. Despite inflammation, CSF analysis findings often reveal clear fluid. White blood cell count and protein levels in CSF are slightly elevated, but the glucose level remains normal.

EEG reveals abnormalities such as generalized slowing of waveforms.

Computed tomography scanning may be ordered to check for temporal lobe lesions that indicate herpesvirus and to rule out cerebral hematoma.

Treatment

The antiviral agent vidarabine is effective only against herpes encephalitis and only if it's administered before the onset of coma.

Treatment of all other forms of encephalitis is supportive. Drug therapy includes reduction of intracranial pressure (ICP) with I.V. mannitol and corticosteroids (to reduce cerebral inflammation and resulting edema); phenytoin or another anticonvulsant, usually given I.V.; sedatives for restlessness; and aspirin or acetaminophen to relieve headache and reduce fever.

Other supportive measures include adequate fluid and electrolyte intake to prevent dehydration and appropriate antibiotics for associated infections, such as pneumonia or sinusitis; maintenance of the patient's airway; administration of oxygen to maintain arterial blood gas levels; and maintenance of nutrition, especially during periods of coma. Isolation is unnecessary.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered thought processes u Anxiety u Hyperthermia u Impaired gas exchange u Impaired physical mobility u Knowledge deficit u Pain u Risk for fluid volume deficit u Risk for impaired skin integrity

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will exhibit fluid balance within normal limits.
- u The patient will exhibit temperature within normal limits.
- u The patient will consume adequate daily calories as required
- u The patient will express feelings of comfort and relief of pain.

Nursing interventions

- u During the acute phase of the illness, assess neurologic function often. Observe LOC and signs of increased ICP (increasing restlessness, plucking at the bedcovers, vomiting, seizures, and changes in pupil size, motor function, and vital signs). Also watch for cranial nerve involvement (ptosis, strabismus, diplopia), abnormal steep patterns, and behavior changes.
- u Maintain adequate fluid intake to prevent dehydration, but avoid fluid overload, which may increase cerebral edema. Measure and record intake and output accurately.
- u As ordered, give vidarabine by slow I.V. infusion only. Watch for adverse reactions, such as tremors, dizziness, hallucinations, anorexia, nausea, vomiting, diarrhea, pruritus, rash, and anemia; also watch for adverse effects of other drugs. Check the infusion sites often to prevent problems such as infiltration and phlebitis.
- u Carefully position the patient to prevent joint stiffness and neck pain, and turn him often. Assist with range-of-motion exercises.
- u Maintain adequate nutrition. Give the patient small, frequent meals, or supplement these meals with nasogastric tube or parenteral feedings.
- u To prevent constipation and minimize the risk of increased ICP resulting from straining at stool, give a mild laxative or stool softener.
- u Provide good mouth care.
- u Maintain a quiet environment. Darkening the room may decrease headache. If the patient naps during the day and is restless at night, plan daytime activities to minimize napping and promote sleep at night.
- u If the patient has seizures, take precautions to protect the patient from injury during the seizures.
- u Provide emotional support, and reassure the patient and family members because the patient is apt to be frightened by the illness and frequent diagnostic tests.
- u If the patient is delirious or confused, attempt to reorient him often. Providing a calendar or a clock in the patient's room may be helpful.

Patient teaching

- u Teach the patient and family members about the disease and its effects. Explain the diagnostic tests and treatment measures. Be sure to explain procedures to the patient even if he's comatose.
- u Explain to the patient and family members that behavior changes caused by encephalitis usually disappear, but permanent problems sometimes occur. If a neurologic deficit is severe and appears permanent, refer the patient to a rehabilitation program as soon as the acute phase has passed.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an acute, rapidly progressive, and potentially fatal form of polyneuritis that causes segmented demyelination of peripheral nerves.

Guillain-Barré syndrome occurs equally in both sexes, usually between the ages of 30 and 50. It affects about 2 of every 100,000 people.

The clinical course of Guillain-Barré syndrome has three phases. The *acute phase* begins when the first definitive symptom develops; it ends 1 to 3 weeks later, when no further deterioration is noted. The *plateau phase* lasts for several days to 2 weeks and is followed by the *recovery phase*, which is believed to coincide with remyelination and axonal process regrowth. The recovery phase extends over 4 to 6 months; patients with severe disease may take up to 2 to 3 years to recover, and recovery may not be complete. The disorder is also known as infectious polyneuritis, Landry-Guillain-Barré syndrome, or acute idiopathic polyneuritis.

Causes

The precise cause of Guillain-Barré syndrome is unknown, but it's thought to be a cell-mediated immunologic attack on peripheral nerves in response to a virus. Risk factors include surgery, rabies or swine influenza vaccination, viral illness, Hodgkin's or some other malignant disease, and lupus erythematosus.

The major pathologic effect is segmental demyelination of the peripheral nerves, which prevents normal transmission of electrical impulses along the sensorimotor nerve roots. (See [Understanding sensorimotor nerve degeneration.](#))

Complications

Because of the patient's inability to use his muscles, complications can occur. These include thrombophlebitis, pressure ulcers, contractures, muscle wasting, aspiration, respiratory tract infections, and life-threatening respiratory and cardiac compromise.

Assessment findings

Most patients seek treatment when the disease is in the acute stage. Typically, the history reveals that the patient experienced a minor febrile illness (usually an upper respiratory tract infection or, less often, GI infection) 1 to 4 weeks before his current symptoms.

The patient may report feelings of tingling and numbness (paresthesia) in the legs. If the disease has progressed further, he may report that the tingling and numbness began in the legs and progressed to the arms, trunk and, finally, face. The paresthesia usually precedes muscle weakness but tends to vanish quickly; in some patients, it may never occur. Some patients may also report stiffness and pain in the back or in the calves such as a severe charley horse.

Neurologic examination uncovers muscle weakness (the major neurologic sign) and sensory loss, usually in the legs. If the disease has progressed, the weakness and sensory loss may also be present in the arms. Keep in mind that the disease progresses rapidly and that symptoms may progress beyond the legs within 24 to 72 hours. (See [Testing for thoracic sensation.](#))

If the cranial nerves are affected—as they often are—the patient may have difficulty talking, chewing, and swallowing. Subsequent cranial nerve testing may reveal paralysis of the ocular, facial, and oropharyngeal muscles.

Muscle weakness sometimes develops in the arms first (descending type), rather than in the legs (ascending type), or in the arms and legs simultaneously. In milder forms of this disease, muscle weakness may affect only the cranial nerves or may not occur at all. Neurologic examination may reveal a loss of position sense and diminished or absent deep tendon reflexes.

Diagnostic tests

Cerebrospinal fluid (CSF) analysis may show a normal white blood cell count, an elevated protein count, and, in severe disease, increased CSF pressure. The CSF protein level begins to rise several days after the onset of signs and symptoms, peaking in 4 to 6 weeks, probably resulting from widespread inflammatory disease of the nerve roots.

Electromyography may demonstrate repeated firing of the same motor unit instead of widespread sectional stimulation.

Electrophysiologic testing may reveal marked slowing of nerve conduction velocities.

Treatment

In Guillain-Barré syndrome, treatment is primarily supportive and may require endotracheal intubation or tracheotomy if the patient has difficulty clearing secretions. Mechanical ventilation is necessary if the patient has respiratory difficulties.

Continuous electrocardiogram monitoring is necessary to identify cardiac arrhythmias. Propranolol may be administered to treat tachycardia and hypotension. Atropine may be administered to treat bradycardia. Marked hypotension may require volume replacement.

Plasmapheresis produces a temporary reduction in circulating antibodies. Now an accepted form of therapy, it's most effective when performed during the first few weeks of the disease. The patient may receive three to five plasma exchanges.

Immune globulin I.V. can be given if plasmapheresis fails or isn't available.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered urinary elimination u Anxiety u Fear u Impaired gas exchange u Impaired physical mobility u Impaired verbal communication u Ineffective breathing pattern

Key outcomes

- u The patient will maintain patent airway and adequate ventilation.
- u The patient will maintain respiratory rate within ±5 of baseline.
- u The patient will develop alternate means of expressing himself.
- u The patient will consume adequate daily calories as required.
- u The patient will establish routine urinary elimination patterns.
- u The patient will maintain joint mobility and range of motion.

PATHOPHYSIOLOGY

Understanding sensorimotor nerve degeneration

Guillain-Barré syndrome attacks the peripheral nerves so that they can't transmit messages to the brain correctly. Heres what goes wrong:

The myelin sheath degenerates for unknown reasons. This sheath covers the nerve axons and conducts electrical impulses along the nerve pathways. With degeneration comes inflammation, swelling, and patchy demyelination. As this disorder destroys myelin, the nodes of Ranvier (at the junctures of the myelin sheaths) widen. This delays and impairs impulse transmission along both the dorsal and the ventral nerve roots.

Because the dorsal nerve roots handle sensory function, the patient may experience sensations such as tingling and numbness when the nerve root is impaired. Similarly, because the ventral roots are responsible for motor function, impairment causes varying weakness, immobility, and paralysis.

Nursing interventions

- u Monitor the patient's vital signs and LOC.
- u Continually assess the patient's respiratory function. If respiratory muscles are weak, take serial vital capacity recordings. Use a spirometer with a mouthpiece or a face mask for bedside testing.
- u Auscultate for breath sounds, turn and position the patient, and encourage coughing and deep breathing. Begin respiratory support at the first sign of dyspnea (in adults, vital capacity less than 800 ml; in children, less than 12 ml/kg of body weight) or decreasing partial pressure of oxygen in arterial blood (Pa O_2).
- u Monitor pulse oximetry to keep oxygen saturation above 93%.
- u Obtain arterial blood gas measurements as ordered.

ALERT Because neuromuscular disease results in primary hypoventilation with hypoxemia and hypercapnea, watch for Pa O_2 below 70 mm Hg, which signals respiratory failure. Be alert for confusion and tachypnea, which are signs of rising partial pressure of carbon dioxide in arterial blood.

- u If respiratory failure becomes imminent, establish an emergency airway with an endotracheal tube. Be prepared to begin and maintain mechanical ventilation.
- u Provide meticulous skin care to prevent skin breakdown and contractures. Establish a strict turning schedule, inspect the skin (especially sacrum, heels, and ankles) for breakdown, and reposition the patient every 2 hours. Use alternating pressure pads at points of contact.

ADVANCED PRACTICE

Testing for thoracic sensation

When Guillain-Barré syndrome progresses rapidly, test for ascending sensory loss by touching the patient or pressing his skin lightly with a pin every hour. Move systematically from the iliac crest (T12) to the scapula, occasionally substituting the blunt end of the pin to test the patient's ability to discriminate between sharp and dull.

Using an indelible pen, mark on the patient the level of diminished sensation to measure any change. If diminished sensation ascends to T8 or higher, the patient's intercostal muscle function (and consequently respiratory function) is likely to be impaired.

As Guillain-Barré syndrome subsides, sensory and motor weakness descend to the lower thoracic segments, heralding a return of intercostal and extremity muscle function.

DISTRIBUTION OF SPINAL NERVES

KEY: T = thoracic segments

- u Perform passive range-of-motion exercises within the patient's pain limits, possibly using a Hubbard tank. Remember that the proximal muscle group of the thighs, shoulders, and trunk are the most tender and cause the most pain on passive movement and turning. When the patient's condition stabilizes, change to gentle stretching and active assistance exercises.
- u To prevent aspiration, test the gag reflex and elevate the head of the bed before giving the patient anything to eat. If the gag reflex is absent, give nasogastric feedings until the reflex returns.
- u As the patient regains strength and can tolerate a vertical position, be alert for postural hypotension. Monitor blood pressure and pulse rate during tilting periods and, if necessary, apply toe-to-groin elastic bandages or an abdominal binder to prevent postural hypotension.
- u Inspect the patient's legs regularly for signs of thrombophlebitis (localized pain, tenderness, erythema, edema, positive Homans' sign). To prevent thrombophlebitis, apply antiembolism stockings and give prophylactic anticoagulants as ordered.
- u If the patient has facial paralysis, give eye and mouth care every 4 hours. Protect the corneas with isotonic eyedrops and conical eye shields.
- u Watch for urine retention. Measure and record intake and output every 8 hours, and offer the bedpan every 3 to 4 hours. Encourage adequate fluid intake (2 L/day [2.1 qt]) unless contraindicated. If urine retention develops, begin intermittent catheterization as ordered. Because the abdominal muscles are weak, the patient may need manual pressure on the bladder (Credé's method) before he can urinate.
- u To prevent and relieve constipation, offer prune juice and a high-fiber diet. If necessary, give daily or alternate-day suppositories (glycerin or bisacodyl) or enemas as ordered.
- u If the patient is unable to communicate because of paralysis, tracheostomy, or intubation, try to establish some form of communication—for example, have the patient blink his eyes once for yes and twice for no.
- u Provide diversions for the patient, such as television, family visits, or audio tapes.
- u Provide emotional support to the patient and family members. Listen to their concerns. Stay with the patient during periods of severe stress.
- u Administer medications as ordered. Analgesics may be prescribed to relieve muscle stiffness and spasm.

Patient teaching

- u Explain the disease and its signs and symptoms to the patient and family members. Explain the diagnostic tests that are to be performed.
- u Explain the treatments that are ordered, and tell the patient why they're necessary For example, if the patient loses his gag reflex, tell him tube feeding is necessary to maintain nutritional status.
- u Advise family members to help the patient maintain mental alertness, fight boredom, and avoid depression. Suggest that they plan frequent visits, read books to the patient, or borrow library books on tape for him.
- u Before discharge, prepare an appropriate home plan of care. Teach the patient how to transfer from bed to wheelchair and from wheelchair to toilet or tub and how to walk short distances with a walker or a cane.
- u Instruct family members on how to help the patient eat, compensating for facial weakness, and how to help him avoid skin breakdown.
- u Emphasize the importance of establishing a regular bowel and bladder elimination routine.
- u Tell the patient to schedule physical therapy sessions.

HUNTINGTON'S DISEASE

In Huntington's disease (also called Huntington's chorea, hereditary chorea, chronic progressive chorea, or adult chorea), degeneration in the cerebral cortex and basal ganglia causes chronic progressive chorea (dancelike movements) and mental deterioration, ending in dementia.

Huntington's disease usually strikes people between ages 25 and 55 (the average age is 35), but 2% of cases occur in children, and 5% occur as late as age 60. Death usually results 10 to 15 years after onset, from heart failure or pneumonia. Because the disease is hereditary, it's prevalent in areas where affected families have lived for several generations.

Recent genetic studies have identified a marker for the gene linked to Huntington's disease, opening the way for the development of a predictive test for those at risk for the disease.

Causes

The cause of Huntington's disease is unknown. Because it's transmitted as an autosomal dominant trait, either sex can transmit and inherit it. Each child of a parent with this disease has a 50% chance of inheriting it; a child who doesn't inherit it can't pass it on to his children.

Complications

Potential complications include choking, aspiration, pneumonia, heart failure, and infections.

Assessment findings

Assessment findings vary depending on disease progression. The patient history usually shows a family history of the disorder, along with emotional and mental changes.

The onset of Huntington's disease is insidious. The patient eventually becomes totally dependent through intellectual decline, emotional disturbances, and loss of musculoskeletal control.

In the early stages, the patient is described as clumsy, irritable, or impatient and subject to fits of anger and periods of suicidal depression, apathy, or elation. As the disease progresses, family members may report that the patient's judgment and memory become impaired. Hallucinations, delusions, and paranoid thinking may occur. (In late stages, emotional symptoms may decrease, but eventually dementia does occur.) The family describes a gradual loss of intellectual ability, but the patient seems to be aware that his symptoms are the result of the disease. (Keep in mind that the dementia doesn't always progress at the same rate as the chorea.)

The patient may be described as having a ravenous appetite, especially for sweets. In late stages, the patient history may note loss of bladder and bowel control.

Inspection usually reveals choreic movements. These movements are rapid, often violent, and purposeless. In the early stages, they're unilateral and more prominent in the face and arms than in the legs. As the disease progresses, the choreic movements progress from mild fidgeting to grimacing, tongue smacking, dysarthria (indistinct speech), athetoid movements (especially of the hands) related to emotional state, and torticollis. In later stages, the movements involve the entire body musculature. Writhing and twitching are constant, speech becomes unintelligible, chewing and swallowing are difficult, and ambulation is impossible. In these late stages, the patient may appear emaciated and exhausted.

Diagnostic tests

Positron emission tomography and deoxyribonucleic acid analysis can detect Huntington's disease, but there is no reliable confirming test.

Helpful tests include magnetic resonance imaging, which shows characteristic butterfly dilation of the brain's lateral ventricles, and computed tomography scanning, which shows brain atrophy.

Treatment

Because there is no known cure for Huntington's disease, treatment is supportive, protective, and based on the patient's symptoms. Tranquilizers, as well as chlorpromazine, haloperidol, or imipramine, help control choreic movements, but they can't stop mental deterioration. They also alleviate discomfort and depression but increase patient rigidity. To control choreic movements without rigidity, choline may be prescribed.

Psychotherapy to decrease anxiety and stress may also be helpful. The patient may require institutionalization because of mental deterioration.

Nursing diagnoses

u Altered health maintenance u Anxiety u Chronic low self-esteem u Impaired physical mobility u Impaired verbal communication u Risk for aspiration u Risk for infection u Risk for injury u Self-care deficit u Total incontinence

Key outcomes

- u The patient will maintain patent airway without evidence of aspiration.
- u The patient will maintain joint mobility and range of motion.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express positive feelings about himself.
- u The patient will perform activities of daily living within confines of the disorder.
- u The patient will develop alternative means of communication.

Nursing interventions

- u Provide psychological support to the patient and family members, and listen to their fears and concerns. Stay with the patient during especially stressful periods. Answer questions honestly.
- u Identify the patient's self-care deficits each time he's admitted to the facility. Provide physical support by attending to his basic needs, such as hygiene, skin care, bowel and bladder care, and nutrition. Increase this support as mental and physical deterioration make him increasingly immobile.

- u Administer medications as ordered. Monitor the patient for desired effects and adverse reactions.
- u Encourage the patient to remain as independent as possible. To help him do this, give short, explicit directions. Provide demonstrations, and give the patient ample time to perform the tasks that he's capable of performing.
- u To help improve the patient's body image, allow him to participate in his care as much as possible. Encourage his efforts to adapt to the changes that he's experiencing.
- u If the patient has difficulty speaking, provide him with communication aids such as an alphabet board. Allow him sufficient time to communicate.
- u Stay alert for possible suicide attempts. Take suicide precautions. Control the patient's environment to protect him from suicide or other self-inflicted injury. Pad the side rails of the bed, but avoid restraints, which may cause the patient to injure himself with violent, uncontrolled movements.
- u If the patient has difficulty walking, provide a walker to help him maintain his balance. If his choreic movements are violent enough to cause injury, pad the bed rails and be sure the patient is secure if he's sitting in a chair or wheelchair.
- u If the patient is confined to bed, turn him every 2 hours. Post a turning schedule at the bedside.
- u Minimize the patient's risk of infection by washing your hands before providing care and helping the patient wash his hands before and after meals and after using the bathroom, bedpan, or urinal.
- u Monitor the patient's temperature and his white blood cell count so that infection can be detected and treated early.
- u Elevate the head of the bed whenever the patient eats to reduce the risk of aspiration. Stay with him while he's eating, and instruct him to eat only small amounts of food at a time.
- u Provide the incontinent patient with bladder elimination devices, such as an indwelling urinary catheter and body-worn drainage devices as appropriate. If the patient has bowel incontinence, provide incontinence aids, such as pad and pants or bed protector pads.

Patient teaching

- u Teach the patient and family members about the disease. Explain the diagnostic tests and any required treatments.
- u Teach family members how to perform home care.
- u Encourage affected families to receive genetic counseling. All affected family members should realize that each of their offspring has a 50% chance of inheriting this disease.
- u Refer the patient and family members to appropriate community organizations, such as home health care agencies, the social service department, psychiatric counseling, and long-term care facilities.
- u For more information about this degenerative disease, refer the patient and family to the Huntington's Disease Society of America.

MENINGITIS

In meningitis, the brain and the spinal cord meninges become inflamed. Such inflammation may involve all three meningeal membranes: the dura mater, arachnoid membrane, and pia mater.

For most patients, meningitis follows the onset of respiratory symptoms: In about 50% of patients, it develops over 1 to 7 days; in about 20% of patients, over 1 to 3 weeks. In about 25% of patients, meningitis is unheralded by respiratory symptoms; it has a sudden onset, causing serious illness within 24 hours.

The prognosis is good and complications are rare, especially if the disease is recognized early and the infecting organism responds to antibiotics. Mortality in untreated meningitis is 70% to 100%. The prognosis is poorer for infants and elderly people.

Causes

Meningitis can be caused by bacteria, viruses, protozoa, or fungi. It most commonly results from bacterial infection, usually due to *Neisseria meningitides*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, or *Escherichia coli*. Sometimes, no causative organism can be found.

In most patients, the infection that causes meningitis is secondary to another bacterial infection, such as bacteremia (especially from pneumonia, empyema, osteomyelitis, and endocarditis), sinusitis, otitis media, encephalitis, myelitis, or brain abscess. Meningitis can also follow a skull fracture, a penetrating head wound, lumbar puncture, or ventricular shunting procedures.

Meningitis caused by a virus is called aseptic viral meningitis. (See [Understanding aseptic viral meningitis.](#))

Infants, children, and elderly people have the highest risk of developing meningitis. Other risk factors include malnourishment, immunosuppression (as from radiation therapy), and central nervous system trauma.

CULTURAL TIP Vaccination with measles, mumps, rubella (MMR) vaccine—a preventive measure—is recommended for children before school age. Some ethnic groups are opposed to vaccination, resulting in a higher level of meningitis occurring among these groups. Education about vaccination is essential.

ADVANCED PRACTICE

Understanding aseptic viral meningitis

Aseptic viral meningitis is a benign syndrome characterized by headache, fever, vomiting, and meningeal symptoms. It results from some form of viral infection, including enteroviruses (most common), arboviruses, herpes simplex virus, mumps virus, or lymphocytic choriomeningitis virus.

Assessment findings

The history of a patient with aseptic viral meningitis usually shows that the disease began suddenly with a fever up to 104° F (40° C), alterations in consciousness (drowsiness, confusion, stupor), and neck or spine stiffness, which is slight at first. (The patient experiences such stiffness when bending forward.) The patient history may also reveal a recent illness.

Other signs and symptoms may include headaches, nausea, vomiting, abdominal pain, poorly defined chest pain, and sore throat.

The patient history and knowledge of seasonal epidemics are essential in differentiating among the many forms of aseptic viral meningitis. Negative bacteriologic cultures and cerebrospinal fluid analysis showing pleocytosis and increased protein suggest the diagnosis. Isolation of the virus from cerebrospinal fluid confirms it.

Supportive treatment

Management of aseptic meningitis involves bed rest, maintenance of fluid and electrolyte balance, analgesics for pain, and exercises to combat residual weakness. Isolation isn't necessary. Careful handling of excretions and good hand-washing technique prevent the spread of the disease.

Complications

Potential complications of meningitis include visual impairment, optic neuritis, cranial nerve palsies, deafness, personality change, headache, paresis or paralysis,

endocarditis, coma, vasculitis, and cerebral infarction. Children may develop sensory hearing loss, epilepsy, mental retardation, hydrocephalus, or subdural effusions.

Assessment findings

The cardinal signs of meningitis are those of infection and increased intracranial pressure (ICP).

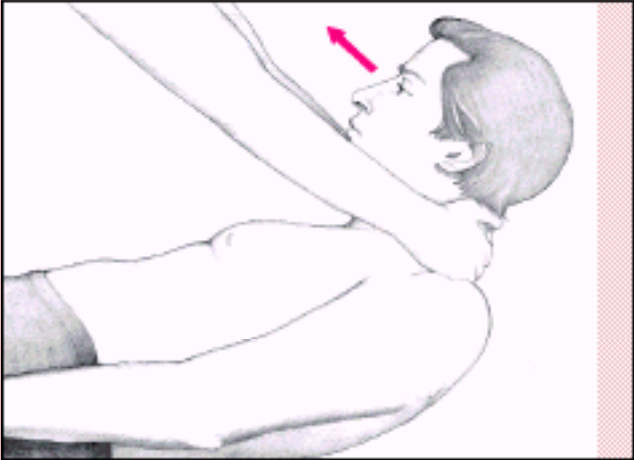

The patient history may detail headache, stiff neck and back, malaise, photophobia, chills and, sometimes, vomiting, twitching, and seizures. The patient or a family member may also report altered level of consciousness (LOC), such as confusion and delirium. Vital signs may reveal fever. (Vomiting and fever occur more often in children than in adults.) In addition, the history for an infant may list fretfulness and refusal to eat.

Two telltale signs of meningitis

A positive response to the following tests helps establish a diagnosis of meningitis.

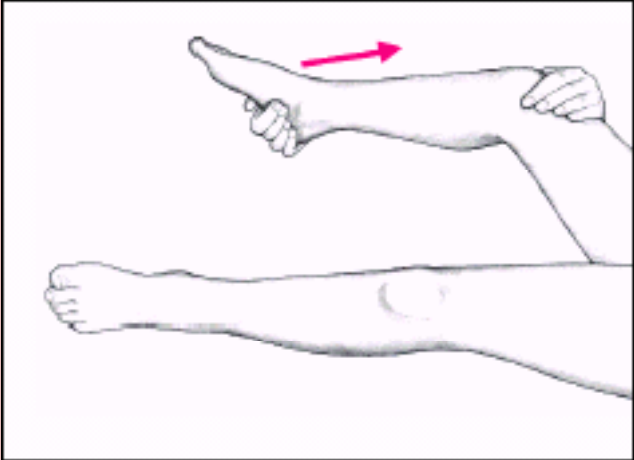

Brudzinski's sign

To test for this sign, place the patient in a dorsal recumbent position, and then put your hands behind his neck and bend it forward. Pain and resistance may indicate meningeal inflammation, neck injury, or arthritis. But if the patient also flexes the hips and knees in response to this manipulation, chances are he has meningitis.

Kernig's sign

To test for this sign, place the patient in a supine position. Flex his leg at the hip and knee, and then straighten the knee. Pain or resistance points to meningitis.

In *pneumococcal meningitis*, the patient history may uncover a recent lung, ear, or sinus infection or endocarditis. It may also reveal the presence of other conditions, such as alcoholism, sickle cell disease, basal skull fracture, recent splenectomy, or organ transplant.

In *H. influenzae meningitis*, the patient history may reveal a recent respiratory tract or ear infection.

Physical findings vary, depending on the severity of the meningitis. You may note opisthotonus, (a spasm in which the back and extremities arch backward so that the body rests on the head and heels), a sign of meningeal irritation. In *meningococcal meningitis*, you may see a petechial, purpuric, or ecchymotic rash on the lower part of the body.

Neurologic examination may uncover other indications of meningeal irritation, including positive Brudzinski's and Kernig's signs and exaggerated and symmetrical deep tendon reflexes. It may also reveal altered LOC, ranging from confusion or delirium to deep stupor or coma. (See [Two telltale signs of meningitis.](#))

Vision testing may demonstrate diplopia and other visual problems. Ophthalmoscopic examination may show papilledema (another sign of increased ICP), but this is rare.

Diagnostic tests

Lumbar puncture shows typical cerebrospinal fluid (CSF) findings associated with meningitis (elevated CSF pressure, cloudy or milky white CSF, high protein level, positive Gram stain and culture that usually identifies the infecting organism unless it's a virus, and depressed CSF glucose concentration).

Chest X-rays are especially important because they may reveal pneumonitis or lung abscess, tubercular lesions, or granulomas secondary to fungal infection. Sinus and skull films may help identify the presence of cranial osteomyelitis, paranasal sinusitis, or skull fracture.

White blood cell count usually indicates leukocytosis, and serum electrolyte levels often are abnormal.

Computed tomography scanning can rule out cerebral hematoma, hemorrhage, or tumor.

Treatment

Medical management of meningitis includes appropriate antibiotic therapy and vigorous supportive care.

Usually, I.V. antibiotics are given for at least 2 weeks, followed by oral antibiotics. Such antibiotics include penicillin G, ampicillin, or nafcillin. If the patient is allergic to penicillin, anti-infective therapy includes tetracycline, chloramphenicol, or kanamycin. Other drugs include a cardiac glycoside such as digoxin to control arrhythmias, mannitol to decrease cerebral edema, an anticonvulsant (usually given I.V.) or a sedative to reduce restlessness, and aspirin or acetaminophen to relieve headache and fever.

Supportive measures consist of bed rest, hypothermia, and fluid therapy to prevent dehydration. Isolation is necessary if nasal cultures are positive. Treatment

includes appropriate therapy for any coexisting conditions such as endocarditis or pneumonia.

Look closely for signs of meningitis in individuals who are at risk, such as after ventricular shunting procedures, skull fracture, or penetrating head wounds.

Nursing diagnoses

- u Anxiety
- u Hyperthermia
- u Impaired gas exchange
- u Pain
- u Risk for fluid volume deficit
- u Risk for impaired skin integrity

Key outcomes

- u The patient will maintain adequate ventilation.
- u The patient will exhibit temperature within normal range.
- u The patient will express feelings of comfort and relief of pain.
- u The patient will maintain fluid volume within normal range.
- u The patient's skin integrity will remain intact.

Nursing interventions

- u Maintain respiratory isolation for 24 hours after the start of antibiotic therapy. Discharges from the nose and the mouth are considered infectious. Follow strict aseptic technique when treating patients with head wounds or skull fractures.
- u Continually assess the patient's clinical status, including neurologic function and vital signs. Monitor for changes in LOC and signs of increased ICP (plucking at the bedcovers, vomiting, seizures, and a change in motor function and vital signs). Also watch for signs of cranial nerve involvement (ptosis, strabismus, diplopia).
- u Watch for signs of deterioration. Be especially alert for a temperature increase, deteriorating LOC, onset of seizures, and altered respirations, all of which may signal an impending crisis.
- u Obtain arterial blood gas measurements, as ordered, and administer oxygen as required to maintain partial pressure of oxygen at desired levels. If necessary, maintain the patient on mechanical ventilation and care for his endotracheal tube or tracheostomy.
- u Monitor fluid balance. Maintain adequate fluid intake to avoid dehydration, but avoid fluid overload because of the danger of cerebral edema. Measure central venous pressure and intake and output accurately.
- u Administer prescribed medications, and note their effects. Watch for adverse reactions.
- u Position the patient carefully to prevent joint stiffness and neck pain. Turn him often, according to a planned positioning schedule. Assist with range-of-motion exercises.
- u Maintain adequate nutrition. You may need to provide small, frequent meals or to supplement these meals with nasogastric tube or parenteral feedings.
- u To prevent constipation and minimize the risk of increased ICP resulting from straining at stool, give the patient a mild laxative or stool softener as ordered.
- u Provide mouth care regularly.
- u Ensure the patient's comfort, and maintain a quiet environment. Darkening the room may decrease photophobia. Relieve headache with a nonnarcotic analgesic, such as aspirin or acetaminophen, as ordered. (Narcotics interfere with accurate neurologic assessment.)
- u Provide reassurance and support. The patient's illness and frequent lumbar punctures may frighten him. If he's delirious or confused, attempt to reorient him often. Reassure family members that the delirium and behavior changes caused by meningitis usually disappear. If a severe neurologic deficit appears permanent, refer the patient to a rehabilitation program as soon as the acute phase of this illness has passed.

Patient teaching

- u Inform the patient and family members of the contagion risks, and tell them to notify anyone who comes into close contact with the patient. Such people require antimicrobial prophylaxis and immediate medical attention if fever or other signs of meningitis develop.
- u To help prevent the development of meningitis, teach patients with chronic sinusitis or other chronic infections the importance of proper medical treatment.

MYELITIS AND ACUTE TRANSVERSE MYELITIS

Inflammation of the spinal cord (myelitis) can result from several diseases. Poliomyelitis affects the cord's gray matter and produces motor dysfunction; leukomyelitis affects only the white matter and produces sensory dysfunction. These types of myelitis can attack any level of the spinal cord, causing partial destruction or scattered lesions.

ADVANCED PRACTICE

Assessing for myelitis

In *poliomyelitis*, assessment findings vary with the type. In *abortive poliomyelitis*, the patient may report headache, vomiting, diarrhea, constipation, and sore throat. Vital signs may reveal fever. Neurologic assessment is normal. Signs of central nervous system involvement are absent.

In *nonparalytic poliomyelitis*, the patient history notes complaints of headache, neck, back, abdominal, and extremity pain as well as vomiting, lethargy, and irritability. Palpation may disclose continuous muscle spasms in the extensor muscles of the neck and back and often in the hamstring and other muscles. The muscles may also be tender on palpation. A vital signs check detects fever.

In *paralytic poliomyelitis*, the patient history may reveal that the patient had a fever and a minor respiratory illness several days before development of poliomyelitis. The patient usually explains that the fever returned accompanied by cramping muscle pain and spasm and twitching in the affected parts.

The patient may develop spinal poliomyelitis, bulbar poliomyelitis, or both. In spinal poliomyelitis, neurologic assessment finds weakness or paralysis of the muscles supplied by the affected spinal nerves. Paralysis of one leg commonly occurs in children under age 5. In patients ages 5 to 15, weakness of one arm and paraplegia are common. In adults, quadriplegia is more likely. You'll also find deep tendon reflexes diminished or lost, often asymmetrically, in areas of involvement.

In *bulbar poliomyelitis*, the patient may report difficulty chewing, inability to swallow or expel saliva, and regurgitation of fluids through the nose. As the patient speaks, you may notice a nasal voice and dysphonia. Neurologic assessment may reveal weakness of the facial, sternocleidomastoid, and trapezius muscles.

In *myelitis caused by herpesvirus type 2 infection in the genital and perineal region*, neurologic examination usually finds a paralyzed sphincter (bladder or anal).

In *acute transverse myelitis*, patient history reveals a rapid onset with motor and sensory dysfunction below the level of spinal cord damage appearing in 1 to 2 days. The patient may report that he had a respiratory tract infection just before the onset of the disorder.

Acute transverse myelitis, which affects the entire thickness of the spinal cord, produces both motor and sensory dysfunction. This form of myelitis, which has a rapid onset, is the most devastating.

The prognosis depends on the severity of cord damage and prevention of complications. If spinal cord necrosis occurs, the prognosis for complete recovery is poor. Even without necrosis, residual neurologic deficits usually persist after recovery. Patients who develop spastic reflexes early in the course of the illness are more likely to recover than those who don't.

Causes

Myelitis may result from poliovirus, herpes zoster, herpesvirus B, or rabies virus; disorders that cause meningeal inflammation, such as syphilis, abscesses and other suppurative conditions, and tuberculosis; smallpox or polio vaccination; parasitic and fungal infections; and chronic adhesive arachnoiditis.

Certain toxic agents (carbon monoxide, lead, and arsenic) can cause a type of myelitis in which acute inflammation (followed by hemorrhage and, possibly, necrosis) destroys the entire circumference (myelin, axis cylinders, and neurons) of the spinal cord.

Acute transverse myelitis has several causes. It often follows acute infectious diseases, such as measles and pneumonia (the inflammation occurs after the infection has subsided), and primary infections of the spinal cord itself, such as syphilis and acute disseminated encephalomyelitis. Acute transverse myelitis can accompany demyelinating diseases, such as acute multiple sclerosis, and inflammatory and necrotizing disorders of the spinal cord such as hematomyelia.

Complications

Common complications include hypertension, urinary tract infection, urolithiasis, pneumonia, skeletal and smooth-muscle deformities, myocarditis, and paralytic ileus.

Assessment findings

In all types of myelitis, the extent of neurologic deficit depends on the level of the spinal cord affected. (See [Assessing for myelitis.](#))

Neurologic examination may reveal flaccid paralysis of the legs, which the patient occasionally reports as beginning in just one leg. This paralysis is often accompanied by loss of sensory and sphincter function. The patient may explain that sensory loss followed pain in the legs or trunk.

Reflexes may be absent in the early stages but may reappear later. Neurologic examination almost always reveals normal arm function. Transverse myelitis rarely involves the arms. If spinal cord damage is severe, the patient may experience shock (hypotension and hypothermia).

Diagnostic tests

Diagnostic evaluation must rule out spinal cord tumor and identify any underlying infection.

White blood cell count may be normal or slightly elevated; cerebrospinal fluid analysis may show normal or increased lymphocyte and protein levels without isolating the causative agent.

Throat washings may reveal the causative virus in patients suspected of having poliomyelitis.

Computed tomography scanning or magnetic resonance imaging is useful to rule out spinal cord tumor.

Treatment

In myelitis, treatment is supportive and focused on relieving the patient's symptoms. An underlying bacterial infection requires appropriate treatment.

Nursing diagnoses

- u Anxiety u Body image disturbance u Impaired gas exchange u Impaired physical mobility u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for aspiration u Risk for infection

Key outcomes

- u The patient will maintain patent airway without risk of aspiration.
- u The patient will maintain adequate ventilation.
- u The patient will maintain joint mobility and range of motion.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will express positive feelings about himself.

Nursing interventions

- u Provide psychological support to the patient and family members. Encourage them to express their concerns, and answer their questions honestly. Allow the patient to participate in care planning as appropriate.
- u Maintain the patient in a comfortable position as much as possible.
- u Prevent contracture development in a patient with paralysis by using footboards and light splints. Perform passive range-of-motion exercises.
- u Frequently assess vital signs. Watch carefully for signs of shock (hypotension and diaphoresis).
- u Perform comfort measures such as massage for the patient with muscle spasms. Administer analgesics as ordered.
- u Watch for signs of urinary tract infection if the patient has an indwelling urinary catheter.
- u Prevent skin infections and pressure ulcers with meticulous skin care. Check pressure points often and keep the patient's skin clean and dry; use a low-air-loss bed, foam pad, or other pressure-relieving device. Turn the patient every 2 hours.
- u Initiate rehabilitation as soon as the patient passes the acute stage of the disorder. For example, as soon as the fever subsides, begin early mobilization and active exercises as directed by the physical therapist.
- u If the patient has trouble dealing with body image changes, point out to him the actions that he performs well, providing encouragement and support whenever possible.
- u Watch for problems that can develop, such as respiratory muscle paralysis in the patient with bulbar poliomyelitis. Provide oxygen and mechanical ventilation as necessary.

Patient teaching

- u Explain the disorder to the patient and family members. Tell them about diagnostic tests. Be sure that the patient and family members understand the possible problems that may follow the acute phase of the disorder.
- u Explain the treatments, such as physical therapy and bowel and bladder training, to help the patient recover as much independence as possible.
- u As appropriate, refer the patient and family members to the social service department and to home health care agencies for assistance with care after discharge.

PARKINSON'S DISEASE

Named for the English doctor who first accurately described the disease in 1817, Parkinson's disease characteristically produces progressive muscle rigidity, akinesia, and involuntary tremors. Deterioration often progresses, culminating in death, which usually results from aspiration pneumonia or some other infection.

Parkinson's disease is also called parkinsonism, paralysis agitans, or shaking palsy. It's one of the most common crippling diseases in the United States. It affects men more often than women and usually occurs in middle age or later. Due to advances in treatment of complications, increased patient longevity is more common.

Causes

The cause of Parkinson's disease is unknown in most cases. Studies of the extrapyramidal brain nuclei (corpus striatum, globus pallidus, and substantia nigra) have established that a dopamine deficiency prevents affected brain cells from performing their normal inhibitory function within the central nervous system.

PATHOPHYSIOLOGY

Understanding Parkinson's disease

New research on the pathogenesis of Parkinson's disease focuses on damage to the substantia nigra from oxidative stress. Oxidative stress is believed to:

- u cause alterations in the brain iron content
- u impair mitochondrial function
- u alter antioxidant and protective systems
- u reduce glutathione
- u damage lipids, proteins, and deoxyribonucleic acid.

Some cases of Parkinson's disease are caused by exposure to toxins, such as manganese dust and carbon monoxide, that destroy cells in the substantia nigra. (See [Understanding Parkinson's disease.](#))

Complications

Common complications associated with Parkinson's disease include injury from falls, food aspiration because of impaired voluntary movements, urinary tract infections, and skin breakdown as the patient becomes less mobile.

Assessment findings

The patient history notes the cardinal symptoms of Parkinson's disease, which include muscle rigidity and akinesia, and an insidious tremor, commonly known as unilateral pill-roll tremor, that begins in the fingers. Although the patient often can't pinpoint exactly when the tremors began, he typically reports their increase during stress or anxiety and decrease with purposeful movement and sleep. He may also report dysphagia.

The patient may complain that he becomes fatigued when he tries to perform activities of daily living and that he experiences muscle cramps of the legs, neck, and trunk. He may also mention oily skin, increased perspiration, insomnia, and mood changes. You may note dysarthria and find that the patient speaks in a high-pitched monotone.

Inspection may reveal drooling, a masklike facial expression, and difficulty walking. The patient's gait often lacks normal parallel motion and may be retropulsive or propulsive. In addition, the patient may demonstrate a loss of posture control when he walks. Typically, the patient who loses posture control walks with the body bent forward. These signs result from akinesia.

You may note another result of akinesia: oculogyric crises (eyes fixed upward, with involuntary tonic movements) or blepharospasm (eyelids closed). You may also discover that the patient takes a long time to initiate movement to perform a purposeful action.

In addition to gait changes, musculoskeletal and neurologic assessment may point to muscle rigidity that results in resistance to passive muscle stretching. Such rigidity may be uniform (lead-pipe rigidity) or jerky (cogwheel rigidity). The patient may also pivot with difficulty and easily lose his balance.

As you assess this patient, keep in mind that Parkinson's disease itself doesn't impair the intellect but that a coexisting disorder such as arteriosclerosis may.

Diagnostic tests

Although urinalysis may reveal decreased dopamine levels, laboratory test results usually have little value in identifying Parkinson's disease.

Computed tomography scanning or magnetic resonance imaging may be performed to rule out other disorders such as intracranial tumors. A conclusive diagnosis is possible only after ruling out other causes of tremor, involuntal depression, cerebral arteriosclerosis and, in patients under age 30, intracranial tremors, Wilson's disease, or phenothiazine or other drug toxicity.

Treatment

No cure exists for Parkinson's disease, so the goal of treatment is to relieve symptoms and keep the patient functional as long as possible. Treatment consists of drugs, physical therapy and, in severe disease unresponsive to drugs, stereotaxic neurosurgery.

Drug therapy usually includes levodopa, a dopamine replacement that is most effective for the 1st few years after it's initiated. The drug is given in increasing doses until signs and symptoms are relieved or adverse reactions appear. Because adverse effects can be serious, levodopa is frequently given in combination with carbidopa (a dopa-decarboxylase inhibitor) to halt peripheral dopamine synthesis. The patient may receive bromocriptine as an additive to reduce the levodopa dose. When levodopa is ineffective or too toxic, alternative drug therapy includes anticholinergics (such as trihexyphenidyl or benztropine) and antihistamines (such as diphenhydramine).

Antihistamines may help decrease tremors because of their central anticholinergic and sedative effects. Anticholinergics may be used to control tremors and rigidity. They may also be used in combination with levodopa.

Amantadine, an antiviral agent, is used early in treatment to reduce rigidity, tremors, and akinesia. Selegiline, an enzyme-inhibiting agent, allows conservation of dopamine and enhances the therapeutic effect of levodopa.

Research in oxidative stress theory has caused a controversy in drug therapy for Parkinson's disease. Although levodopa and carbidopa has traditionally been a first-line drug for management, it's been associated with an acceleration of the disease process. Selegiline following levodopa and carbidopa may be more effective.

When drug therapy fails, stereotaxic neurosurgery sometimes offers an effective alternative. In this procedure, electrical coagulation, freezing, radioactivity, or ultrasound destroys the ventrolateral nucleus of the thalamus to prevent involuntary movement. Such neurosurgery is most effective in comparatively young, otherwise healthy people with unilateral tremor or muscle rigidity. Like drug therapy, neurosurgery is a palliative measure that can only relieve symptoms.

Physical therapy complements drug treatment and neurosurgery to maintain the patient's normal muscle tone and function. Appropriate physical therapy includes both active and passive range-of-motion exercises, routine daily activities, walking, and baths and massage to help relax muscles.

Tricyclic antidepressants may be given to decrease the depression that often accompanies the disease.

Nursing diagnoses

u Altered family processes u Altered nutrition: Less than body requirements u Body image disturbance u Chronic low self-esteem u Constipation u Impaired physical mobility u Impaired social interaction u Impaired verbal communication u Ineffective family coping: Disabling u Ineffective individual coping u Risk for injury u Self-care deficit: Bathing or hygiene u Self-care deficit: Dressing or grooming u Self-care deficit: Feeding

Key outcomes

- u The patient will perform activities of daily living within the confines of the disorder.
- u The patient will develop alternative means of communication.
- u The patient will remain free from injury.
- u The patient will consume adequate daily calories as required.
- u The patient will express positive feelings about himself.
- u The patient and family members will seek support resources and develop adequate coping behaviors.

Nursing interventions

- u Provide emotional and psychological support to the patient and family members. Listen to their concerns and answer their questions. To promote independence, encourage the patient to participate in care decisions and to perform as much of his own care as possible.
- u Monitor drug treatment so dosage can be adjusted to minimize adverse reactions. Report adverse reactions.
- u If the patient has surgery, watch for signs of hemorrhage and increased intracranial pressure by frequently checking level of consciousness and vital signs.
- u Encourage independence by helping the patient recognize the activities of daily living that he can perform. Provide assistive devices as appropriate. For example, to help the patient turn himself in bed, tie a rope to the foot of the bed and extend it to the patient so that he can grasp it and pull himself to a sitting position.
- u To help the patient with severe tremors achieve partial control of his body, have him sit on a chair and use its arms to steady himself.
- u Remember that fatigue may cause the patient to depend more on others, so provide rest periods between activities.
- u Help the patient overcome problems related to eating and elimination. For example, if he has difficulty eating, offer supplementary feedings or small, frequent meals to increase caloric intake. Help establish a regular bowel elimination routine by encouraging him to drink at least 2 L (2.1 qt) of liquids daily and eat high-fiber foods. He may need an elevated toilet seat to assist him from a standing to a sitting position.
- u Work with the physical therapist to develop a program of daily exercises to increase muscle strength, decrease muscle rigidity, prevent contractures, and improve coordination. The program should include stretching exercises, swimming, use of a stationary bicycle, and postural exercises.
- u Provide frequent warm baths and massage to help relax muscles and relieve muscle cramps.
- u Protect the patient from injury by using the bed's side rails and assisting the patient as necessary when he walks and eats.
- u To decrease the possibility of aspiration, have the patient sit in an upright position when eating. Keep in mind that these patients are often silent aspirators. Even they don't realize that they're aspirating.
- u Provide the patient with a semisolid diet, which is easier to swallow than a diet consisting of solids and liquids.

Patient teaching

- u Teach the patient and family members about the disease, its progressive stages, and treatments that may help the patient. Explain the actions of prescribed medications and possible adverse effects.
- u If appropriate, show family members how to prevent pressure ulcers and contractures by proper positioning.
- u Explain household safety measures, such as installing or using side rails in halls and stairs and removing throw rugs from frequently traveled floors to prevent patient injury.
- u Explain the importance of daily bathing to the patient with oily skin and increased perspiration.
- u To make dressing easier, teach the patient to wear clothing fitted with zippers or Velcro fasteners rather than buttons.
- u To improve communication, instruct the patient to make a conscious effort to speak, to speak slowly, to take a few deep breaths before he begins to speak, and to think about what he wants to say before he begins to speak.
- u If appropriate, advise the patient how to eat. Tell him to place food on the tongue, close the lips, chew first on one side and then the other, and then lift the tongue up and back and make a conscious effort to swallow. Because these patients eat slowly, allow plenty of time for meals.
- u Refer the patient and family members to the National Parkinson Foundation, the American Parkinson Disease Association, or the United Parkinson Foundation for more information.

REYE'S SYNDROME

Reye's syndrome is an acute childhood illness that causes fatty infiltration of the liver with concurrent hyperammonemia, encephalopathy, and increased intracranial pressure (ICP). In addition, fatty infiltration of the kidneys, brain, and myocardium may occur. Reye's syndrome affects children from infancy to adolescence and occurs equally in boys and girls. It affects whites over age 1 more often than blacks.

Reye's syndrome almost always follows within 1 to 3 days of an acute viral infection, such as an upper respiratory tract infection, type B influenza, or varicella (chickenpox).

The prognosis depends on the severity of central nervous system depression. Previously, mortality was as high as 90%. Today, though, increased awareness of Reye's syndrome, early detection, and prompt, aggressive treatment have reduced mortality to about 5%. Death is usually a result of cerebral edema or respiratory arrest. Most comatose patients who survive have some residual brain damage, such as developmental and neuropsychological difficulties.

Causes

The cause of Reye's syndrome is unknown, but viral and toxic agents, especially salicylates, have been implicated. Studies have proven a relation between aspirin administration during a viral infection and onset of Reye's syndrome. Since this finding was published, pediatric use of aspirin has declined and Reye's syndrome has become less common. (See [Understanding Reye's syndrome.](#))

Complications

Increased ICP is the worst complication of Reye's syndrome. The child's ICP is commonly so fragile that even standard nursing care, such as turning and bathing the child, may precipitate a large increase in ICP.

Other possible complications include respiratory alkalosis and subsequent impaired gas exchange, respiratory arrest, and decreased cardiac output.

Assessment findings

The severity of the child's signs and symptoms varies with the degree of encephalopathy and cerebral edema.

Most commonly, the patient history reveals a viral infection followed by a brief period of several days during which the child seems to recover. Later, he develops intractable vomiting and progressive changes in level of consciousness, from drowsiness and lethargy to stupor and coma.

Vital signs may include a low-grade fever or normal temperature, slight tachycardia, rapid respirations, and a normal blood pressure. Inspection may reveal diaphoresis and a child who appears healthy but may be agitated, confused, or combative. Jaundice is usually absent. The liver isn't usually palpable.

Neurologic examination usually is normal except for hyperreflexia. Signs of increased ICP are rare. Pupils are usually reactive, and ophthalmoscopic examination

reveals no evidence of papilledema.

If the child is assessed late in the disease, respiratory distress (progressing from hyperventilation to Cheyne-Stokes and apneic respirations) is usually evident. Then, as the child passes into coma, he may develop unilateral or bilateral fixed and dilated pupils (with severe encephalopathy), seizures, and decorticate or decerebrate posturing.

Diagnostic tests

Laboratory tests disclose elevated serum ammonia levels; normal or (in 15% of cases) low serum glucose levels; and increased serum fatty acid and lactate levels. Liver function studies indicate aspartate aminotransferase and alanine aminotransferase at twice the normal levels. Bilirubin levels are normal.

Coagulation studies demonstrate increased prothrombin time and partial thromboplastin time.

Liver biopsy reveals fatty droplets uniformly distributed throughout liver cells.

Cerebrospinal fluid (CSF) analysis shows a white blood cell count of less than 10/mm³; coma causes increased CSF pressure.

Treatment

In Reye's syndrome, treatment depends on the disease's stage and must be started as soon as Reye's syndrome is diagnosed because the disease progresses rapidly. Initially, therapy consists of I.V. administration of glucose to prevent onset of coma. Other treatments include airway maintenance, adequate oxygenation, and control of cerebral edema. (See [Reye's syndrome: Stages and treatment.](#))

Nursing diagnoses

u Altered tissue perfusion (cerebral) u Anxiety u Fear u Impaired gas exchange u Impaired physical mobility u Ineffective breathing pattern u Risk for impaired skin integrity

Key outcomes

- u The patient will maintain respiratory rate within ±5 of baseline.
- u The patient will maintain adequate ventilation.
- u The patient will maintain orientation to environment without evidence of deficit.
- u The patient will maintain joint mobility and range of motion.
- u The patient will maintain skin integrity.

Nursing interventions

- u Provide emotional and psychological support to the child, as appropriate, and family members. Listen to their concerns, and stay with them during periods of acute stress.
- u Continuously monitor vital signs, and assess the child's level of consciousness. Watch for increasing lethargy. Immediately report any signs of coma. Continuously assess the child for loss of reflexes and signs of flaccidity.

PATHOPHYSIOLOGY

Understanding Reye's syndrome

In Reye's syndrome, damaged hepatic mitochondria disrupt the urea cycle, which normally changes ammonia to urea for its excretion from the body. This results in hyperammonemia, hypoglycemia, and an increase in serum short-chain fatty acids, leading to encephalopathy. As the ammonia level increases, the brain, a secondary site of urea metabolism, swells markedly. At the same time, fatty infiltration occurs in renal tubular cells, neuronal tissue, and muscle tissue, including the heart.

- u Anticipate the possible need for intubation and mechanical ventilation to help control increasing ICP and maintain adequate oxygenation. Keep the necessary supplies available. If mechanical ventilation is begun, be prepared to administer a paralyzing agent such as pancuronium I.V. and an analgesic as ordered.
- u Keep the head of the bed elevated at a 30-degree angle (if the patient's blood pressure tolerates it) to increase venous outflow and decrease ICP.
- u Monitor ICP and report changes.
- u Monitor cardiovascular status with a pulmonary artery catheter or central venous line.
- u Administer ordered I.V. fluids and medications as directed. Monitor the child for the desired effect. As ordered, give mannitol I.V., thiopental I.V., or glycerol by nasogastric tube to control ICP.
- u Maintain seizure precautions during the acute stage; seizures may occur at any time.
- u Hyperventilate the child with 100% oxygen before suctioning to forestall precipitous falls in partial pressure of oxygen in arterial blood (Pa O₂) and increases in partial pressure of carbon dioxide in arterial blood (Pa CO₂), either of which may lead to sudden changes in ICP.
- u Provide good skin care, and perform range-of-motion exercises.
- u If the child begins to recover from the illness, reorient him as often as necessary because he usually can't remember anything that occurred during the acute stage of the illness. Be sure to explain all procedures to the child to decrease his anxiety. Encourage the parents to bring familiar things from home and to spend as much time as possible with their child.

ADVANCED PRACTICE

Reye's syndrome: Stages and treatment

Each stage of Reye's syndrome presents its own set of signs and symptoms, which require appropriate medical treatments and nursing interventions as outlined below.

SIGNS AND SYMPTOMS	TREATMENT	NURSING INTERVENTIONS
--------------------	-----------	-----------------------

Stage I Vomiting, lethargy, hepatic dysfunction	<ul style="list-style-type: none"> Give glucose I.V. to help decrease the possibility of coma. Give I.V. fluids at two-thirds of maintenance dose and an osmotic diuretic or furosemide administered to decrease intracranial pressure and cerebral edema. Give vitamin K to decrease hypoprothrombinemia; if unsuccessful, give fresh frozen plasma. 	<ul style="list-style-type: none"> Obtain serum ammonia, blood glucose, and plasma molality values every 4 to 8 hours to monitor patient progress. Monitor fluid intake and output to prevent fluid overload. Maintain urine output at 1 ml/kg/hour, plasma osmolality at 290 mOsm/kg, and blood glucose levels at 150 mg/dl. (Goal: Keep glucose levels high, osmolality normal to high, and ammonia levels low.) Also, restrict protein intake.
Stage II Hyperventilation, delirium, hepatic dysfunction, hyperactive reflexes	<ul style="list-style-type: none"> Continue baseline treatment. 	<ul style="list-style-type: none"> Institute seizure precautions. Be prepared for invasive supportive therapy such as intubation.
Stage III Coma, hyperventilation, decorticate rigidity, hepatic dysfunction	<ul style="list-style-type: none"> Continue baseline treatment and supportive care. 	<ul style="list-style-type: none"> Continue seizure precautions. Monitor intracranial pressure. Perform endotracheal intubation, and institute ventilation to control Paco₂ levels. <p>Administering a paralyzing agent such as pancuronium I.V. may help maintain ventilation.</p> <ul style="list-style-type: none"> Administer mannitol I.V., thiopental I.V., or glycerol by nasogastric tube to help control intracranial pressure. When ventilating the patient, maintain Paco₂ between 20 and 30 mm Hg and Pao₂ between 80 and 100 mm Hg. Insert a pulmonary artery catheter or central venous pressure catheter to monitor cardiovascular status.
Stage IV Deepening coma; decerebrate rigidity; large, fixed pupils; minimal hepatic dysfunction	<ul style="list-style-type: none"> Continue baseline treatment and supportive care. If all previous measures fail, some pediatric centers use barbiturate coma, decompressive craniotomy, hypothermia, or exchange transfusion. 	<ul style="list-style-type: none"> Check the patient for loss of reflexes and signs of flaccidity. Give the family the extra support they need, considering their child's poor prognosis.
Stage V Seizures, loss of deep tendon reflexes, flaccidity, respiratory arrest, ammonia level greater than 300 mg/dl	<ul style="list-style-type: none"> Continue baseline and supportive care. The prognosis is very poor at this stage; usually the child doesn't recover. 	<ul style="list-style-type: none"> Help the family face the patient's impending death.

Patient teaching

- Teach family members and, as appropriate, the child about the disorder, its signs and symptoms, the diagnostic tests, and the treatments that are necessary. Discuss the prognosis with the parents. Reinforce teaching as necessary.
- Advise the parents to give nonsalicylate analgesics and antipyretics such as acetaminophen.
- Refer the parents to the National Reye's Syndrome Foundation.

Neuromuscular disorders

In neuromuscular disorders—amyotrophic lateral sclerosis, multiple sclerosis, and myasthenia gravis—a neurologic problem causes muscle degeneration.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease of muscular atrophy. It's also known as Lou Gehrig's disease (after a well-known baseball player who died of the disease in 1941). ALS is a chronic, progressive, and debilitating disease that is invariably fatal. It's characterized by progressive degeneration of the anterior horn cells of the spinal cord and cranial nerves and of the motor nuclei in the cerebral cortex and corticospinal tracts.

ALS is about three times more common in men than in women. Generally, ALS affects people ages 40 to 70. Most patients with ALS die after about 3 years, but some may live as long as 10 to 15 years. Death usually results from a complication, such as aspiration pneumonia or respiratory failure.

Causes

The exact cause of ALS is unknown, but about 10% of ALS patients inherit the disease as an autosomal dominant trait. ALS may also be caused by a virus that creates metabolic disturbances in motor neurons or by immune complexes such as those formed in autoimmune disorders.

Precipitating factors that can cause acute deterioration include severe stress, such as myocardial infarction, traumatic injury, viral infections, and physical exhaustion.

Complications

Common complications of ALS include respiratory tract infections, such as pneumonia, respiratory failure, and aspiration, and complications of physical immobility, such as pressure ulcers and contractures.

Assessment findings

Signs and symptoms of ALS depend on the location of the affected motor neurons and the severity of the disease. Keep in mind that muscle weakness, atrophy, and fasciculations are the principal symptoms of the disorder, the disease may begin in any muscle group and, eventually, all muscle groups become involved. Unlike other degenerative disorders such as Alzheimer's disease, ALS doesn't affect mental function.

The patient history may reveal other family members with ALS if the problem was inherited. In the early disease stages, the patient may report asymmetrical weakness first noticed in one limb. He also usually reports fatigue and easy cramping in the affected muscles. Inspection may reveal fasciculations in the affected muscles if

these muscles aren't concealed by adipose tissue and muscle atrophy. Fasciculations and atrophy are most obvious in the feet and hands.

As the disease progresses, the patient may report progressive weakness in muscles of the arms, legs, and trunk. Inspection reveals atrophy and fasciculations. Neurologic examination often reveals brisk and overactive stretch reflexes. Muscle strength tests confirm the reported muscle weakness.

When the disease progresses to involve the brain stem and the cranial nerves, the patient has difficulty talking, chewing, swallowing and, ultimately, breathing. In these patients, auscultation may reveal decreased breath sounds.

In some patients (about 25%), muscle weakness begins in the musculature supplied by the cranial nerves. When this occurs, initial patient history reveals difficulty talking, swallowing, and breathing. Occasionally, the patient may report choking. Inspection may reveal some shortness of breath and, occasionally, drooling.

Diagnostic tests

Although no diagnostic tests are specific to this disease, the following tests may aid in its diagnosis.

HOME CARE

Modifying the home for a patient with ALS

To help your patient with ALS live safely at home, follow these guidelines:

- u Explain basic safety precautions, such as keeping stairs and pathways free of clutter; using nonskid mats in the bathroom and in place of loose throw rugs; keeping stairs well lit; installing handrails in stairwells and the shower, tub, and toilet areas; and removing electrical and telephone cords from traffic areas.
- u Discuss the need for rearranging the furniture, moving items in or out of the patient's care area, and obtaining such equipment as a hospital bed, a commode, or oxygen equipment.
- u Recommend devices to ease the patient's and caregiver's work, such as extra pillows or a wedge pillow to help the patient sit up, a draw sheet to help him move up in bed, a lap tray for eating, or a bell for calling the caregiver.
- u Help the patent adust to changes in the environment. Encourage independence.
- u Advise the patient to keep a suction machine handy to reduce the fear of choking due to secretion accumulation and dysphagia. Teach him to suction himself.

Electromyography may show abnormalities of electrical activity of involved muscles. Nerve conduction studies are usually normal.

Muscle biopsy may disclose atrophic fibers interspersed among normal fibers. Cerebrospinal fluid analysis reveals increased protein content in one-third of patients.

Other studies, such as computed tomography scanning and EEG, may help rule out other disorders, including multiple sclerosis, spinal cord neoplasms, syringo-myelias, myasthenia gravis, and progressive muscular dystrophy.

Treatment

ALS has no cure. Treatment, which is supportive and based on the patient's symptoms, may include diazepam, dantrolene, or baclofen for spasticity and quinidine for relief of painful muscle cramps that occur in some patients. I.V. or intrathecal administration of thyrotropin-releasing hormone temporarily improves motor function in some patients but has no long-term benefits. Klonopin or inderal may be given for cerebellar dysfunction. Rehabilitative measures can help patients function effectively for a longer period, and mechanical ventilation can help them survive longer.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anticipatory grieving u Anxiety u Hopelessness u Impaired physical mobility u Impaired verbal communication u Ineffective airway clearance u Ineffective breathing pattern u Ineffective family coping u Knowledge deficit u Risk for impaired skin integrity u Risk for infection u Self-care deficit: Bathing or hygiene u Self-care deficit: Dressing or grooming u Self-care deficit: Feeding

Key outcomes

- u The patient will maintain a patent airway and adequate ventilation.
- u The patient will maintain orientation to environment without evidence of deficit.
- u The patient will maintain joint mobility and range of motion.
- u The patient will consume adequate daily calories as required.
- u The patient and family members will seek support systems and exhibit adequate coping behaviors.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Provide emotional and psychological support to the patient and family members. Stay with the patient during periods of severe stress and anxiety. Keep in mind that because mental status remains intact while progressive physical degeneration takes place, the patient acutely perceives every change in his condition.
- u Implement a rehabilitation program designed to help the patient maintain his independence as long as possible.
- u Have the patient perform active exercises and range-of-motion exercises on unaffected muscles to help strengthen these muscles. Stretching exercises are also helpful.
- u Depending on the patient's muscular capacity, assist with bathing, personal hygiene, and transfers from wheelchair to bed. Help establish a regular bowel and bladder elimination routine.
- u To prevent skin breakdown, provide good skin care when the patient's mobility decreases. Turn him often, keep his skin clean and dry, and use pressure-reducing devices such as an alternating air mattress.
- u Help the patient obtain equipment, such as a walker or a wheelchair, when this becomes necessary.
- u If the patient can't talk, provide an alternate means of communication, such as message boards, eye blinks for yes and no, or a computer.
- u Administer ordered medications as necessary to relieve the patient's symptoms. Check with the pharmacist to see if tablets can be crushed or capsules opened and mixed with semisolid food for the patient who has dysphagia.
- u Have the patient with breathing difficulty perform deep-breathing and coughing exercises. Suctioning, chest physiotherapy, and incentive spirometry can also help.
- u If the patient chooses to use mechanical ventilation to assist with his breathing, provide necessary care. Carefully assess the patient with respiratory involvement for infection because respiratory complications may be fatal.
- u If the patient has trouble swallowing, give him soft, semisolid foods and position him upright during meals. Have suctioning equipment available to prevent aspiration. Use a soft cervical collar to help the patient hold his head upright if he has difficulty doing so. Gastrostomy and nasogastric tube feedings may be necessary if he can no longer swallow.

Patient teaching

u Teach the patient and family members about ALS and its signs and symptoms. Explain that this is a progressive, incurable disease, but reassure the patient that there are treatments to make him more comfortable and to help him stay independent and live at home as long as possible. (See [Modifying the home for a patient with ALS.](#))

- u Teach the patient who has trouble chewing to cut up his food or mince food in a blender or food processor. Suggest adding baby cereal to minced foods to help thicken them.
- u Urge the caregiver to take breaks from patient care; recommend agencies or support personnel for respite care.
- u Refer the patient and family to a local ALS support group. Prepare them for his eventual death, and help them grieve.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic disease caused by progressive demyelination of the white matter of the brain and spinal cord. These sporadic patches of demyelination in the central nervous system (CNS) cause widespread and varied neurologic dysfunction. (See [When myelin breaks down.](#))

MS is a major cause of chronic disability in young adults ages 20 to 40. Exacerbations and remissions characterize it. MS may progress rapidly, causing death within months or disability by early adulthood. The prognosis varies; about 70% of patients lead active, productive lives with prolonged remissions.

PATHOPHYSIOLOGY

When myelin breaks down

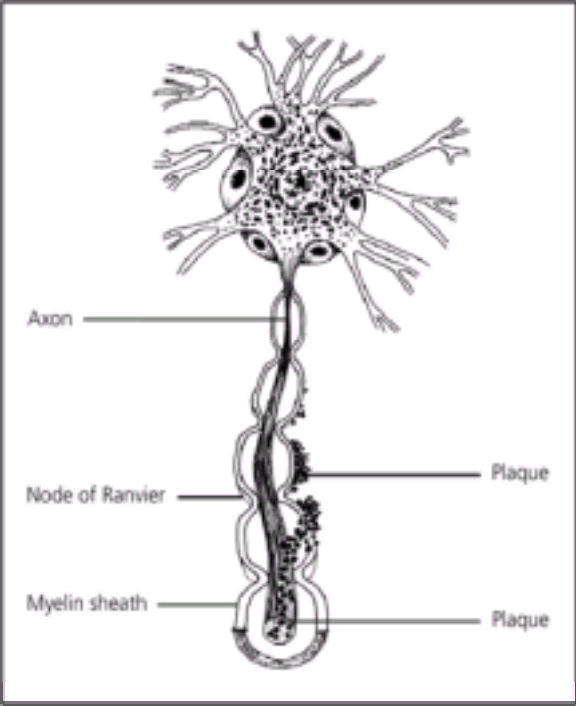

Myelin plays a key role in speeding electrical impulses to the brain for interpretation. A lipoprotein complex formed of glial cells or oligodendrocytes, the myelin sheath protects the neuron's long nerve fiber (the axon) much like the insulation on an electrical wire. Its high electrical resistance and low capacitance allow the myelin sheath to permit sufficient conduction of nerve impulses from one node of Ranvier to the next.

Myelin is susceptible to injury by hypoxemia, toxic chemicals, vascular insufficiency, and autoimmune responses. As a result, the myelin sheath becomes inflamed and the membrane layers break down into smaller components that become well-circumscribed plaques (filled with microglial elements, macroglia, and lymphocytes). This process is called demyelination.

The damaged myelin sheath impairs normal conduction, causing partial loss or dispersion of the action potential and consequent neurologic dysfunction.

New evidence of nerve fiber loss may explain the invisible neurologic deficits experienced by many patients with multiple sclerosis. The axons control the presence or absence of function. Loss of myelin doesn't correlate with loss of function.

ABNORMAL NEURON

The diagram illustrates a neuron with its cell body at the top, branching out into several axons. One axon is shown extending downwards, covered by a myelin sheath. The myelin sheath is composed of segments separated by gaps called Nodes of Ranvier. Two areas of the myelin sheath are labeled as 'Plaque', indicating areas of demyelination. Labels with leader lines point to the 'Axon', 'Node of Ranvier', 'Myelin sheath', and 'Plaque'.

ADVANCED PRACTICE

Describing multiple sclerosis

Multiple sclerosis (MS) may be described in various terms:

- u *Relapsing-remitting*: clear relapses (or acute attacks or exacerbations) with full recovery and lasting disability. Between the attacks there is no worsening of the disease.
- u *Primary progressive*: steady progression or worsening of the disease from the onset with minor recovery or plateaus. This form is uncommon and may involve different brain and spinal cord damage than other forms.
- u *Secondary progressive*: begins as a pattern of clear-cut relapses and recovery but becomes steady progressive and worsens between acute attacks.
- u *Progressive relapsing*: steadily progressive from the onset but also has clear, acute attacks. This form is rare. In addition, differential diagnosis must rule out spinal cord compression, foramen magnum tumor (which may mimic the exacerbations and remission of MS), multiple small strokes, syphilis or another infection, thyroid disease, and chronic fatigue syndrome.

The incidence of MS is highest in women and among people in northern urban areas and higher socioeconomic groups. Incidence is low in Japan. A family history of MS increases the risk, as does living in a cold, damp climate.

Causes

The exact cause of MS is unknown but may be a slowly acting viral infection, an autoimmune response of the nervous system, or an allergic response. Other possible factors include trauma, anoxia, toxins, nutritional deficiencies, vascular lesions, and anorexia nervosa, all of which may help destroy axons and the myelin sheath.

Emotional stress, overwork, fatigue, pregnancy, or acute respiratory tract infections may precede the onset of this illness. Genetic factors may also be involved.

Complications

In MS, complications include injuries from falls, urinary tract infections, constipation, joint contractures, pressure ulcers, rectal distention, and pneumonia.

Assessment findings

Clinical findings in MS correspond to the extent and site of myelin destruction, extent of remyelination, and adequacy of subsequent restored synaptic transmission. Symptoms may be transient or may last for hours or weeks. They may vary from day to day, be unpredictable, and be difficult for the patient to describe. In most patients, visual problems and sensory impairment, such as burning, pins and needles, and tingling sensations are the first signs that something might be wrong.

The patient history commonly reveals initial visual problems and sensory impairment such as paresthesia. After the initial episode, findings may vary widely and include blurred vision or diplopia, urinary problems, emotional lability and, possibly, dysphagia.

As the patient speaks, you may notice poorly articulated speech. Neurologic examination and muscle function tests may reveal muscle weakness of the involved area and spasticity, hyperreflexia, intention tremor, gait ataxia, and paralysis, ranging from monoplegia to quadriplegia. Visual examination may reveal nystagmus, scotoma, optic neuritis, or ophthalmoplegia. (See [Describing multiple sclerosis.](#))

ASSESSMENT TIP The patient with MS may present with various signs and symptoms. Characteristic changes to look for in your assessment include:

- u ocular disturbances—optic neuritis, diplopia, ophthalmoplegia, blurred vision, and nystagmus
- u muscle dysfunction—weakness, paralysis ranging from monoplegia to quadriplegia, spasticity, hyperreflexia, intention tremor, and gait ataxia
- u urinary disturbances—incontinence, frequency, urgency, and frequent urinary infections
- u bowel disturbances—involuntary evacuation or constipation
- u fatigue—often the most disabling symptom
- u neurologic problems—poorly articulated speech, scanning speech, or dysarthria disturbances.

In addition, clinical effects may be so mild that the patient is unaware of them or so intense that they're disabling.

Diagnostic tests

This difficult diagnosis may require years of testing and observation. The following tests help diagnose MS:

EEG shows abnormalities in one-third of patients.

Cerebrospinal fluid analysis reveals elevated immunoglobulin G (IgG) levels but normal total protein levels. Elevated IgG levels are significant only when serum gamma globulin levels are normal, and they reflect hyperactivity of the immune system due to chronic demyelination. The white blood cell count may be slightly increased.

ADVANCED PRACTICE

Treating signs and symptoms of MS

Signs and symptoms of multiple sclerosis (MS) include spasticity, fatigue, bladder and bowel problems. sensory symptoms, and cognitive and motor dysfunction. Each symptom is treated with a variety of medications and supportive measures.

- u *Spasticity* occurs as a result of opposing muscle groups relaxing and contracting at the same time. Stretching and range-of-motion exercises, coupled with correct positioning, are helpful in relaxing muscles and maintaining function. Drug therapy for spasticity includes baclofen (Lioresal) and tizanidine (Zanaflex). For severe spasticity, Botox injections, intrathecal injections, nerve blocks, and surgery may be necessary.
- u *Fatigue* in multiple sclerosis (MS) is characterized by an overwhelming feeling of exhaustion that can occur at any time of the day without warning. The cause is unknown. Changes in environmental conditions, such as heat and humidity, can aggravate fatigue. Symmetrel, Cylert, and Ritalin are beneficial, as are antidepressants to manage fatigue.
- u *Bladder problems* may arise from failure to store urine, failure to empty the bladder or, more commonly, a combination of both. Treatment ranges from simple strategies such as drinking cranberry juice to the placement of an indwelling urinary catheter and suprapubic tubes. Intermittent self-catheterization programs are beneficial. In addition, anticholinergic medications may be helpful.
- u *Bowel problems*, such as constipation and involuntary evacuation of stool, can be managed by increasing fiber. Bulking agents such as Metamucil assist in relief and prevention of bowel problems. Other bowel-training strategies, such as daily suppositories and rectal stimulation, may be necessary.
- u *Sensory symptoms*, such as pain, numbness, burning, and tingling sensations, can be well managed by low-dose tricyclic antidepressants, phenytoin, or carbamazepine.
- u *Cognitive dysfunction* is experienced by 50% of patients with MS. Cognitive problems tend to be minor in nature with retrieval of information being the most frequently experienced symptom. For more severe issues, a neuropsychological consultation could be beneficial.
- u *Motor dysfunction*, such as problems with balance, strength, and muscle coordination, may present in MS. Adaptive devices and physical therapy intervention help to maintain mobility.
- u *Other symptoms* such as tremors may be treated with beta-adrenergic blockers, sedatives, or diuretics. Dysarthria requires speech therapy consultation. Vertigo may be managed with antihistamines, vision therapy, or exercises. Vision changes may require vision therapy or adaptive lenses.

Evoked potential studies demonstrate slowed conduction of nerve impulses in 80% of MS patients.

Magnetic resonance imaging is the most sensitive method of detecting MS lesions. More than 90% of patients with MS show multifocal white matter lesions when this test is performed. It's also used to evaluate disease progression. Computed tomography scanning also may disclose lesions within the brain's white matter.

Electrophoresis can be used to detect oligoclonal bands of immunoglobulin in CSF. They're present in most patients and can be found even when the percentage of gamma globulin in CSF is normal.

Other tests, such as neuropsychological tests, may help rule out other disorders.

Treatment

The goal of treatment is threefold: to treat acute exacerbations, the disease, and its related signs and symptoms.

Acute exacerbations are treated with I.V. methylprednisolone followed by oral prednisone. This is effective for speeding recovery from acute attacks. Other drugs, such as azathioprine (Imuran) or methotrexate and cytotoxin may be used.

Three drugs are used for treating the disease: Betaseron (interferon beta-1b), Avonex (interferon beta-1a), and glatiramer (Copaxone or Copolymer-1), which may reduce the frequency and severity of relapses and slow CNS damage. Copaxone is a combination of four amino acids and all the medications are immunomodulating agents, targeting the autoimmune response. They are all currently used for relapsing-remitting MS.

Associated signs and symptoms are treated with medications, supportive measures, and aggressive management to prevent deterioration. (See [Treating signs and symptoms of MS.](#))

Nursing diagnoses

- u Activity intolerance
- u Altered family processes
- u Altered nutrition: Less than body requirements
- u Altered role performance
- u Altered thought processes

PREVENTION

Avoiding exacerbations of MS

- u Educate the patient and her family about multiple sclerosis (MS). Emphasize the need to avoid stress, infections, and fatigue and to maintain independence by developing new ways of performing daily activities. Be sure to tell the patient to avoid exposure to bacterial and viral infections.
- u Emphasize the importance of exercise. Tell the patient that walking may improve gait. If her motor dysfunction causes coordination or balance problems, teach walking with a wide base of support. If the patient has trouble with position sense, tell her to watch her feet while walking. If she's still in danger of falling, a walker or a wheelchair may be required.
- u Stress the importance of taking rest periods, preferably lying down.
- u Teach the importance of eating a nutritious, well-balanced diet that contains sufficient roughage to prevent constipation.
- u Encourage adequate fluid intake and regular urination.
- u Provide bowel and bladder training if necessary. Teach the patient how to use suppositories to establish a regular bowel elimination schedule.
- u Inform the patient that exacerbations are unpredictable, necessitating physical and emotional adjustments in lifestyle.
- u Help the patient and family members establish a routine to maintain optimal functions.

- u Altered urinary elimination
- u Chronic low self-esteem
- u Constipation
- u Fatigue
- u Impaired physical mobility
- u Ineffective family coping: Disabled
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient will perform activities of daily living within confines of the disease.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain joint mobility and range of motion.
- u The patient will express feelings of increased energy and decreased fatigue.
- u The patient will develop regular bowel and bladder habits.
- u The patient and family members will use support systems and coping mechanisms.

Nursing interventions

- u Provide emotional and psychological support for the patient and the family, and answer their questions honestly. Stay with them during crisis periods. Encourage the patient by suggesting ways to help her cope with this disease.
- u Assist with physical therapy. Increase patient comfort with massages and relaxing baths. Make sure the water isn't too hot because it may temporarily intensify otherwise subtle symptoms. Assist with active, resistive, and stretching exercises to maintain muscle tone and joint mobility, decrease spasticity, improve coordination, and boost morale. Provide rest periods between exercises because fatigue may contribute to exacerbations.
- u Administer medications as ordered, and watch for adverse reactions. For instance, dantrolene may cause muscle weakness and decreased muscle tone.
- u Promote emotional stability. Help the patient establish a daily routine to maintain optimal functioning. Her tolerance level regulates her activity level. Encourage regular rest periods to prevent fatigue and daily physical exercise.
- u Keep the bedpan or urinal readily accessible because the need to void is immediate.
- u Evaluate the need for bowel and bladder training during hospitalization. Encourage adequate fluid intake and regular urination. Eventually, the patient may require urinary drainage by self-catheterization or, in men, condom catheter.
- u Nonsteroidal anti-inflammatory drugs (NSAIDs) administered with bedtime injections of Betaseron help minimize adverse effects (flulike symptoms, site reactions, and suicidal ideation). Subcutaneous site rotation is necessary. Give Betaseron injections every other day, and refrigerate the medication. Avonex reactions are similar to those of Betaseron; give I.M. injections once per week. Copaxone is administered in daily subcutaneous injections.
- u Watch for adverse reactions to drug therapy.
- u Copaxone reactions occur immediately after injection. The patient may experience transient flushing, chest pain, palpitations, and dyspnea that lasts only a few seconds. Usually no additional treatment is needed.
- u Patients receiving Betaseron or Avonex require routine laboratory monitoring (complete blood count with differential) of blood urea nitrogen, creatinine, alanine aminotransferase, and urinalysis.

Patient teaching

- u Review the disease process, emphasizing the need for optimizing the patient's potential and avoiding exacerbations as possible (See [Avoiding exacerbations of MS.](#))
- u Teach adverse effects of drug therapy and the medication regimen.
- u Emphasize the need to avoid stress, infections, and fatigue and to maintain independence by developing new ways of performing daily activities.
- u Be sure to tell the patient to avoid exposure to bacterial and viral infections.
- u Stress the importance of eating a nutritious, well-balanced diet that contains sufficient fiber to prevent constipation.
- u Encourage adequate fluid intake and regular urination.
- u Promote emotional stability. Help the patient establish a daily routine to maintain optimal functioning.
- u Inform the patient that exacerbations are unpredictable, necessitating physical and emotional adjustments in his lifestyle.
- u Refer the patient to the social service department when appropriate and to a local chapter of the National Multiple Sclerosis Society

MYASTHENIA GRAVIS

Myasthenia gravis produces sporadic but progressive weakness and abnormal fatigability of striated (skeletal) muscles. Muscle weakness is exacerbated by exercise and repeated movement but improved by anticholinesterase drugs. Usually, myasthenia gravis affects muscles innervated by the cranial nerves (face, lips, tongue, neck, and throat), but it can affect any muscle group. It commonly accompanies immune and thyroid disorders. In fact, 15% of myasthenic patients have thymomas. When the disease involves the respiratory system, it may be life-threatening.

Myasthenia gravis follows an unpredictable course of recurring exacerbations and periodic remissions. No cure is known, but drug treatment has improved the prognosis and allows patients to lead relatively normal lives except during exacerbations.

Myasthenia gravis occurs at any age, but incidence is highest in women ages 18 to 25 and in men ages 50 to 60. About three times as many women as men develop this disease.

About 20% of infants born to myasthenic mothers have transient (or occasionally persistent) myasthenia. Spontaneous remissions occur in about 25% of patients.

Causes

Myasthenia gravis is thought to be an autoimmune disorder. For an unknown reason, the patient's blood cells and thymus gland produce antibodies that block, destroy, or weaken the neuroreceptors that transmit nerve impulses, causing a failure in transmission of nerve impulses at the neuromuscular junction. (See [Impaired](#)

Complications

In myasthenia gravis, complications include respiratory distress, pneumonia, and chewing and swallowing difficulties, possibly leading to choking and food aspiration.

Assessment findings

Depending on the muscles involved and the severity of the disease, assessment findings may vary. Muscle weakness is progressive, and eventually some muscles may lose function entirely.

Expect the patient to complain of extreme muscle weakness and fatigue. The muscles most often initially involved are those innervated by the cranial nerves; thus, the patient often mentions ptosis and diplopia (the most common sign and symptom). She may also report that chewing and swallowing are difficult, her jaw hangs open (especially when she's tired), and her head bobs. She may also say that she must tilt her head back to see properly. Some patients (about 15%) report weakness of arm or hand muscles and, rarely, a patient may report leg weakness.

The patient usually notes that symptoms are milder on awakening and worsen as the day progresses and that short rest periods temporarily restore muscle function. With questioning, the patient may report that symptoms become more intense during menses and after emotional stress, prolonged exposure to sunlight or cold, or infections.

On inspection, the patient may have a sleepy, masklike expression (caused by involvement of the facial muscles) and a drooping jaw if she's tired. Inspection may also confirm ptosis. Auscultation may reveal hypoventilation if the respiratory muscles are involved.

Respiratory muscle involvement may lead to decreased tidal volume, making breathing difficult; this may predispose the patient to pneumonia and other respiratory tract infections. Progressive weakness of the diaphragm and the intercostal muscles may eventually lead to severe respiratory distress and myasthenic crisis.

PATHOPHYSIOLOGY

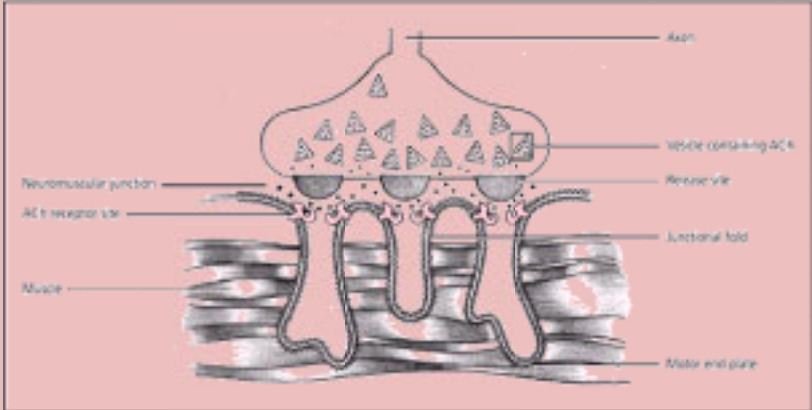

Impaired transmission in myasthenia gravis

During normal neuromuscular transmission, a motor nerve impulse travels to a motor nerve terminal, stimulating the release of a chemical neurotransmitter called acetylcholine (ACh).

When ACh diffuses across the synapse, ACh receptor sites in the motor end plate react and depolarize the muscle fiber. The depolarization spreads through the muscle fiber, causing muscle contraction.

In myasthenia gravis, antibodies attach to the ACh receptor sites. The antibodies block, destroy, and weaken these sites, leaving them insensitive to ACh, thereby blocking neuromuscular transmission.

Diagnostic tests

A positive Tensilon test confirms a diagnosis of myasthenia gravis. This test shows temporarily improved muscle function after an I.V. injection of edrophonium (or, occasionally, neostigmine). In myasthenic patients, muscle function improves within 30 to 60 seconds and lasts up to 30 minutes. Long-standing ocular muscle dysfunction often fails to respond to such testing. The Tensilon test can also differentiate a myasthenic crisis from a cholinergic crisis, which is caused by acetylcholine overactivity at the neuromuscular junction, possibly caused by anticholinesterase overdose.

Electromyography measures the electrical potential of muscle cells and helps differentiate nerve disorders from muscle disorders.

Nerve conduction studies measure the speed at which electrical impulses travel along a nerve and help distinguish nerve disorders from muscle disorders.

Chest X-rays or computed tomography scanning may identify a thymoma.

Treatment

Measures to relieve symptoms may include anticholinesterase drugs, such as neostigmine and pyridostigmines. These drugs counteract fatigue and muscle weakness and allow about 80% of normal muscle function. They become less effective as the disease worsens. Corticosteroids may also help to relieve symptoms. I.V. immune globulin is also used for acute exacerbations.

Some patients may undergo plasmapheresis if medications prove ineffective. This procedure is used to remove acetylcholine-receptor antibodies and temporarily reduce the severity of symptoms. I.V. immune globulin is also used for acute exacerbations.

Patients with thymomas require thymectomy, which leads to remission in adult-onset myasthenia in about 40% of patients if done in the first 2 years after diagnosis.

Acute exacerbations that cause severe respiratory distress (myasthenic crisis) necessitate emergency treatment. Tracheotomy, ventilation with a positive-pressure ventilator, and vigorous suctioning to remove secretions usually bring improvement in a few days. Because anticholinesterase drugs aren't effective in myasthenic crisis, they're discontinued until respiratory function begins to improve. Such a crisis requires immediate hospitalization and vigorous respiratory support.

Nursing diagnoses

- u Anxiety
- u Chronic low self-esteem
- u Fatigue
- u Impaired gas exchange
- u Impaired physical mobility
- u Ineffective airway clearance
- u Self-care deficit: Bathing or hygiene
- u Self-care deficit: Dressing or grooming
- u Self-care deficit: Feeding

Key outcomes

- u The patient will maintain a patent airway and adequate ventilation.
- u The patient will maintain a respiratory rate within ± 5 of baseline.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient will maintain range of motion and joint mobility.
- u The patient will express positive feelings about herself.

Nursing interventions

- u Provide psychological support. Listen to the patient's concerns, and answer questions honestly. Encourage the patient to participate in her own care.
- u Establish an accurate neurologic and respiratory baseline. Thereafter, regularly monitor tidal volume, vital capacity, and inspiratory force.
- u Be alert for signs of impending myasthenic crisis (increased muscle weakness, respiratory distress, difficulty talking or chewing). The patient may need a ventilator and frequent suctioning to remove accumulating secretions.
- u Administer medications at evenly spaced intervals, and give them on time, as ordered, to prevent relapses. Be prepared to give atropine for anticholinesterase overdose or toxicity.
- u Plan exercise, meals, patient care, and activities to make the most of energy peaks. For example, administer the patient's medication 20 to 30 minutes before meals to facilitate chewing or swallowing.
- u When swallowing is difficult, give soft, semisolid foods (applesauce, mashed potatoes) instead of liquids to lessen the risk of choking.
- u After a severe exacerbation, try to increase social activity as soon as possible.
- u If surgery is scheduled, prepare the patient according to facility policy.

Patient teaching

- u Help the patient plan daily activities to coincide with energy peaks.
- u Stress the need for frequent rest periods throughout the day. Emphasize that periodic remissions, exacerbations, and day-to-day fluctuations are common.
- u Teach the patient how to recognize adverse effects and signs and symptoms of toxicity of anticholinesterase drugs (headaches, weakness, sweating, abdominal cramps, nausea, vomiting, diarrhea, excessive salivation, and bronchospasm) and corticosteroids (decreased or blurred vision; increased thirst; frequent urination; rectal bleeding, burning, or itching; restlessness; depression).
- u Warn the patient to avoid strenuous exercise, stress, infection, and needless exposure to the sun or cold weather. All of these things may worsen signs and symptoms. Wearing an eye patch or glasses with one frosted lens may help the patient with diplopia.
- u Teach the patient with swallowing difficulties to eat semisolid foods and to avoid alcohol because it increases weakness. Tell her that eating warm (not hot) foods can help ease swallowing.
- u If surgery is scheduled, provide preoperative teaching. Explain to the patient that before surgery, her chest will be cleaned and she'll receive a general anesthetic. Tell her that depending on where the surgeon makes the incision, she may awaken from surgery with a chest tube or a drain in place. Also tell her that she may require intubation and mechanical ventilation after surgery and that she'll have antimuscarinic drugs administered I.V. or I.M. until she's well enough to take them orally. Explain that these medications are progressively withdrawn so that the doctor can assess muscle strength after surgery.
- u For information and an opportunity to meet patients with myasthenia gravis who lead productive lives, refer the patient to the Myasthenia Gravis Foundation.

Peripheral nerve disorders

Peripheral nerve disorders include Bell's palsy and trigeminal neuralgia.

BELL'S PALSY

In Bell's palsy, impulses from the seventh cranial nerve—the nerve responsible for motor innervation of the facial muscles—are blocked. The conduction block results from an inflammatory reaction around the nerve (usually at the internal auditory meatus) and produces unilateral facial weakness or paralysis.

Although Bell's palsy affects all age-groups, it occurs most often in people ages 20 to 60. Onset is rapid. In 80% to 90% of patients, the disorder subsides spontaneously, with complete recovery in 1 to 8 weeks. Recovery may be delayed in elderly people. If recovery is partial, contractures may develop on the paralyzed side of the face. The disorder may recur on the same or the opposite side of the face.

Causes

Bell's palsy results from an unknown cause, possibly ischemia, viral disease such as herpes simplex or herpes zoster, local traumatic injury, or autoimmune disease.

Complications

Potential complications of Bell's palsy include corneal ulceration and blindness because of the eye's not closing; impaired nutrition secondary to paralysis of the lower face; and long-term psychosocial problems because of the patient's altered body image.

Assessment findings

The patient history may reveal that pain occurred on the affected side around the angle of the jaw or behind the ear for a few hours or days before the onset of weakness. The patient may also report difficulty eating on the affected side because of relaxation of the facial muscle. When you speak with the patient, you may notice that he has difficulty speaking clearly, which also may result from facial muscle relaxation.

On inspection, you may find that the mouth droops (causing the patient to drool saliva from the corner of his mouth) on the affected side and the forehead appears smooth.

Neurologic assessment may reveal that taste perception is distorted over the affected anterior portion of the tongue and that the patient is unable to raise his eyebrow, smile, show his teeth, or puff out his cheek. In addition, the patient's ability to close his eye on the weak side is markedly impaired. With any attempt to close the eye, the eye rolls upward (Bell's phenomenon) and shows excessive tearing. Although Bell's phenomenon occurs in normal people, in Bell's palsy incomplete eye closure makes this upward motion obvious. (See [Facial paralysis in Bell's palsy.](#))

Diagnostic tests

Diagnosis is based on clinical presentation. After 10 days, electromyography helps predict the level of expected recovery by distinguishing temporary conduction defects from a pathologic interruption of nerve fibers.

Treatment

Appropriate treatment consists of prednisone, an oral corticosteroid that reduces facial nerve edema and improves nerve conduction and blood flow. Prednisone treatment is especially helpful when begun in the 1st week after the disorder's onset. After the 14th day of prednisone therapy, electrotherapy may help prevent facial muscle atrophy.

Analgesics are used to control facial pain and discomfort. Heat may also be applied to the affected side to provide comfort.

If the patient fails to recover from facial paralysis, surgery that involves exploration of the facial nerve may be necessary.

Nursing diagnoses

u Altered family processes u Altered nutrition: Less than body requirements u Altered role performance u Anxiety u Body image disturbance u Chronic low self-esteem u Knowledge deficit u Pain

Key outcomes

- u The patient will experience increased comfort and relief of pain.
- u The patient will consume adequate daily calories as required.
- u The patient will state positive feelings about himself.
- u The patient will verbalize an understanding of the condition and treatment regimen.

Nursing interventions

- u Provide psychological support to the patient. Reassure him that he hasn't had a stroke. Tell him that spontaneous recovery usually occurs within 8 weeks. This should help decrease his anxiety and help him adjust to the temporary change in his body image.
- u During treatment with prednisone, watch for steroid adverse reactions, especially GI distress and fluid retention. If GI distress is troublesome, an antacid given concomitantly usually provides relief. If the patient has diabetes, prednisone must be used with caution and necessitates frequent monitoring of serum glucose levels.
- u To reduce pain, apply moist heat to the affected side of the face as ordered. Be careful to avoid burning the patient's skin.
- u To help maintain muscle tone, massage the patient's face with a gentle upward motion two to three times daily for 5 to 10 minutes, or have him massage his face himself.
- u Apply a facial sling, if necessary, to improve lip alignment. Give the patient frequent and complete mouth care, taking special care to remove residual food that collects between the cheeks and gums.
- u Provide a soft, nutritionally balanced diet, eliminating hot foods and fluids. Arrange for privacy at mealtimes to reduce embarrassment.
- u If surgery is necessary, provide the patient with complete preoperative and postoperative care.

Patient teaching

- u Teach the patient about Bell's palsy, its signs and symptoms, and its treatments.
- u Advise the patient to protect his affected eye by covering it with an eye patch, especially when outdoors. Tell him to keep warm and avoid exposure to dust and wind. When exposure is unavoidable, instruct him to cover his face.
- u When the patient is ready for active exercises, teach him to exercise the facial muscles by grimacing in front of a mirror.
- u Prevent excessive weight loss and help the patient cope with difficulty in eating and drinking. Instruct him to chew on the unaffected side of his mouth and to eat semisolid foods.

Facial paralysis in Bell's palsy

Unilateral facial paralysis typifies Bell's palsy. The paralysis produces a distorted appearance and an inability to wrinkle the forehead, close the eyelid, smile, show the teeth, or puff out the cheek.

SMILING

TRIGEMINAL NEURALGIA

Trigeminal neuralgia—also known as tic douloureux—is a painful disorder of one or more branches of the fifth cranial (trigeminal) nerve. This nerve affects chewing movements and sensations of the face, scalp, and teeth. On stimulation of a trigger zone, the patient experiences paroxysmal attacks of excruciating facial pain, probably produced by an interaction or short-circuiting of touch and pain fibers.

The disease occurs mostly in people over age 40 (about 25% more women than men) and on the right side of the face more often than the left. Trigeminal neuralgia can subside spontaneously, with remissions lasting from several months to years.

Causes

Although the cause remains unknown, trigeminal neuralgia may reflect an afferent reflex phenomenon located centrally in the brain stem or more peripherally in the sensory root of the trigeminal nerve. Such neuralgia may also be related to compression of the nerve root by posterior fossa tumors, middle fossa tumors, or vascular lesions, although such lesions usually produce simultaneous loss of sensation. Occasionally, trigeminal neuralgia results from multiple sclerosis or herpes zoster.

Complications

In this disorder, pain may be so severe and incapacitating that the patient fails to care for himself properly. This leads to complications, such as excessive weight loss, depression, and social isolation.

Assessment findings

Typically, the patient reports a searing or burning pain that occurs in lightning-like jabs and lasts from 1 to 15 minutes (usually 1 to 2 minutes). The pain is localized in an area innervated by a division of the trigeminal nerve and initiated by a light touch to a hypersensitive area, such as the tip of the nose, the cheeks, or the gums. The patient may also report that although attacks can occur at any time, they may follow a draft of air, exposure to heat or cold, eating, smiling, talking, or drinking hot or cold beverages.

Between attacks, most patients report that they are free of pain, although some may complain of a constant, dull ache. Keep in mind that all patients fear the next

attack and that the frequency of attacks varies greatly, from many times a day to several times a month or year.

On inspection, you may observe the patient favoring (splinting) the affected area. If he has a painful attack during the assessment, you may notice that to ward off the attack, he may hold his face immobile when talking. He may also leave the affected side of his face unwashed and unshaven or protect it with a coat collar. When asked where the pain occurs, he points to—but never touches—the affected area. Witnessing a typical attack helps to confirm the diagnosis.

Neurologic assessment shows no impairment of sensory or motor function. If sensory impairment is found, a space-occupying lesion may be the cause.

Diagnostic tests

Skull X-rays, computed tomography scanning, and magnetic resonance imaging are performed to rule out sinus or tooth infections and tumors. If the patient has trigeminal neuralgia, these test results are normal.

Treatment

Oral administration of carbamazepine or phenytoin may temporarily relieve or prevent pain because they reduce the transmission of nerve impulses at affected nerve terminals. Narcotics may be helpful during the acute pain episode.

Before surgery is performed, nonsurgical treatment—injecting small amounts of glycerol into the subarachnoid space – may be tried. If this treatment fails, the procedure of choice is percutaneous electrocoagulation of nerve rootlets under local anesthesia. An alternative is a percutaneous radio frequency procedure, which causes partial root destruction and relieves pain. One to three treatments are usually necessary. The procedure causes partial numbness of the face.

Microsurgery for vascular decompression of the trigeminal nerve involves an intracranial approach. This major procedure requires postoperative management similar to that for craniotomy. Its advantage is that it preserves normal sensation in the face.

Radiosurgery is another option in which a stereotactic technique is used. The nerve root is localized, and focused high-dose radiation is delivered. It's done as an outpatient technique and is a knifeless surgery. The focused radiation allows for interruption of the nerve without damage to the surrounding tissue.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered role performance u Anxiety u Fatigue u Ineffective individual coping u Knowledge deficit u Pain

Key outcomes

- u The patient will experience increased comfort and relief of pain.
- u The patient will perform activities of daily living within the confines of the disorder.
- u The patient will consume adequate daily calories as required.
- u The patient will express feelings of energy and decreased fatigue.
- u The patient will perform routine roles within the confines of the disorder.

Nursing interventions

- u Provide emotional support, and encourage the patient to express his concerns. Promote independence through self-care and maximum physical activity. Encourage the patient to stay as active as possible, and explain that this will improve his sense of well-being and help him cope with the pain.
- u Observe and record the characteristics of each attack, including the patient's protective mechanisms.
- u Provide small, frequent meals at room temperature to maintain adequate nutrition.
- u Recognize which factors may precipitate an attack, and urge the patient to avoid stimulation (air, heat, cold) of trigger zones (lips, cheeks, gums).
- u If the patient is receiving carbamazepine, watch for cutaneous and hematologic reactions (such as erythematous and pruritic rashes, urticaria, photosensitivity, exfoliative dermatitis, leukopenia, agranulocytosis, eosinophilia, aplastic anemia, thrombocytopenia) and, possibly, urine retention and transient drowsiness. Complete blood count and liver function tests should be monitored weekly for the first 3 months of carbamazepine therapy and then monthly.
- u If the patient is receiving phenytoin, watch for adverse reactions, including ataxia, skin eruptions, gingival hyperplasia, and nystagmus.
- u After any neurosurgical procedure, check neurologic and vital signs frequently.
- u After trigeminal microsurgery, if the patient elects to have this procedure, provide all care required for the patient who has had a craniotomy. This includes fluid, respiratory, pain, and neurologic management.

Patient teaching

- u Teach the patient about trigeminal neuralgia, the procedures ordered, and the treatments he's chosen. Be sure the patient knows the complications that may occur. Reinforce the doctor's explanations as necessary.
- u Warn the patient to immediately report fever, sore throat, mouth ulcers, easy bruising, or petechial or purpuric hemorrhage because these may signal thrombocytopenia or aplastic anemia and may require discontinuation of drug therapy.
- u If the patient is losing weight because of poor appetite due to the pain, help him select foods that are high in calories and nutrients so that he can get more nourishment with less chewing. Suggest that he eat many frequent, small meals instead of three large ones. To minimize jaw movements when eating, suggest that he puree foods and eat soft or liquid foods, such as soups, custards, and stews.
- u Teach the patient about prescribed medications. Be sure that he understands the desired and adverse effects to watch for and that he knows when to notify the doctor if adverse reactions occur.
- u Teach the patient how to ward off neuralgia attacks. For example, tell the patient to protect his trigger zones from such stimuli as wind and temperature changes by wearing a scarf or turning up his coat collar. If brushing the teeth is painful, suggest trying a water-powered dental device because this reduces jaw movement.
- u If the patient is to undergo craniotomy, provide extensive preoperative teaching so that he fully understands the procedure and the postoperative treatment. Counsel the patient to review his options with the doctor carefully and to ask about potential complications, such as facial numbness and paralysis.

INTRODUCTION

The musculoskeletal system is a complex of muscles, tendons, ligaments, bones, and other connective tissue that gives the body form and shape. It also protects vital organs, allows movement, stores calcium and other minerals, and provides the site for hematopoiesis.

Muscles

The body contains three major muscle types: skeletal (voluntary, striated), visceral (involuntary, smooth), and cardiac. This chapter focuses on skeletal muscle, which is attached to bone. Viewed through a microscope, skeletal muscle appears as long bands or striations. (See [Anatomy of a muscle.](#))

Skeletal muscle functions voluntarily; its contraction can be controlled at will. Muscle develops when musculoskeletal fibers hypertrophy. Exercise, nutrition, sex, and genetics account for muscle strength and size in individuals.

Tendons

Tendons are bands of fibrous connective tissue that attach muscle to the periosteum, which is the fibrous membrane covering the bone. Tendons enable bones to move when skeletal muscles contract.

Ligaments

Ligaments are dense, strong, flexible bands of fibrous connective tissue that attach one bone to another. The ligaments of concern in a musculoskeletal assessment are those that connect the joint ends (articular ends) of the bones. These ligaments either limit or facilitate movement and provide structural stability.

Bones

The human skeleton contains 206 bones consisting of inorganic minerals and salts, such as calcium and phosphate, embedded in a framework of collagen fibers. Bones are classified by shape and location. A bone may be long (such as the humerus, radius, femur, and tibia), short (such as the carpals and tarsals), flat (such as the scapula, ribs, and skull), irregular (such as the vertebrae and mandible), or sesamoid (such as the patella).

Bones of the *axial skeleton* (the head and trunk) include the facial and cranial bones, hyoid bone, vertebrae, ribs, and sternum. Bones of the *appendicular skeleton* (the extremities) include the clavicle, scapula, humerus, radius, ulna, metacarpals, pelvic bone, femur, patella, fibula, tibia, and metatarsals. (See [Anatomy of a bone.](#))

Bone function

Bones perform an anatomic (or mechanical) and a physiologic function. They protect internal tissues and organs (for example, 33 vertebrae surround and protect the spinal cord); they stabilize and support the body; and they provide a surface for muscle, ligament, and tendon attachments (which facilitates “levered action” when the muscles contract). They also produce red blood cells in the marrow (hematopoiesis), and they store minerals (about 99% of the body's calcium).

Bone formation

A 3-month-old fetus has a beginning skeletal structure composed entirely of cartilage. By fetal age 6 months, much of the cartilage is bony skeleton. Some bones harden (ossify) only after birth, particularly the carpals and tarsals. The change results from endochondral ossification, a process by which bone-forming cells (osteoblasts) produce a collagenous material (osteoid) that hardens (ossifies).

Two types of bone cells (or osteocytes)—osteoblasts and osteoclasts—are involved in a continuous process known as remodeling, whereby bone is created and destroyed. *Osteoblasts* deposit new bone, and *osteoclasts* increase long-bone diameter by resorbing previously deposited bone. These processes promote longitudinal bone growth, which continues until the epiphyseal growth plates at the ends of bones close during adolescence.

Researchers are studying the function of the endocrine system in bone formation. The hormone estrogen plays a significant role in regulating calcium uptake and release and in regulating osteoblastic activity. Researchers think that decreased estrogen levels may lead to diminished osteoblastic activity.

CULTURAL TIP A patient's age, race, and sex affect bone mass, structural integrity (ability to withstand stress), and bone loss. For example, blacks commonly have denser bones than whites, and men typically have denser bones than women. Bone density and structural integrity decrease after age 30 in women and after age 45

in men. Thereafter, the bone matrix undergoes a relatively steady loss.

Cartilage

Cartilage is a dense connective tissue that consists of fibers embedded in a strong, gel-like substance. Cartilage is avascular and lacks innervation.

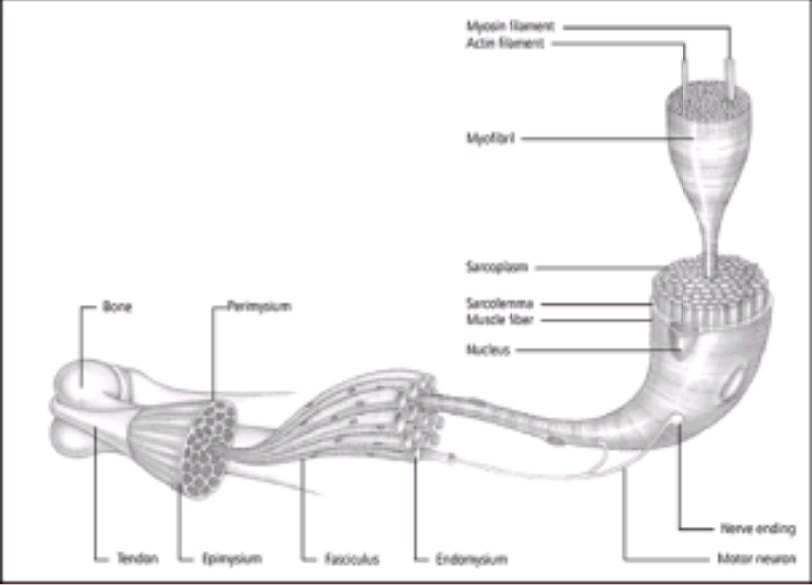

Cartilage may be fibrous, hyaline, or elastic. *Fibrous cartilage* forms the symphysis pubis and the intervertebral disks. *Hyaline cartilage* covers the articular bone surfaces (where one or more bones meet at a joint); connects the ribs to the sternum; and appears in the trachea, bronchi, and nasal septum. Elastic cartilage is located in the auditory canal, external ear, and epiglottis.

Anatomy of a muscle

The human body has about 600 skeletal muscles, each classified by the kind of movement for which it's responsible. For example, flexors facilitate flexion; adductors, adduction; circumductors, circumduction; and external rotators, rotation.

Each muscle contains cell groups called muscle fibers that extend the length of the muscle. The perimysium—a sheath of connective tissue—binds the fibers into a bundle, or fasciculus. A stronger sheath, the epimysium, binds fasciculi together to form the fleshy part of the muscle. The epimysium becomes a tendon that extends from the muscle.

A plasma membrane—the sarcolemma—surrounds each muscle fiber. Within the sarcoplasm (cytoplasm) of the muscle fiber lie tiny myofibrils, which run lengthwise. Each myofibril contains still finer filament-like fibers—about 1,500 myosin (thick) and about 3,000 actin (thin) fibers.

The diagram illustrates the structure of a muscle and its components. On the left, a bone is connected to a muscle by a tendon. The muscle is shown as a bundle of fasciculi, which are bundles of muscle fibers. The muscle is surrounded by the epimysium, and each fasciculus is surrounded by the perimysium. A single muscle fiber is shown in cross-section, revealing the sarcolemma (plasma membrane), the sarcoplasm (cytoplasm), and the nucleus. A myofibril is shown within the sarcoplasm, composed of myosin filaments (thick) and actin filaments (thin). A motor neuron is shown innervating the muscle fiber at a nerve ending.

Cartilage supports and shapes various structures, such as the auditory canal and the intervertebral disks. It also cushions and absorbs shock, preventing direct transmission to the bone.

Joints

The junction of two or more bones is a joint. The major human joints are classified by the extent of their movement. *Synarthrodial joints* such as cranial sutures permit no movement. In this joint type, a thin layer of fibrous connective tissue separates the bones. *Amphiarthrodial joints* such as the symphysis pubis allow slight movement. A hyaline cartilage separates the bones in this kind of joint. *Diarthrodial joints*, such as the ankle, wrist, knee, hip, and shoulder, permit free movement.

Separating the bones that form a diarthrodial joint is a cavity lined by a synovial membrane that secretes a viscous lubricating substance called synovial fluid. The membrane is encased in a fibrous joint capsule. This capsule—along with ligaments, tendons, and muscles—helps to stabilize the joint.

Anatomy of a bone

The human skeleton contains 206 bones: 80 in the axial skeleton and 126 in the appendicular skeleton.

Bone consists of layers of calcified matrix with spaces occupied by osteocytes (bone cells). Bone layers (lamellae) are arranged concentrically around central canals (haversian canals). Small cavities (lacunae) lying between the lamellae contain osteocytes. Tiny canals (canaliculi) connect the lacunae. They form the structural units of bone and provide nutrients to bone tissue.

A typical long bone has a diaphysis (main shaft) and an epiphysis (end). The epiphyses are separated from the diaphysis by cartilage at the epiphyseal line. Beneath the epiphyseal articular surface lies the articular cartilage, which cushions the joint.

Internal characteristics

Each bone consists of an outer layer of dense, compact bone containing haversian systems (osteons) and an inner layer of spongy (cancellous) bone consisting of thin plates, called trabeculae, that interlace to form a latticework. Red marrow fills the spaces between the trabeculae of some bones. Cancellous bone doesn't contain haversian systems.

Compact bone is located in the diaphyses of long bones and the outer layers of short, flat, and irregular bones. Cancellous bone fills central regions of the epiphyses and the inner portions of short, flat, and irregular bones. Periosteum—specialized fibrous connective tissue—consists of an outer fibrous layer and an inner, bone-forming layer. Endosteum (tissue) lines the medullary cavity (inner surface of bone), which contains the marrow.

Blood reaches bone by way of arterioles in haversian canals; vessels in Volkmann's canals, which enter bone matrix from the periosteum; and vessels in the bone ends and marrow. A child's periosteum is thicker than an adult's and has an increased blood supply to assist new bone formation around the shaft (diaphysis).

INTERNAL VIEW OF A LONG BONE

Shape and motion are other criteria used to further classify joints. For example, there are ball-and-socket joints, hinge joints, and pivot joints.

Bursae

Bursae—located at friction points and around joints between tendons, ligaments, and bones—are small synovial fluid sacs that act as cushions, decreasing stress on adjacent structures. Examples of bursae include the shoulder's subacromial bursa and the knee's prepatellar bursa.

Skeletal movement

Although skeletal movement results primarily from muscle contractions, other musculoskeletal structures play a role. To contract, a skeletal muscle (richly supplied with blood vessels and nerves) needs an impulse from the nervous system, and oxygen and nutrients from the circulatory system.

A skeletal muscle contraction applies force to the tendon. The force pulls the bone toward, away from, or around a second bone, depending on the type of muscle contracted. Usually, one bone moves less than the other. The muscle-tendon attachment to the more stationary bone is called the *origin*. The muscle-tendon attachment to the more movable bone is called the *insertion site*. The origin usually lies on the proximal end of the bone; the insertion site, on the distal end.

In skeletal movement, the bones act as levers, and the joints act as fulcrums, or fixed points. Each bone's function is partially determined by the location of the fulcrum, which establishes the relationship between resistance (a force to be overcome) and effort (a force to be resisted). Most movement calls for muscle groups rather than one muscle. (See [Basic joint movements](#).)

Musculoskeletal assessment

Musculoskeletal disorders typically affect patients facing prolonged immobilization, elderly patients, patients with concurrent medical conditions, or victims of traumatic injury. For these patients, you need to obtain a complete history and perform a careful physical examination.

Patient history

Compile a full medical, social, family, and personal history. Ask about general daily activity, occupation, diet, sexual activity, and elimination habits, and try to assess how the patient's disorder may alter his body image. Find out how he functions at home. Can he perform daily activities? Does he have trouble getting around? Does he need assistive devices? Can family members help with his care?

Obtain an accurate account of the musculoskeletal problem. When did symptoms begin, and how have they progressed? Was the patient or a family member previously treated for the same problem?

Assess the location, duration, and intensity of pain. Evaluate past and current responses to treatment. For instance, if the patient takes anti-inflammatory agents or other medications for arthritis, ask about their effectiveness. Does he require more or less medication than before? Has he tried other forms of treatment? In addition, ask the patient if muscle weakness, fatigue, or tissue or joint swelling accompanies the current musculoskeletal problem.

Physical examination

Data collected during the physical examination are used to establish a diagnosis and form a basis for planning and evaluating treatment. Perform a head-to-toe assessment, simultaneously evaluating muscle and joint function of each body area. Observe the patient's gait and coordination. Inspect and palpate his muscles, joints, and bones.

Evaluate the patient's posture—the attitude or position that his body parts assume in relation to one another and to the external environment. Inspect spinal curvature and knee positioning. Inspect the patient's overall body symmetry as he assumes different positions and makes various movements. Note marked discrepancies in bilateral size, shape, and motion.

Perform inspection and palpation simultaneously during the musculoskeletal assessment. Evaluate the patient's muscle tone, mass, and strength. Take care to palpate the muscles gently. Never force movement when the patient reports pain or appears injured. Look carefully for localized edema, a change in pigmentation, reddening of pressure points, point tenderness, and deformities.

Check mobility and gait. To evaluate range of motion (ROM), ask the patient to abduct, adduct, and flex affected muscles. Palpate arterial pulses for symmetry and arterial blood return to fingertips and toes. Press momentarily on the toenails of both feet and compare the time needed for normal color to return. Palpate for fine crepitus over joints.

Check the patient's neurovascular status, including motion sensation and circulation. Measure and record discrepancies in muscle circumference or length.

Diagnostic tests

- u X-rays are probably the most useful diagnostic tools for evaluating structural or functional changes in musculoskeletal diseases.
- u *Myelography*, an invasive procedure, may be used to evaluate abnormalities of the spinal canal and cord. The study entails injecting a radiopaque contrast medium into the subarachnoid space of the spine. Then, serial X-rays show how the contrast medium moves through the subarachnoid space. Displacement of the contrast medium indicates a space-occupying lesion.
- u *Arthrography* also involves injecting contrast medium to show the shape and integrity of a joint capsule.

Basic joint movements

Diarthrodial joints permit 13 angular and circular motions. (All are evaluated in a musculoskeletal assessment.) The shoulder demonstrates circumduction; the elbow, flexion and extension; the arm, abduction and adduction; the jaw, retraction and protraction; the hand, pronation and supination; the hip, internal and external rotation; and the foot, eversion and inversion

EXTERNAL ROTATION
Turning away from midline

INVERSION
Turning inward

Kinds of traction

Your patient may need traction—the manual or mechanical application of a steady pulling force—to reduce a fracture, minimize muscle spasms, immobilize a bone, or align a joint. The kind of traction he has—skin, skeletal, or manual—depends on his musculoskeletal disorder.

Skin traction

Skin traction involves indirect application of a pulling force to the skeletal system through skin and soft tissues. A common example is Buck's traction, which uses pulleys and weights to improve body alignment.

Skeletal traction

The direct application of traction to bones is known as skeletal traction. It may be accomplished by traversing the affected bone with a pin (Steinmann pin) or wire (Kirschner wire) or by gripping the bone with calipers or a tonglike device (Gardner-Wells tongs or halo vest). This kind of traction can immobilize healing bones such as the vertebrae.

Manual traction

Used in an emergency, manual traction is the direct application of pulling force to a body part by hand. It may be used, for instance, to realign a broken bone after an accident.

- u *Arthroscopy* is the visual examination of the interior of a joint with a fiber-optic endoscope.
- u *Bone scan*, involving injected radioisotopes, is used to identify areas of increased bone activity or active bone formation.
- u *Magnetic resonance imaging (MRI)* produces images of soft tissues. An MRI can reveal lesions of the spinal cord and white matter.
- u *Computed tomography scanning* can be used to detect herniated disks, spinal stenosis, and tumors by showing variations in tissue density.

Other useful tests include bone and muscle biopsies, electromyography, microscopic examination of synovial fluid, and laboratory analyses of urine and blood to identify systemic abnormalities.

Treatment and nursing care

Depending on the patient's disorder, therapy and care measures usually involve relieving pain and managing at least one of the following: traction, casts, braces, splints, crutches, or intermittent range-of-motion (ROM) devices. Of equal importance is nursing care to prevent complications of immobility.

Controlling pain

Analgesics, including patient-controlled analgesia delivery devices, can relieve pain and promote mobility. Analgesics delivered by an epidural catheter are gaining popularity for postoperative pain management. Preservative-free morphine administered epidurally can relieve pain for up to 12 hours.

Other measures include transcutaneous electrical nerve stimulation units. These external devices provide dermal stimulation of nerve pathways to manage acute or chronic pain. Relaxation achieved by progressive muscle relaxation, deep breathing, biofeedback, and dissociative visualization techniques may also be helpful.

CULTURAL TIP Ask if there is any particular method of relaxation or pain relief that might reduce your patient's discomfort. For example, many Asian cultures have alternative methods of pain control, which the patient may practice.

Coping with traction casts, and other devices

- u If the patient must use *traction devices*, explain how traction works. (See [Kinds of traction.](#)) Define his activity limits, and estimate how long he is to be in traction. Also discuss whether he can remove the traction devices and when, and teach active ROM exercises.
- u Make sure that the patient has a firm mattress, that the traction ropes remain whole and unfrayed and stay on the center track of the pulley, and that the traction weights hang freely.
- u Check the patient's neurovascular status to prevent nerve damage.
- u Thoroughly investigate any patient complaints.
- u Check for signs of infection (odor, local inflammation, drainage, and fever) at pin sites if the patient is in skeletal traction. Also check facility policy regarding pin site care measures, such as cleaning and protection.
- u If the patient must have a cast, remember that it provides immobility without adding too much weight. A good cast fits snugly, not constrictively. It has a smooth inner surface and smooth edges to prevent pressure or skin irritation. Check skin integrity frequently.
- u Forewarn the patient that a wet cast takes 24 to 48 hours to dry. To prevent indentations, caution him not to squeeze the cast with his fingers, not to cover or walk on the cast until it dries, and not to bump a damp cast on a hard surface because dents in the cast can exert pressure on underlying areas. Warn the patient that he may feel a transient sensation of heat under the cast as it's applied and dries.
- u If a fiberglass cast is used, the cast may feel dry and the patient may be able to bear weight immediately. Advise the patient not to get the cast wet. A fiberglass cast doesn't disintegrate as plaster does, but if the padding gets wet it could macerate the skin.
- u If the patient needs a cast on any part of the arm or leg, emphasize that he must keep that body part above heart level for 24 hours after cast application. This helps to minimize swelling in the extremity.

ALERT Until the cast dries completely, have the patient watch for and immediately report persistent pain in the casted body part or in an area distal to the cast. Other danger signs and symptoms include edema, changes in skin color, coldness, and tingling or numbness in the area. If any of these complications occurs, tell the patient to keep the casted body part above heart level and notify the doctor.

- u If the patient doesn't stay in the facility after the cast is applied, instruct him to report any drainage through the cast or any odor that may indicate infection. Warn against inserting foreign objects under the cast, getting it wet, pulling out its padding, or scratching inside it. Suggest that he blow air from a hair dryer (cool setting) into the cast to relieve itching. Tell him to seek immediate attention for a broken cast.
- u Instruct the patient to exercise the joints above and below the cast to prevent stiffness and contractures.
- u If the patient needs a brace, splint, or sling, explain that these devices provide alignment, immobilization, and pain relief for musculoskeletal disorders. Splints and slings are typically used for short-term immobilization.
- u As needed, show the patient and family members how to apply a brace, splint, or sling for optimal benefit. Teach how to walk with crutches, if needed.

u Inform the patient how long he needs to use the device and list activity limitations. If the patient has a brace, check with his orthotist about proper care.

Coping with immobility

An immobilized patient requires meticulous care to prevent complications. Without constant care, a bedridden patient is more susceptible to skin breakdown caused by increased pressure on tissues over bony prominences. He's especially vulnerable to cardiopulmonary complications.

- u To prevent pressure ulcers, turn the patient regularly, and massage areas over bony prominences. Place a flotation pad, a sheepskin pad, an alternating-air-current mattress, or a convoluted foam mattress under bony prominences. Be sure to show the patient how to use a Balkan frame with a trapeze to move about in bed.
- u Increase fluid intake to minimize the risk of renal calculi.
- u Perform passive ROM exercises on the patient's affected side as ordered to prevent contractures. Teach the patient how to perform active ROM exercises on the unaffected side. Apply footboards or high-topped sneakers to prevent footdrop.
- u Because most bedridden patients involuntarily perform Valsalva's maneuver when using the upper arms and trunk to move, instruct the patient to exhale instead of holding his breath as he turns. This prevents possible cardiac complications from increased intrathoracic pressure.
- u Emphasize the importance of coughing and deep breathing. Teach the patient to use an incentive spirometer, if ordered.
- u Because constipation commonly occurs in bedridden patients, establish a bowel elimination program (fluids, fiber, laxatives, stool softeners) as needed. Monitor the effectiveness of the bowel regimen, and document bowel movements.
- u Provide a diet high in protein, carbohydrates, and vitamins to enhance healing.

Rehabilitation

Restoring the patient's former good health isn't always possible. If this is the case with your patient, help him adjust to a modified lifestyle. During hospitalization, promote independence by letting him perform as many tasks as he can by himself. If necessary, refer him to a community facility for continued rehabilitation.

Congenital disorders

Arising before or at birth, congenital disorders of the musculoskeletal system include clubfoot, developmental dysplasia of the hip, muscular dystrophy, and osteogenesis imperfecta.

CLUBFOOT

Clubfoot—also known as talipes—is the most common congenital disorder of the lower extremities. The affected patient has a deformed talus and shortened Achilles tendon, which give the foot a characteristic clublike appearance.

Clubfoot is classified according to the orientation of the deformed foot. In talipes equinovarus, the foot points downward (equinus) and inward (varus) and the front of the foot curls toward the heel (forefoot adduction). (See [Recognizing clubfoot.](#))

Recognizing clubfoot

Clubfoot is given a specific name depending on the orientation of the deformity, as shown in the illustrations below.

TALIPES EQUINUS

TALIPES CALCANEUS

TALIPES CAVUS

TALIPES VARUS

TALIPES EQUINOVARUS

TALIPES CALCANEOVARUS

TALIPES VALGUS

TALIPES CALCANEO-VALGUS

TALIPES EQUINO-VALGUS

The deformity usually is obvious at birth, allowing an early diagnosis, but clubfoot that causes only subtle deformity must be distinguished from apparent clubfoot such as metatarsus varus (pigeon toe). Such apparent clubfoot results when a fetus maintains a position in utero that gives his feet the appearance of clubfoot; unlike true clubfoot, it can usually be corrected without surgery. Inversion of the feet, another type of apparent clubfoot, may result from the peroneal type of progressive muscular atrophy or dystrophy.

Clubfoot typically affects both feet. It may be associated with other birth defects, such as myelomeningocele, spina bifida, or arthrogryposis. The deformity occurs in about 1 in every 1,000 live births and is twice as common in boys as in girls. Treated promptly, it can be corrected.

Causes

Clubfoot appears to result from a combination of genetic factors and environmental conditions that arise in utero. The mechanism of genetic transmission is unknown, but researchers are convinced that such a mechanism exists. The sibling of a child born with clubfoot has a 1 in 35 chance of being affected. The child of a parent with clubfoot has a 1 in 10 chance of inheriting the disorder.

Among children who have no family history of clubfoot, the anomaly may be linked to arrested development during the 10th to 12th week of gestation, when the feet form. Researchers also suspect muscle abnormalities, which lead to variations in tendon length and insertion points, as possible causes.

Clubfoot may arise in older children secondary to paralysis, poliomyelitis, or cerebral palsy. In these instances, treatment for clubfoot must be accompanied by treatment of the underlying disorder.

Complications

The feet may retain some deformity despite treatment.

Assessment findings

The patient may have a family history of clubfoot. Older patients may have a history of a related primary disorder, such as poliomyelitis or cerebral palsy.

Inspection usually reveals the deformity, which may vary greatly in severity. It may be only mildly apparent, or it may be so severe that the neonate's toes touch the inside of the ankle. In all patients, the talus is deformed, the Achilles tendon shortened, and the calcaneus somewhat shortened and flattened. Depending on the degree of varus deformity, the calf muscles are shortened and underdeveloped, with soft-tissue contractures at the site of the deformity.

In the patient with true clubfoot, the foot is tight in its deformed position and resists efforts to push it back into position. In a normal neonate, the dorsum of the foot can be made to touch the outer side of the shin. Clubfoot is painless except in older, arthritic patients.

Diagnostic tests

X-rays show the talus superimposed on the calcaneus. The metatarsals have a ladderlike appearance.

Treatment

Correction of clubfoot requires three stages: correcting the deformity, maintaining the correction until the foot regains normal muscle balance, and observing the foot closely for several years to prevent the deformity from recurring.

In neonates, corrective treatment begins immediately. An infant's foot contains large amounts of cartilage, and the muscles, ligaments, and tendons are supple. The ideal time to begin treatment is in the first few weeks after birth when the foot is most malleable. Deformities are usually corrected sequentially: first forefoot adduction, then varus (or inversion), then equinus (or plantar flexion). Trying to correct all three deformities at the same time creates a misshapen, rocker-bottomed foot.

Correction begins with manipulating the foot appropriately and casting the foot in that position. The procedure is repeated several times until the foot assumes a normal or nearly normal shape (usually in about 3 months).

The Denis Browne splint, a device that consists of two padded, metal footplates connected by a flat, horizontal bar, is sometimes used as a follow-up measure (when the foot is large enough) to help promote bilateral correction and strengthen the foot muscles. In addition, night splints and orthopedic shoes are used in correcting clubfoot.

More than half of all patients who have clubfoot—even those who receive conservative treatment—also need surgical correction. Typically, the doctor orders surgery if 3 months of casting hasn't corrected the condition or if the forefoot dorsiflexes and the hindfoot remains in equinus. Surgical correction may involve tenotomy, tendon transfer, stripping of the plantar fascia, and capsulotomy. If the patient has a severe deformity that persists into later life, surgery may involve wedge resection, osteotomy, or talectomy. The patient must wear a cast to preserve the correction. Clubfoot that is severe enough to require surgical correction usually can't be corrected completely.

After corrective treatment, proper alignment must be maintained actively through exercise, splints, and orthopedic shoes. The patient may need to wear a device such as a polypropylene above-the-knee splint at night and during naps, and a prewalker clubfoot shoe during the day.

Nursing diagnoses

- Body image disturbance
- Fear
- Impaired physical mobility
- Knowledge deficit
- Risk for impaired skin integrity
- Risk for injury

Key outcomes

- The patient will maintain joint mobility and range of motion (ROM).
- The patient will maintain muscle strength.
- The patient will show no evidence of complications, such as contractures, venous stasis, thrombus formulation, or skin breakdown.

Nursing interventions

- Look for exaggerated positions in the neonate's feet. If he seems to have a deformity, gently try to manipulate the foot. In apparent clubfoot, the foot moves easily. Avoid excessive force when manipulating a clubfoot.
- After application of a cast, elevate the child's feet with pillows. Check the toes every 1 to 2 hours for temperature, color, sensation, motion, and capillary refill time; watch for edema.
- Insert plastic petals over the top edges of a new cast while it's still wet to keep urine from soaking and softening the cast. After the cast dries, petal the edges with adhesive tape to keep out plaster crumbs and prevent skin irritation. (See [How to petal a cast.](#))
- Care for the skin under the cast edges every 4 hours. After washing and drying the skin, rub it with alcohol. Don't use oils or powders because they tend to macerate the skin.

ALERT If the doctor uses wedging maneuvers to reshape the existing cast (rather than recasting), check circulatory status frequently; it may be compromised by increased pressure on tissues and blood vessels. The equinus correction places considerable strain on ligaments, blood vessels, and tendons.

- After surgery, elevate the child's feet with pillows to decrease swelling and pain. Report signs of discomfort or pain immediately. Try to locate the source of pain—it may result from cast pressure rather than the incision. If bleeding develops under the cast, circle the location and mark the time on the cast. If bleeding spreads, report it to the doctor.
- Perform ROM exercises at least once every shift, unless contraindicated, to prevent contractures and muscle atrophy.
- Encourage the patient (if he's old enough) and family members to express their concerns about his disorder and his appearance. Answer their questions, and offer reassurance and support when necessary.

Patient teaching

- Explain the disorder to the patient (if he's old enough) and family members. Make sure they understand that clubfoot demands immediate therapy and orthopedic supervision throughout the growth process.

How to petal a cast

Rough cast edges can be cushioned by petaling them with adhesive tape or moleskin. To do this, first cut several 4" 9 x 2" 9 (10.2 x 5.1 cm) strips. Round off one end of each strip to keep it from curling. Then, making sure the rounded end of the strip is on the outside of the cast, tuck the straight end just inside the cast edge.

Smooth the moleskin with your finger until you're sure it's secured inside and out. Repeat the procedure, overlapping the moleskin pieces until you've gone all the way around the cast edge.

- u Before a child in a clubfoot cast goes home, teach the family cast care and the signs of circulatory impairment.
- u Stress to parents that correcting this defect takes time and patience. Teach them exercises that they and the child can do at home to help maintain the correction. Urge parents to apply corrective shoes and splints when the child takes naps and goes to sleep at night.
- u After an older child has had his foot placed in a cast, warn him and the parents to avoid letting the cast wear thin and get soft around the foot area. If it does, much of the correction can be lost.
- u If appropriate, explain to an older child and the parents that surgery may improve the clubfoot enough to ensure adequate function, but the affected calf muscle will remain slightly underdeveloped.

DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (DDH) is the most common disorder affecting the hip joints of children under age 3. DDH occurs when structures in the hip joint articulate abnormally. The condition may be unilateral or bilateral. It occurs in three forms of varying severity:

- u unstable hip dysplasia, in which the hip is positioned normally but the ligaments around the hip are loose, predisposing it to dislocation, especially by manipulation
- u subluxation or incomplete dislocation, in which the head of the femur is partially displaced and rides on the edge of the acetabulum
- u complete dislocation, in which the head of the femur lies completely outside the acetabulum. (See [Degrees of hip dysplasia.](#))

About 60% to 70% of affected infants are female. Dislocation is 10 times more common after breech delivery than after normal cephalic delivery. It also may be more common among large neonates and twins. With prompt treatment, the prognosis is good.

Causes

Experts are uncertain about the cause of DDH. Some theorize that the hormones that relax maternal ligaments in preparation for labor may also relax the ligaments around the infant's hip joint.

Complications

If treatment doesn't begin until after the child reaches age 2, DDH may cause degenerative hip changes, lordosis (increased lumbar curvature), joint malformation, and soft-tissue damage. A unilateral dislocation, which shortens one of the child's legs, can result in functional scoliosis.

Untreated DDH can lead to crippling osteoarthritis and a progressive limp by the time the patient reaches early adulthood.

Assessment findings

The patient may have a history of a breech delivery or may have been a large neonate or one of twins. An older child may have a history of delayed walking or, as the child begins to walk, limited abduction on the dislocated side.

When you inspect an affected infant in the supine position, you may observe extra thigh folds on the side of subluxation or dislocation. Extra folds may also appear when the child lies prone. The buttock fold on the affected side appears higher. You may also discover dysplasia by palpation.

In complete dysplasia, the hip rides above the acetabulum, making the child's knees uneven. In an older child, one leg is shorter than the other.

A child with bilateral dysplasia may sway from side to side when walking—a sign called “duck waddle.” Unilateral dysplasia can cause a limp. (See [Ortolani's and Trendelenburg's signs.](#))

Diagnostic tests

X-rays reveal the location of the femur head and a shallow acetabulum and allow monitoring of the progress of the disorder or treatment. X-rays are difficult to

interpret because the femoral head isn't evident until ossification begins at age 3 to 4 months.

Ultrasonography can define the relationship between the head of the femur and the acetabulum without the use of ionizing radiation.

Treatment

The earlier an infant receives treatment, the better the chances of normal development. Treatment for an older child depends on the patient's age.

Infants younger than age 3 months receive gentle manipulation to reduce the dislocation, followed by placement of a splintlike brace or harness (such as the Frejka pillow or the Pavlik harness) to maintain the hips in a flexed and abducted position. The infant must wear the appliance continuously for 2 to 3 months and then wear a night splint for another month so the joint capsule can tighten and stabilize in correct alignment.

If treatment doesn't begin until after age 3 months, it may include bilateral skin traction (Bryant's traction). Skeletal traction may be necessary if the child has started walking. Both treatments are used to reduce the dislocation by gradually abducting the hips.

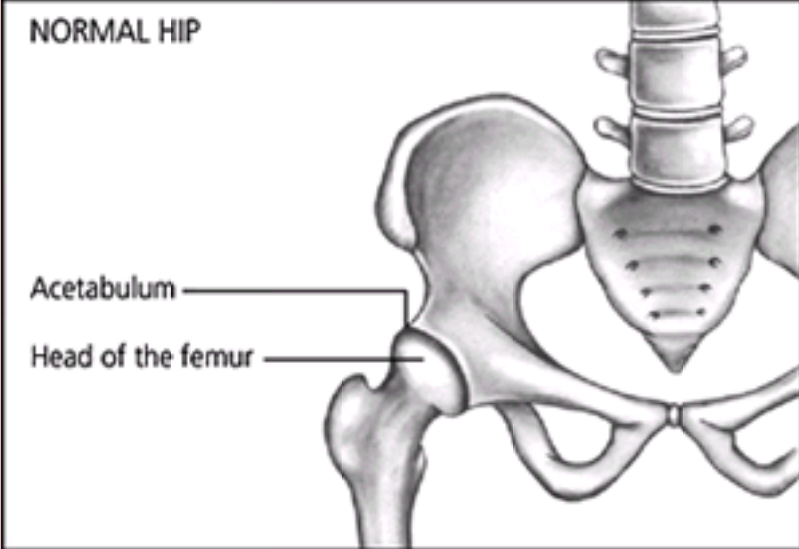

Degrees of hip dysplasia

Normally, the head of the femur fits snugly into the acetabulum, allowing the hip to move properly. In congenital hip dysplasia, flattening of the acetabulum prevents the head of the femur from rotating adequately. The child's hip may be unstable, subluxated (partially dislocated), or completely dislocated, with the femoral head lying totally outside the acetabulum. The degree of dysplasia—and the child's age—are considered in determining the treatment choice.

Head of the femur

SUBLUXATED HIP

DISLOCATED HIP

Ortolani's and Trendelenburg's signs

Two signs can help you assess for developmental dysplasia of the hip.

Ortolani's sign

Place the infant on his back, with the hips flexed in a neutral position. Grasp the legs just below the knees with the long fingers of each hand extending down the lateral side of the thigh to the greater trochanter.

Then gently abduct the hips from a neutral position. If you exert slight pressure upward and inward beneath the greater trochanter with your long finger, the dislocated head of the femur may slip into the acetabulum with a palpable click.

Trendelenburg's sign

Have the child rest her weight on the side of the dislocation and lift the other knee (as shown). Her pelvis drops on the normal side because of the weak abductor muscles in the affected hip. (Also note how the spine curves in this position.) When the child stands with her weight on the normal side and lifts the other knee, the pelvis remains horizontal or is elevated.

If traction fails, gentle closed reduction under general anesthesia can further abduct the hips; the infant then wears a spica cast for 4 to 6 months. If closed reduction fails, the doctor may perform open reduction and apply a spica cast for about 6 months, or he may perform an osteotomy.

Treatment for children ages 2 to 5 is difficult; it includes skeletal traction and subcutaneous adductor tenotomy. Treatment started after age 5 usually fails to restore satisfactory hip function.

Nursing diagnoses

u Body image disturbance u Fear u Fluid volume deficit u Impaired physical mobility u Knowledge deficit u Risk for impaired skin integrity u Risk for injury

Key outcomes

- u The patient will maintain joint mobility and range of motion.
- u The patient will maintain muscle strength.

- u The patient will show no evidence of complication, such as contractures, venous stasis, thrombus formation, or skin breakdown.
- u The patient will achieve the highest level of mobility possible within the confines of the disease.
- u The patient will express positive feelings about himself.
- u The patient or family member will demonstrate the mobility regimen.

Nursing interventions

- u When transferring the child immediately after application of a spica cast, use your palms to avoid making dents in the cast. Such dents can cause pressure ulcers. Remember that the cast needs 24 to 48 hours to dry naturally. Don't use heat to make it dry faster; that makes it more fragile.
- u Use strips of plastic sheet to protect the edges of the cast from moisture around the perineum and buttocks. Cut the strips long enough to cover the outside of the cast, and then overlap them around the edge and tuck each one about a finger length beneath the edge. Using overlapping strips of tape, tack the corner of each strip to the outside of the cast. Remove the plastic under the cast every 4 hours; then wash, dry, and retuck it. Disposable diapers folded lengthwise over the perineum may also be used.
- u Position the child either on a Bradford frame elevated on blocks, with a bedpan under the frame, or on pillows to support the child's legs. Keep the cast dry, and change the child's diapers often.
- u Wash and dry the skin under the cast edges every 2 to 4 hours, and rub it with alcohol. Don't use oils or powders; they can macerate the skin.
- u Turn the child every 2 hours during the day and every 4 hours at night. Check color, sensation, and motion in her legs and feet, and examine all her toes. Notify the doctor if they're dusky or cool, or if you suspect they're numb.
- u Shine a flashlight under the cast every 4 hours to check for foreign objects and crumbs of food. Check the cast daily for odors, which may indicate infection. Record temperature daily.
- u If a child complains of itching, she may benefit from diphenhydramine, or you may use a hair dryer to blow cool air at the cast edges.
- u Provide adequate nutrition and fluid intake to avoid renal calculi and constipation.
- u Provide adequate stimuli to promote growth and development.
- u Encourage parents to stay with their child as much as possible for the first few days after a cast or brace is applied to calm and reassure her while she adapts to restricted movement.
- u Assure the parents that the child will adjust to this restriction and return to normal sleeping, eating, and playing behavior in a few days.
- u If the patient is in Bryant's traction, make sure that the amount of weight is sufficient to lift her buttocks slightly off the bed.
- u Take steps to maintain the patient's skin integrity.
- u Monitor the patient's respiratory status and watch for aspiration.

Patient teaching

- u Explain possible causes of DDH, and reassure the parents that early, prompt treatment usually results in complete correction.
- u Teach the parents how to splint or brace the hips correctly. Stress the need for frequent checkups.
- u If the patient is using a Bradford frame, teach the parents how to apply the traction and how to care for the child while she's in traction. Remind them to keep her from bearing weight on her legs while she rests between periods of traction.
- u If the child's hips are abducted in a froglike position (which prevents sitting in a high chair), encourage the parents to let her sit at a table (by seating her on pillows on a chair), put her on the floor for short periods of play, and let her play with other children her age.
- u If the doctor orders it, instruct the parents to remove braces and splints while bathing the infant. Tell them they need to replace them immediately afterward.
- u Stress the importance of cleanliness; the parents should bathe and change the child frequently and wash her perineum with warm water and soap at each diaper change.
- u Tell the parents to watch for signs that the child is outgrowing the cast, such as cyanosis, cool extremities, and pain.
- u If the child wears a Pavlik harness or spica cast, urge the parents to modify a commercially manufactured car seat to ensure the child's safety when riding in a car.
- u Tell the parents that treatment for DDH may be prolonged and require patience.
- u Teach the parents to recognize signs of respiratory distress.

MUSCULAR DYSTROPHY

Muscular dystrophy is a group of hereditary disorders characterized by progressive symmetrical wasting of skeletal muscles but no neural or sensory defects. Four main types of muscular dystrophy occur: Duchenne's (pseudohypertrophic) muscular dystrophy, which accounts for 50% of all cases; Becker's (benign pseudohypertrophic) muscular dystrophy; Landouzy-Dejerine (facioscapulohumeral) dystrophy; and Erb's (limb-girdle) dystrophy. Duchenne's and Becker's muscular dystrophies affect males almost exclusively. The other two types affect both sexes about equally.

Depending on the type, the disorder may affect vital organs and lead to severe disability, even death. Early in the disease, muscle fibers necrotize and regenerate in various states. Over time, regeneration slows and degeneration dominates. Fat and connective tissue replace muscle fibers, causing weakness.

The prognosis varies. Duchenne's muscular dystrophy typically begins during early childhood and causes death within 10 to 15 years. Patients with Becker's muscular dystrophy may live into their 40s. Landouzy-Dejerine and Erb's dystrophies usually don't shorten life expectancy.

Causes

Muscular dystrophy is caused by various genetic mechanisms. The basic defect can be mapped genetically to band Xp 21. Duchenne's and Becker's muscular dystrophies are X-linked recessive, and Landouzy-Dejerine dystrophy is autosomal dominant. Erb's dystrophy may be inherited in several ways but usually is autosomal recessive.

Exactly how these inherited defects cause progressive muscle weakness isn't known. They may create an abnormality in the intracellular metabolism of muscle cells. The abnormality may be related to an enzyme deficiency or dysfunction, or to an inability to synthesize, absorb, or metabolize an unknown substance vital to muscle function.

Complications

Duchenne's and Becker's muscular dystrophies lead to crippling disability and contractures. Progressive skeletal deformity and thoracic muscle weakness inhibit pulmonary function, increasing the risk of pneumonia and other respiratory infections. These diseases can also lead to such cardiac problems as arrhythmias and hypertrophy; sudden heart failure may cause death. Most patients with Duchenne's or Becker's muscular dystrophy die from respiratory complications.

Complications from other types of dystrophy vary with the site and severity of muscle involvement.

Assessment findings

The patient's family history may point to evidence of genetic transmission. If another family member has muscular dystrophy, its clinical characteristics can indicate the type of dystrophy the patient has and how he may be affected.

The patient may complain of progressive muscle weakness. The onset and characteristics of the increasing weakness vary with the type of dystrophy involved.

Duchenne's muscular dystrophy begins insidiously. Onset typically occurs when the child is between ages 3 and 5. Weakness begins in the pelvic muscles and interferes with the child's ability to run, climb, and walk. The disease progresses rapidly; by age 12, the child usually can't walk.

Signs and symptoms of Becker's muscular dystrophy resemble those of Duchenne's but progress more slowly. They start after age 5, but the patient can still walk well beyond age 15 and, in some cases, into his 40s.

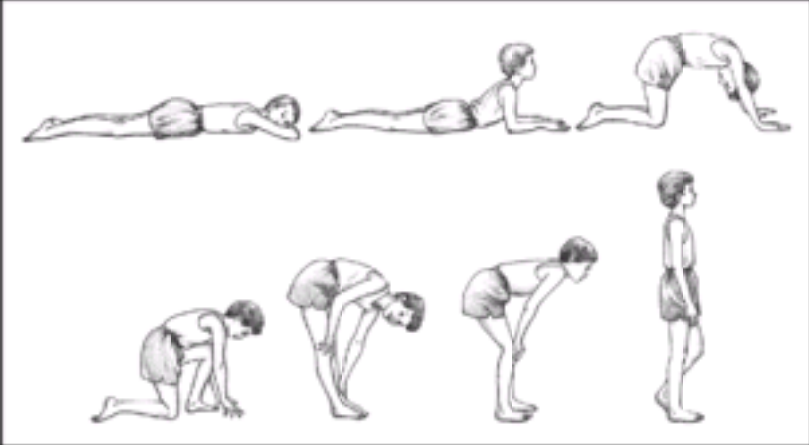

Landouzy-Dejerine dystrophy, a slowly progressive and relatively benign form of muscular dystrophy, typically begins before age 10. However, symptoms may develop during adolescence. Early symptoms include weakness of the eye, face, and shoulder muscles. The patient may complain that he's unable to raise his arms over his head or close his eyes completely. The patient or the patient's parents may notice other early signs, including an inability to pucker the lips or whistle, abnormal facial movements, and the absence of facial movements when laughing or crying. Pelvic muscles weaken as the disease progresses.

Observing Gowers' sign

Because Duchenne's and Becker's muscular dystrophies weaken pelvic and lower extremity muscles, the patient must use his upper body to maneuver from a prone to an upright position.

Lying on his stomach with his arms stretched in front of him, the patient raises his head, backs into a crawling position, and then into a half-kneel.

Then stooping, he braces his legs with his hands at the ankles and walks his hands (one after the other) up his legs until he pushes himself upright.

Erb's dystrophy follows a similarly slow course and commonly causes only slight disability. Onset usually occurs when the child is between ages 6 and 10 but may occur in early adulthood. Muscle weakness first appears in the upper arm and pelvic muscles. Inspection reveals the effects of muscle weakness and, eventually, muscle wasting. Findings vary according to the type of dystrophy. Early in Duchenne's and Becker's muscular dystrophies, you may notice that the patient has a wide stance and a waddling gait. He may also display Gowers' sign when rising from a sitting or supine position. (See [Observing Gowers' sign.](#))

During the initial stage, you may notice muscle hypertrophy. As the disease progresses, most muscles atrophy. The calves remain enlarged because of fat infiltration into the muscle. As abdominal and paravertebral muscles weaken, you may observe posture changes. The patient develops lordosis and a protuberant abdomen. Weakened thoracic muscles may cause scapular “winging” or flaring when the patient raises his arms. Bone outlines become prominent as surrounding muscles atrophy. In later stages, you may note contractures and pulmonary signs, such as tachypnea and shortness of breath.

A patient with Landouzy-Dejerine dystrophy may develop a pendulous lower lip, and the nasolabial fold may disappear. Diffuse facial flattening leads to a masklike expression. Infants can't suckle. The scapulae develop a winglike appearance, and the patient can't raise his arms above his head.

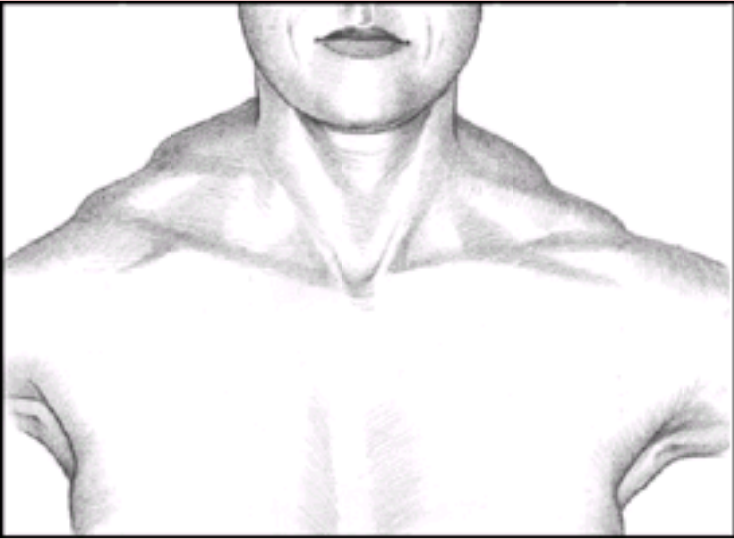

With Erb's dystrophy, you may note winging of the scapulae, lordosis with abdominal protrusion, a waddling gait, poor balance, and an inability to raise the arms. (See [Detecting muscular dystrophy.](#))

ADVANCED PRACTICE

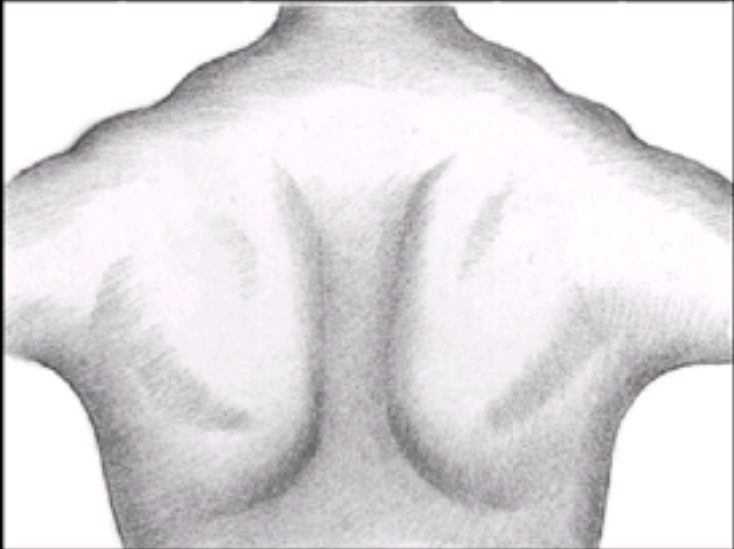

Detecting muscular dystrophy

In muscular dystrophy, the trapezius muscle typically rises, creating a stepped appearance at the shoulder's point.

From the posterior view, the scapulae ride over the lateral thoracic region, giving them a winged appearance. In Duchenne's and Becker's dystrophies, this winglike sign appears when the patient raises his arms. In other dystrophies, the sign is obvious without arm raising. (In fact, the patient can't raise his arms.)

Diagnostic tests

Several tests are used to help confirm the diagnosis:

- Muscle biopsy shows fat and connective tissue deposits and confirms the diagnosis. It also shows degeneration and necrosis of muscle fibers and, in Duchenne's and Becker's muscular dystrophies, a deficiency of the muscle protein dystrophin.
- Immunologic and biological techniques available in specialized medical centers facilitate prenatal and postnatal diagnosis of Duchenne's and Becker's muscular dystrophies. These techniques also help identify a person as a carrier. In addition, newer techniques are replacing muscle biopsy and serum creatinine kinase (CK) test as diagnostic procedures.
- Electromyography typically demonstrates short, weak bursts of electrical activity in affected muscles.
- Urine creatinine, serum CK, lactate dehydrogenase, alanine aminotransferase, and aspartate aminotransferase levels are elevated. CK levels increase before muscle weakness becomes severe, providing an early indicator of Duchenne's and Becker's muscular dystrophies. These diagnostic tests are also useful for genetic screening because unaffected carriers also show elevated enzyme levels.
- Amniocentesis can't detect muscular dystrophy definitively, but because it reveals the sex of the fetus, it may be recommended for pregnant women known to carry the gene for Duchenne's or Becker's muscular dystrophy.
- Genetic testing can be used to detect the gene defect that leads to muscular dystrophy in some families.

Treatment

Currently, no treatment can stop the progressive muscle impairment. Orthopedic appliances, exercise, physical therapy, and surgery to correct contractures can help preserve the patient's mobility and independence.

Nursing diagnoses

- Activity intolerance
- Body image disturbance
- Impaired physical mobility
- Ineffective breathing pattern
- Ineffective family coping
- Ineffective individual coping
- Self-care deficit: Bathing or hygiene

Key outcomes

- The patient will perform activities of daily living without muscle fatigue or intolerance.
- The patient will maintain muscle strength.
- The patient will maintain joint mobility and range of motion (ROM).
- The patient will show no evidence of complications.
- The patient will achieve the highest level of mobility possible within the confines of the disease.
- The patient will maintain adequate respiratory rate within ± 5 of baseline.

Nursing interventions

- If a patient with Duchenne's or Becker's muscular dystrophy develops respiratory involvement, encourage coughing and deep-breathing exercises.
- Help the patient to preserve joint mobility and prevent muscle atrophy by encouraging and assisting with active and passive ROM exercises.
- The patient may need splints, braces, grab bars, and overhead slings. For comfort and to prevent footdrop, use a footboard or high-topped shoes and a foot cradle.
- Because inactivity can cause constipation, encourage adequate fluid intake, increase dietary bulk, and obtain an order for a stool softener. Because the patient is prone to obesity from reduced physical activity, provide him with a low-calorie, high-protein, high-fiber diet.
- Allow the patient plenty of time to perform even simple physical tasks.

Patient teaching

- Encourage communication between the family members and the patient to help them handle emotional strain and cope with changes in body image.
- Encourage the patient and family members to express their concerns. Listen to them and answer their questions.
- Help a child with Duchenne's muscular dystrophy maintain peer relationships and realize his intellectual potential by encouraging the parents to keep him in a regular school as long as possible.
- Teach the patient and parents ways to maintain his mobility and independence for as long as possible.
- Inform the patient and parents about possible complications and steps they can take to prevent them.
- Explain the possibility of respiratory tract infections, signs to watch for, and what to do if the patient develops a respiratory infection. Urge the patient and the parents to report signs of infection to the doctor immediately.
- When the patient becomes confined to a wheelchair, help him and family members to see the chair as a way to preserve his independence. Have an occupational therapist teach the patient about his wheelchair and other supportive devices that can help him with activities of daily living.
- Help the patient and family members plan a low-calorie, high-protein, high-fiber diet to prevent obesity caused by reduced physical activity.
- Advise the patient to avoid long periods of bed rest and inactivity; if necessary, he should limit television viewing and other sedentary activities.
- If desired, refer adult patients for sexual counseling.
- Refer the patient for appropriate physical therapy, vocational rehabilitation, social services, and financial assistance. Suggest the Muscular Dystrophy Association as a source of information and support.
- Refer family members who carry the muscular dystrophy trait to genetic counseling so they understand the risk of transmitting this disorder.

OSTEOGENESIS IMPERFECTA

Also called brittle bones, osteogenesis imperfecta is a hereditary disease of bones and connective tissue. It causes fragile bones, thin skin, blue sclera, poor teeth, hypermobility of the joints, and progressive deafness.

The disease occurs in many forms. In the rare congenital form, in which fractures are present at birth, the patient usually dies during the first few days or weeks after birth. In the late-appearing form (osteogenesis imperfecta tarda), the child appears normal at birth but develops recurring fractures—mostly of the extremities—after age 1.

Some children with osteogenesis imperfecta tarda have gross multiple fractures and deformities; others have an increased tendency to fracture but no significant deformities. Some have multiple fractures during childhood, improve after puberty, and then begin to fracture more frequently later in life, particularly during pregnancy and then again after menopause.

Causes and pathophysiology

Osteogenesis imperfecta may result from autosomal dominant or recessive inheritance. Clinical signs may result from defective osteoblastic activity and defective mesenchymal collagen (embryonic connective tissue) and its derivatives (sclera, bones, and ligaments). The reticulum fails to differentiate into mature collagen or may cause collagen to develop abnormally, leading to immature and coarse bone formation. Cortical bone thinning also occurs.

Complications

One-third of patients become deaf between ages 30 and 40 because of osteosclerosis, pressure on the auditory nerve, and neurogenic deafness. Other complications include scoliosis, multiple deformities, and dwarfism.

Assessment findings

The patient has a history of repeated fractures that result from even slight trauma. He may complain of a progressive hearing loss.

In congenital and delayed osteogenesis imperfecta, inspection may show a bilaterally bulging skull, triangle-shaped head and face, prominent eyes, and blue sclera. You may also observe thin, translucent skin; signs of possible subcutaneous hemorrhages; and discolored (blue-gray or yellow-brown) teeth, which break easily and are prone to cavities. Other findings include poorly developed (atrophied) skeletal muscles and hypermobility of the joints.

You may notice that the patient is short. In congenital osteogenesis, epiphyseal fractures result in deformities and stunted growth.

Diagnostic tests

X-rays show evidence of multiple old fractures and skeletal deformities. A skull X-ray shows wide sutures with small, irregularly shaped islands of bone (wormian bones) between them. These findings can help differentiate osteogenesis imperfecta from child abuse.

Serum calcium and serum phosphorus levels are normal.

Analysis of deoxyribonucleic acid may reveal the diagnosis in some families.

Treatment

Because no cure exists, the goal of treatment is to prevent deformities through the use of traction, immobilization, or both and to aid normal development and rehabilitation. Limb deformities may be corrected by multiple osteotomies and rod placement.

Other measures include assessing for and treating scoliosis, a common complication, and promoting preventive dental care and repair of dental caries.

Patients with mild osteogenesis imperfecta may need little treatment after age 15, when the fracture rate begins to decrease. Women need special attention during pregnancy and after menopause, when their tendency to fracture may return.

Nursing diagnoses

u Altered growth and development u Impaired physical mobility u Knowledge deficit u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will demonstrate appropriate skills and behaviors to the greatest extent possible.
- u The patient will maintain joint mobility and range of motion.
- u The patient will maintain muscle strength.
- u The patient will show no evidence of complications.
- u The patient will express feelings of comfort and decreased pain.

Nursing interventions

- u Emphasize the importance of coughing and deep breathing, and teach the patient how to use an incentive spirometer, if ordered.
- u If the patient has a cast, monitor his circulatory, motor, and sensory abilities.
- u Monitor skin condition, especially over bony prominences and areas under pressure from a cast or brace.
- u If the patient is in skeletal traction, check for signs of infection (odor, fever, local inflammation, and drainage) at pin sites. Care for the pin sites with peroxide or povidone-iodine or as the doctor orders.
- u Provide a diet high in protein, carbohydrates and vitamins to enhance healing.
- u Administer analgesics as ordered, and monitor the patient's response.
- u Monitor dental and hearing needs.
- u Encourage the patient and the parents to express their concerns about the disorder, and answer any questions they have. Involve them in all phases of care.

Patient teaching

- u Teach the patient and the parents how to recognize a fracture and how to splint it correctly.
- u If the patient needs a cast, explain that it dries in 24 to 48 hours. To avoid making indentations in the cast while it's still wet, tell the patient to avoid squeezing it with his fingers, covering it, walking on it, and bumping it on hard surfaces. Doing so could cause dents that can press against the underlying skin. Tell the patient that he'll feel a transient sensation of heat under the cast while it's drying.
- u Teach the patient and the parents how to care for the cast. Instruct them to report any odors or drainage through the cast; these signs may indicate infection. Warn against inserting foreign objects under the cast, getting it wet, pulling out its padding, or scratching inside it. Tell the patient to seek immediate treatment for a broken cast.
- u Instruct the patient to exercise the joints above and below the cast to prevent stiffness and contractures.
- u If the patient needs a brace, splint, sling, or traction for alignment or immobilization, explain why he needs the appliance, and show him and family members how to apply it properly. Tell them how long the appliance should be worn, and advise them of any activity restrictions. If the patient has a brace, check with his orthotist about proper care. Encourage the patient to refer further questions to his doctor.
- u If the patient needs a cast or brace, teach him and family members how to assess for skin breakdown.
- u Teach the patient how to walk with crutches as necessary.
- u Stress the importance of meticulous dental hygiene and routine dental checkups. Also stress the importance of routine hearing tests to detect hearing loss.
- u Emphasize the importance of good nutrition (which helps to heal bones) and immunizations.
- u Advise parents to encourage their child to develop interests that don't require strenuous physical activity and to develop his fine-motor skills to promote the child's self-esteem.
- u To help foster independence, teach the child to assume some responsibility for precautions during physical activity.
- u Refer the family for genetic counseling.

Joint disorders

Joint disorders, which attack the body's centers of mobility, are painful and disabling. Causes of joint disorders may range from chronic conditions to acute infections. No matter what the cause, they all need a team treatment approach that emphasizes patient participation.

This section covers gout, neurogenic arthropathy, osteoarthritis, and septic arthritis.

GOUT

Gout—also known as gouty arthritis—is a metabolic disease marked by monosodium urate deposits that cause red, swollen, and acutely painful joints. Gout can affect any joint but mostly affects those in the feet, especially the great toe, ankle, and midfoot.

Primary gout typically occurs in men over age 30 and in postmenopausal women who take diuretics. It follows an intermittent course that may leave patients

symptom-free for years between attacks. Secondary gout occurs in older people.

In asymptomatic patients, serum urate levels rise but produce no symptoms. In symptom-producing gout, the first acute attack strikes suddenly and peaks quickly. Although it may involve only one or a few joints, this attack causes extreme pain. Mild, acute attacks usually subside quickly yet tend to recur at irregular intervals. Severe attacks may persist for days or weeks.

Intercritical periods are the symptom-free intervals between attacks. Most patients have a second attack between 6 months and 2 years after the first; in some patients, the second attack is delayed for 5 to 10 years. Delayed attacks, which may be polyarticular, are more common in untreated patients. These attacks tend to last longer and produce more symptoms than initial episodes. A migratory attack strikes various joints and the Achilles tendon sequentially and may be associated with olecranon bursitis.

Eventually, *chronic polyarticular gout* sets in. This final, unremitting stage of the disease (also known as tophaceous gout) is marked by persistent painful polyarthritis. An increased concentration of uric acid leads to urate deposits—called tophi—in cartilage, synovial membranes, tendons, and soft tissue.

Tophi form in the fingers, hands, knees, feet, ulnar sides of the forearms, pinna of the ear, Achilles tendon and, rarely, in such internal organs as the kidneys and myocardium. Renal involvement may adversely affect renal function.

Patients who receive treatment for gout have a good prognosis.

Causes

Although the underlying cause of primary gout is unknown, in many patients the disease results from decreased renal excretion of uric acid. In a few patients, gout is linked to a genetic defect in purine metabolism that causes overproduction of uric acid (hyperuricemia).

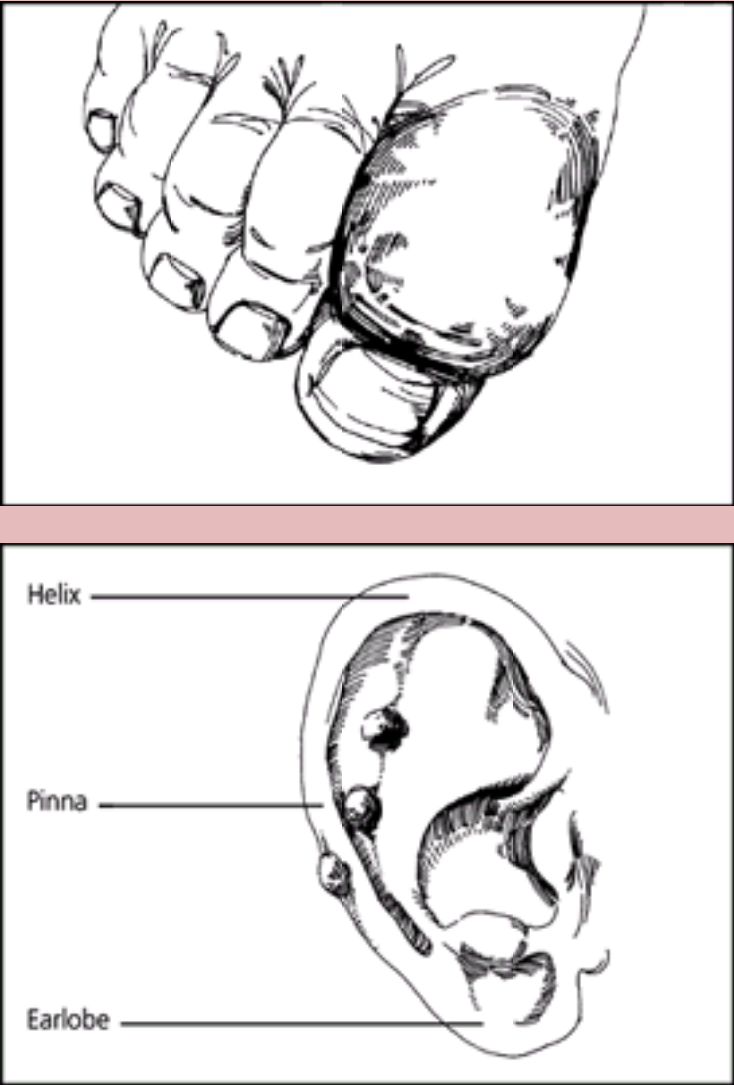

Secondary gout develops during the course of another disease, such as obesity, diabetes mellitus, hypertension, polycythemia, leukemia, myeloma, sickle cell anemia, and renal disease. Secondary gout can also follow treatment with such drugs as hydrochlo-rothiazide or pyrazinamide.

Complications

Potential complications include renal disorders such as renal calculi; circulatory problems, such as atherosclerotic disease, cardiovascular lesions, cerebrovascular accident, coronary thrombosis, and hypertension; and infection that develops with tophi rupture and nerve entrapment.

Recognizing gouty tophi

In advanced gout, urate crystal deposits develop into hard, irregular, yellow-white nodules called tophi. These bumps commonly protrude from the great toe and pinna.

Assessment findings

Patient history may reveal that the patient has a sedentary lifestyle and a history of hypertension and renal calculi. He may report waking during the night with pain in his great toe or another location in the foot. He may complain that initially moderate pain has grown intense so that eventually he can't bear the weight of bedsheets or the vibrations of a person walking across the room. He may report accompanying chills and a mild fever.

Inspection typically reveals a swollen, dusky red or purple joint with limited movement. You may also notice tophi, especially in the outer ears, hands, and feet. (See [Recognizing gouty tophi.](#))

Late in the chronic stage of gout, the skin over the tophi may ulcerate and release a chalky white exudate or pus. Chronic inflammation and tophaceous deposits prompt secondary joint degeneration. Erosions, deformity, and disability may develop.

Palpation may reveal warmth over the joint and extreme tenderness. The vital signs assessment may disclose fever and hypertension. If the patient has a fever, possible occult infection must be investigated.

Diagnostic tests

Needle aspiration of synovial fluid (arthrocentesis) or of tophaceous material for examination under polarized light microscopy reveals needlelike intracellular crystals of sodium urate. Monosodium urate monohydrate crystals in synovial fluid taken from an inflamed joint or tophus establish the diagnosis. If test results identify calcium pyrophosphate crystals, the patient probably has pseudogout, a disease similar to gout. (See [Understanding pseudogout.](#))

Serum uric acid levels may be normal, but the higher the level (especially when it's greater than 10 mg/dl), the more likely a gout attack.

Urine uric acid levels are high in about 20% of gout patients.

X-ray studies initially produce normal results but, in chronic gout, X-ray findings show damage to the articular cartilage and subchondral bone. Outward displacement of the overhanging margin from the bone contour characterizes gout.

Treatment

Correct management has three goals:

- u First, terminate the acute attack.
- u Next, treat hyperuricemia to reduce urine uric acid levels.
- u Finally, prevent recurrent gout and renal calculi.

Treatment for an acute attack consists of bed rest; immobilization and protection of the inflamed, painful joints; and local application of cold. Analgesics such as acetaminophen relieve the pain associated with mild attacks. Acute inflammation requires nonsteroidal anti-inflammatory drugs or intramuscular corticotropin. Colchicine, oral or parenteral, or intra-articular corticosteroids are occasionally necessary to treat acute attacks.

Treatment for chronic gout involves decreasing the serum uric acid level to less than 6.5 mg/dl. This may be accomplished with various medications after a 24-hour urinalysis is used to determine whether the patient excretes too much or too little uric acid. If the patient overexcretes uric acid, he may be given allopurinol (in reduced doses if he has decreased renal function). If he underexcretes uric acid, he may be treated with probenecid or sulfinpyrazone (if he has no history of renal calculi). Taken once or twice daily, colchicine effectively prevents acute gout attacks, but it doesn't affect uric acid levels.

Adjunctive therapy emphasizes avoidance of alcohol (especially beer and wine) and sparing use of purine-rich foods, such as anchovies, liver, sardines, kidneys, sweetbreads, and lentils. Obese patients should begin a weight loss program because weight reduction decreases uric acid levels and eases stress on painful joints.

Nursing diagnoses

- u Anxiety
- u Impaired physical mobility
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for injury
- u Sleep pattern disturbance

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will express adequate coping skills and decreased anxiety.
- u The patient will maintain joint mobility and range of motion.
- u The patient will perform activities of daily living within the confines of the disease.
- u The patient and family members will demonstrate knowledge of the condition and treatment regimen.

Nursing interventions

- u To diffuse anxiety and promote coping mechanisms, encourage the patient to express his concerns about his condition. Listen supportively. Include him and family members in care-related decisions and all phases of care. Answer the patient's questions about his disorder as honestly as possible.
- u Urge the patient to perform as much self-care as his immobility and pain allow. Provide him with adequate time to perform these activities at his own pace.
- u Encourage bed rest, but use a bed cradle to keep bed linens off of sensitive, inflamed joints.
- u Carefully evaluate the patient's condition after joint aspiration. Provide emotional support during diagnostic tests and procedures.
- u Give pain medication as needed, especially during acute attacks. Monitor the patient's response to this medication. Apply cold packs to inflamed joints to ease discomfort and reduce swelling.
- u To promote sleep, administer pain medication at times that allow for maximum rest. Provide the patient with sleep aids, such as a bath, a back rub, or an extra pillow.

ADVANCED PRACTICE

Understanding pseudogout

Pseudogout—also known as calcium pyrophosphate disease—results when calcium pyrophosphate crystals collect in periarticular joint structures.

Signs and symptoms

Like true gout, pseudogout causes sudden joint pain and swelling—most commonly of the knee, wrist, ankle, or other peripheral joints.

Pseudogout attacks are self-limiting and triggered by stress, trauma, surgery, severe dieting, thiazide therapy, or alcohol abuse. Associated symptoms resemble those of rheumatoid arthritis.

Establishing a diagnosis

Diagnosis of pseudogout involves joint aspiration and synovial biopsy to detect calcium pyrophosphate crystals. X-rays show calcium deposits in the fibrocartilage and linear markings along the bone ends. Blood tests may detect an underlying endocrine or metabolic disorder.

Relieving pressure and inflammation

Management of pseudogout may include aspirating the joint to relieve pressure; instilling corticosteroids and administering analgesics, salicylates, phenylbutazone, or other nonsteroidal anti-inflammatory drugs to treat inflammation; and, if appropriate, treating the underlying disorder.

Without treatment, pseudogout leads to permanent joint damage in about half of those it affects, most of whom are elderly.

- u Help the patient identify techniques and activities that promote rest and relaxation. Encourage him to perform them.
- u Administer anti-inflammatory medication and other drugs as ordered. Watch for adverse reactions. Be alert for GI disturbances if the patient takes colchicine.
- u When forcing fluids, record intake and output accurately. Be sure to monitor serum uric acid levels regularly. As ordered, administer sodium bicarbonate or other agents to alkalinize the patient's urine.
- u Provide a nutritious, but purine-poor diet.
- u Watch for acute gout attacks 24 to 96 hours after surgery. Even minor surgery can trigger an attack. Before and after surgery, administer colchicine to help prevent gout attacks, as ordered.

Patient teaching

- u Urge the patient to drink plenty of fluids (up to 2 L [2.1 qt] a day) to prevent renal calculi.
- u Explain all treatments, tests, and procedures. Warn the patient before his first needle aspiration that it will be painful.
- u Make sure the patient understands the rationale for evaluating serum uric acid levels periodically.
- u Teach the patient relaxation techniques. Encourage him to perform them regularly.
- u Instruct the patient to avoid purine-rich foods, such as anchovies, liver, sardines, kidneys, and lentils, because these substances raise the urate level.
- u Discuss the principles of gradual weight reduction with an obese patient. Explain the advantages of a diet containing moderate amounts of protein and little fat.
- u If the patient receives allopurinol, probenecid, or other drugs, instruct him to report any adverse reactions immediately. (Reactions may include nausea, vomiting, drowsiness, dizziness, urinary frequency, and dermatitis.) Warn the patient taking probenecid or sulfinpyrazone to avoid aspirin or any other salicylate. Their combined effect causes urate retention.
- u Inform the patient that long-term colchicine therapy is essential during the first 3 to 6 months of treatment with uricosuric drugs or allopurinol. Stress the importance of compliance.
- u Urge the patient to control hypertension, especially if he has tophaceous renal deposits. Keep in mind that diuretics aren't advised for the gout patient; alternative antihypertensives are preferred.

NEUROGENIC ARTHROPATHY

Neurogenic arthropathy (also called Charcot's arthropathy) is most common in men over age 40. It's a progressively degenerative disease of peripheral and axial joints that results from impaired sensory innervation. Trauma or disease results in loss of sensation in the joint, which damages the supporting ligaments. Eventually, the affected joint disintegrates.

The specific joints affected vary. Diabetes mellitus usually attacks joints and bones of the feet. Tabes dorsalis affects large, weight-bearing joints, such as the knee, hip, ankle, or lumbar and dorsal vertebrae. Syringomyelia involves the shoulder, elbow, or cervical intervertebral joint. Neurogenic arthropathy caused by intra-articular corticosteroid injections may develop in the hip or knee joint.

Causes

In adults, the most common cause of neurogenic arthropathy is diabetes mellitus. Other causes include syringomyelia (which progresses to neurogenic arthropathy in about one of four patients), myelopathy of pernicious anemia, spinal cord trauma, paraplegia, hereditary sensory radicular neuropathy, and Charcot-Marie-Tooth disease. Rarely, tabes dorsalis, amyloidosis, peripheral nerve injury, myelomeningocele (in children), leprosy, or alcoholism cause neurogenic arthropathy.

Frequent intra-articular injection of corticosteroids has also been linked to neurogenic arthropathy. The analgesic effect of the corticosteroids may mask symptoms and allow continuous damaging stress to accelerate joint destruction.

Complications

Neurogenic arthropathy can lead to joint subluxation or dislocation, pathologic fractures, infection, pseudogout, or neurovascular compression.

Assessment findings

The patient's history may reveal an insidious onset, underlying neurologic disease, previous pathologic fractures, trauma and swelling in the affected area, and progressively worsening symptoms. Even with marked swelling over the joints, the patient may report no pain.

Inspection and other physical assessment techniques disclose extreme joint swelling, increased joint range of motion (ROM), joint deformity and instability, dislocation or subluxation, and loss of muscle tone around the joint.

Palpation may disclose warmth or tenderness over the involved joints and loose objects and abnormal calcification in the joint. (The joint may feel like a “bag of bones.”)

Diagnostic tests

X-rays confirm the diagnosis and allow evaluation of damage. Early in the disease, soft-tissue swelling or effusion may be the only overt effect. Late in the disease, X-rays may display articular fracture, subluxation, and cartilaginous erosion; periosteal new bone formation; and excessive growth of marginal loose bodies (osteophytosis). Bone resorption may also be evident.

Vertebral examination shows narrowed disk spaces, vertebral deterioration, and osteophyte formation, leading to ankylosis and deforming kyphoscoliosis.

Synovial biopsy detects bony fragments and bits of calcified cartilage.

Neuromuscular tests may reveal motor and sensory deficits and diminished deep tendon reflexes.

Treatment

Pain relief—the immediate treatment goal—may be achieved with analgesics, nonsteroidal anti-inflammatory drugs, and joint immobilization (crutches, splints, braces, and weight-bearing restrictions). Surgical correction, such as joint fusion or amputation, may be necessary in severe disease although surgical treatment has a high failure rate because of nonunion, infection, or dislocation.

Nursing diagnoses

u Anxiety u Fear u Impaired physical mobility u Risk for impaired skin integrity u Risk for injury u Self-care deficit

Key outcomes

- u The patient will maintain joint mobility and ROM.
- u The patient will recognize methods to avoid injury.
- u The patient will maintain adequate skin integrity.
- u The patient will perform activities of daily living within the confines of the disease.
- u The patient will express feelings of comfort and decreased anxiety.

Nursing interventions

- u Assist the patient to overcome anxiety and fear by expressing his feelings and concerns about the disorder. Listen, offering support and encouragement when appropriate. Include the patient and family members in all phases of care. Answer questions as honestly as you can.
- u Encourage the patient to perform as much self-care as immobility and pain allow. Recognize that he may need extra time to perform activities at his own pace.
- u Maintain neutral joint alignment. Apply splints and restrict weight bearing as ordered.
- u Assess the patient's pain pattern, and give analgesics as needed. Monitor his response.
- u Check sensory perception, ROM, alignment, joint swelling, and the status of underlying disease.

- u Assess the patient's skin regularly for breakdown.

Patient teaching

- u Instruct the patient to report severe joint pain, swelling, or instability. Suggest applying warm compresses to relieve local pain and tenderness.

HOME CARE

Preventing injury

Because the patient is prone to pathologic fractures and injuries, stress the importance of preventive measures in the home plan of care. Also teach the patient joint protection techniques. Advise him to avoid physical stress that could cause pathologic fractures and to take safety precautions to avoid falls. Tell him to remove throw rugs and clutter from passageways. Perform a home inspection, and complete a checklist to discover areas of hazard to the patient. Discuss these findings with the patient and family members.

- u Teach the patient how to use crutches or other orthopedic devices. Stress the importance of proper fitting and regular professional readjustment of such devices. Forewarn him that impaired sensation might allow these aids to cause tissue damage without causing discomfort.
- u Explain all treatments, tests, and procedures.
- u Review prescribed medications and possible adverse reactions. Tell the patient to notify his doctor if adverse reactions persist.
- u Urge the patient to continue with regular treatment of the underlying disease.
- u As necessary, refer the patient to an occupational therapist or a home health nurse to help him cope with activities of daily living. (See [Preventing injury.](#))

OSTEOARTHRITIS

Osteoarthritis is the most common form of arthritis. It causes deterioration of the joint cartilage and formation of reactive new bone at the margins and subchondral areas of the joints. This chronic degeneration results from a breakdown of chondrocytes, most often in the hips and knees.

Osteoarthritis occurs equally in both sexes, after age 40, with the earliest symptoms occurring in middle age and progressing with advancing age.

Depending on the site and severity of joint involvement, disability can range from minor limitation of the fingers to near immobility in people with hip or knee disease. Progression rates vary; joints may remain stable for years in the early stage of deterioration.

Causes and pathophysiology

Primary osteoarthritis may be related to aging, but researchers don't understand why. This form of the disease seems to lack any predisposing factors. In some patients, it may be hereditary.

Secondary osteoarthritis usually follows an identifiable event—most commonly a traumatic injury or a congenital abnormality such as hip dysplasia. Endocrine disorders such as diabetes mellitus, metabolic disorders such as chondrocalcinosis, and other types of arthritis also can lead to secondary osteoarthritis. (See [Understanding osteoarthritis.](#))

Complications

Osteoarthritis can cause flexion contractures, subluxation and deformity, ankylosis, bony cysts, gross bony overgrowth, central cord syndrome (with cervical spine osteoarthritis), nerve root compression, and cauda equina syndrome.

Assessment findings

The patient usually complains of gradually increasing signs and symptoms. He may report a predisposing event such as a traumatic injury. Most commonly, the patient has deep, aching joint pain, particularly after he exercises or bears weight on the affected joint. Rest may relieve the pain.

Additional complaints include stiffness in the morning and after exercise, aching during changes in weather, a “grating” feeling when the joint moves, contractures, and limited movement. These symptoms tend to be worse in patients with poor posture, obesity, or occupational stress.

Inspection may reveal joint swelling, muscle atrophy, deformity of the involved areas, and gait abnormalities (when arthritis affects the hips or knees). Osteoarthritis of the interphalangeal joints produces hard nodes on the distal and proximal joints. Painless at first, these nodes eventually become red, swollen, and tender. The fingers may become numb and lose their dexterity (See [Signs of osteoarthritis.](#))

Palpation may reveal joint tenderness and warmth without redness, grating with movement, joint instability, muscle spasms, and limited movement.

Diagnostic tests

X-rays of the affected joint may help confirm the diagnosis, but findings may be normal in the early stages. X-ray studies may require many views. Typical findings include a narrowing of the joint space or margin, cystlike bony deposits in the joint space and margins, sclerosis of the subchondral space, joint deformity caused by degeneration or articular damage, bony growths at weight-bearing areas, and joint fusion in patients with erosive, inflammatory osteoarthritis.

Synovial fluid analysis can be used to rule out inflammatory arthritis.

Radionuclide bone scan can also be used to rule out inflammatory arthritis by showing normal uptake of the radionuclide.

Arthroscopy is used to identify soft-tissue swelling by showing internal joint structures.

Magnetic resonance imaging produces clear cross-sectional images of the affected joint and adjacent bones. Results also show disease progression.

Neuromuscular tests may disclose reduced muscle strength (reduced grip strength, for example).

Treatment

To relieve pain, improve mobility, and minimize disability, treatment includes medications, rest, physical therapy, assistive mobility devices and, possibly, surgery.

Medications include aspirin and other salicylates and such nonsteroidal anti-inflammatory drugs as phenylbutazone, propoxyphene, indomethacin, fenoprofen, and ibuprofen. In some patients, intra-articular injections of corticosteroids may be necessary. Such injections, given every 4 to 6 months, may delay nodal development in the hands.

Adequate rest is essential and should be balanced with activity. Physical therapy includes massage, moist heat, paraffin dips for the hands, supervised exercise to decrease muscle spasms and atrophy, and protective techniques for preventing undue joint stress. Some patients may reduce stress and increase stability by using crutches, braces, a cane, a walker, a cervical collar, or traction. Weight reduction may help an obese patient.

In some cases, a patient with severe disability or uncontrollable pain may undergo surgery, including:

- u *arthroplasty (partial or total)*—replacement of the deteriorated part of a joint with prosthetic appliance
- u *arthrodesis*—surgical fusion of bones, used primarily in the spine (laminectomy)
- u *osteoplasty*—scraping and lavage of deteriorated bone from the joint
- u *osteotomy*—excision or cutting of a wedge of bone (usually in the lower leg) to change alignment and relieve stress.

PATHOPHYSIOLOGY

Understanding osteoarthritis

The characteristic breakdown of articular cartilage is a gradual response to aging or predisposing factors, such as joint abnormalities or traumatic injury. The illustrations below will help you understand how osteoarthritis progresses.

Normal anatomy

Normally, bones fit together. Cartilage a smooth, fibrous tissue cushions the end of each bone, and synovial fluid fills the joint space. This fluid lubricates the joint and eases movement, much like brake fluid functions in a car.

Early stage

Cartilage may begin to break down long before symptoms surface. In early osteoarthritis, the patient typically has no symptoms or has a mild, dull ache when he uses the joint. Rest relieves the discomfort. Or he may feel stiffness in the affected joint, especially in the morning. The stiffness usually lasts 15 minutes or less.

Later stage

As the disease progresses, whole sections of cartilage may disintegrate, osteophytes (bony spurs) form, and fragments of cartilage and bone float freely in the joint. More common now, pain may be present even during rest. It typically worsens throughout the day. Movement becomes increasingly limited, and stiffness may persist even after limbering exercises.

Signs of osteoarthritis

Heberden's nodes appear on the dorsolateral aspect of the distal interphalangeal joints. These bony and cartilaginous enlargements are usually hard and painless. They typically occur in middle-aged and elderly osteoarthritis patients. Bouchard's nodes are similar to Heberden's nodes but are less common and appear on the proximal interphalangeal joints.

Nursing diagnoses

u Anxiety u Body image disturbance u Impaired physical mobility u Ineffective individual coping u Pain u Self-care deficit u Sleep pattern disturbance

Key outcomes

- u The patient will express feelings of increased comfort and decreased pain.
- u The patient will maintain joint mobility and range of motion (ROM).
- u The patient will perform activities of daily living within the confines of the disease.
- u The patient will achieve the highest level of mobility possible within the confines of the disease.
- u The patient will express positive feelings about himself.

Nursing interventions

- u Provide emotional support and reassurance to help the patient cope with limited mobility. Give the patient opportunities to voice his feelings about immobility and nodular joints. Include him and family members in all phases of his care. Answer questions as honestly as you can.
- u Encourage the patient to perform as much self-care as his immobility and pain allow. Provide him with adequate time to perform activities at his own pace.
- u To help promote sleep, adjust pain medications to allow maximum rest. Provide the patient with normal sleep aids, such as a bath, back rub, or extra pillow.
- u Assess the patient's pain pattern, and give analgesics as needed. Monitor his response.
- u Help the patient identify techniques and activities that promote rest and relaxation. Encourage him to perform them.
- u Administer anti-inflammatory medication and other drugs as ordered. Watch for adverse reactions.
- u For joints in the hand, provide hot soaks and paraffin dips to relieve pain as ordered.
- u For lumbosacral spinal joints, provide a firm mattress (or bed board) to decrease morning pain.
- u For cervical spinal joints, adjust the patient's cervical collar to avoid constriction; watch for irritated skin with prolonged use.
- u For the hip, use moist heat pads to relieve pain. Administer antispasmodic drugs, as ordered.
- u For the knee, assist with prescribed ROM exercises twice daily to maintain muscle tone. Help perform progressive resistance exercises to increase the patient's muscle strength.
- u Provide elastic supports or braces if needed.
- u Check crutches, cane, braces, or walker for proper fit. A patient with unilateral joint involvement should use an orthopedic appliance (such as a cane or walker) on the normal side.

Patient teaching

- u Instruct the patient to plan for adequate rest during the day, after exertion, and at night. Encourage him to learn and use energy conservation methods, such as pacing, simplifying work procedures, and protecting joints.
- u Instruct him to take medications exactly as prescribed. Tell him which adverse reactions to report immediately.
- u Advise against overexertion. Tell the patient that he should take care to stand and walk correctly, to minimize weight-bearing activities, and to be especially careful when stooping or picking up objects.
- u Tell the patient to wear well-fitting support shoes and to repair worn heels.
- u Recommend having safety devices installed in the home, such as grab bars in the bathroom.
- u Teach the patient to do ROM exercises, performing them as gently as possible.
- u Advise maintaining proper body weight to minimize strain on joints.
- u Teach the patient how to use crutches or other orthopedic devices properly. Stress the importance of proper fitting and regular professional readjustment of such devices. Warn that impaired sensation might allow tissue damage from these aids without discomfort.

- u Recommend using cushions when sitting. Also suggest using an elevated toilet seat. Both reduce stress when rising from a seated position.
- u Positively reinforce the patient's efforts to adapt. Point out improving or stabilizing physical functioning.
- u As necessary, refer the patient to an occupational therapist or a home health nurse to help him cope with activities of daily living.

SEPTIC ARTHRITIS

Pyogenic septic arthritis is a medical emergency also known as infectious arthritis. It occurs when bacteria invade a joint and cause inflammation of the synovial lining. If the organisms enter the joint cavity, effusion and pyogenesis follow, with eventual bone and cartilage destruction.

The disorder usually affects a single joint. It most often develops in a large joint but can strike any joint, including the spine and small peripheral joints. Migratory polyarthritis sometimes precedes localized joint inflammation.

Septic arthritis can lead to ankylosis and fatal septicemia, but prompt antibiotic therapy and aspiration or drainage of the joint cure most patients.

Causes

In most cases of septic arthritis, bacteria spread from a primary site of infection, usually in adjacent bone or soft tissue, through the bloodstream to the joint. Common infecting organisms include:

- u four strains of gram-positive cocci—*Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *Streptococcus viridans*
- u two strains of gram-negative cocci—*Neisseria gonorrhoeae* and *Haemophilus influenzae*
- u various gram-negative bacilli, including *Escherichia coli*, *Salmonella*, and *Pseudomonas*.

Rarely, fungi or mycobacteria cause the infection. Anaerobic organisms such as gram-positive cocci may infect children over age 2 and adults. *H. influenzae* most often infects children under age 2.

Various factors can predispose a person to septic arthritis. Any concurrent bacterial infection (of the genitourinary or upper respiratory tract, for example) or serious chronic illness (such as cancer, renal failure, rheumatoid arthritis, septic lupus erythematosus, diabetes, or cirrhosis) heightens susceptibility. Consequently, alcoholics and the elderly run an increased risk of developing septic arthritis.

Susceptibility also increases among patients with immune system depression or a history of immunosuppressive therapy. I.V. drug abuse can also lead to septic arthritis. Other predisposing factors include recent articular trauma, joint surgery, intra-articular injections, and local joint abnormalities.

Complications

Septic arthritis may cause infection of the bone (osteomyelitis) or other adjacent structures and a loss of joint cartilage that leads to joint destruction.

Assessment findings

The patient may have a history of a known infection outside the involved joint, an immunosuppressive condition, or I.V. drug abuse. He may complain of an abrupt onset of intense pain in the affected joint. He may also have fever and chills if he has a systemic infection. These findings can help differentiate septic arthritis from other types. (See [Other types of arthritis and treatment.](#))

Inspection may show that the patient prefers to keep the affected joint flexed. This position eases pain by minimizing intra-articular pressure. You may observe redness and edema over the affected joint and severely reduced range of motion (ROM)—both active and passive.

On palpation, warmth and extreme tenderness over the involved joint is usually noted.

ASSESSMENT TIP Systemic signs of inflammation may not appear in some patients. Migratory polyarthritis sometimes precedes localization of the infection. If the bacteria invade the hip, pain may occur in the groin, upper thigh, or buttock, or may be referred to the knee.

ADVANCED PRACTICE

Other types of arthritis and treatment

You may care for patients with several other types of arthritis besides septic arthritis. The information below will help you differentiate among those types.

Traumatic arthritis

Traumatic arthritis results from blunt, penetrating, or repeated trauma or from forced inappropriate motion of a joint or ligament. Clinical effects may include swelling, pain, tenderness, joint instability, and internal bleeding.

Treatment includes analgesics, anti-inflammatory drugs, application of cold followed by heat and, if needed, compression dressings, splints, joint aspiration, casting or, possibly, surgery

Schönlein-Henoch purpura

Schönlein-Henoch purpura is a vasculitic syndrome marked by palpable purpura, abdominal pain, renal disease, and arthralgia that most commonly affects the knees and ankles. It produces swollen, warm, tender joints without joint erosion or deformity.

Most patients have microscopic hematuria and proteinuria 4 to 8 weeks after onset. Incidence is highest in children and young adults, occurring most often in the spring after a respiratory tract infection.

Treatment may include corticosteroids.

Hemophilic arthritis

Hemophilic arthritis may arise when the patient is between ages 1 and 5 and tends to recur until about age 10. It produces transient or permanent joint changes. Attacks are typically precipitated by trauma, but they may be spontaneous.

Hemophilic arthritis usually affects only one joint at a time—most commonly the knee, elbow, or ankle—and tends to recur in the same joint. Initially, the patient may feel only mild discomfort; later, he may experience warmth, swelling, tenderness, and severe pain with adjacent muscle spasms that prompt him to hold the extremity in a flexed position. Mild hemophilic arthritis causes limited stiffness that subsides within a few days.

Severe hemophilic arthritis may be accompanied by fever and leukocytosis; severe, prolonged, or repeated bleeding can lead to chronic hemophilic joint disease.

Treatment includes I.V. infusion of the deficient clotting factor, bed rest with the affected extremity elevated, application of ice packs, analgesics, and possibly joint aspiration. Physical therapy includes progressive range-of-motion and muscle-strengthening exercises to restore motion and to prevent contractures and muscle atrophy.

Intermittent hydrarthrosis

Intermittent hydrarthrosis is a benign and rare condition characterized by regular, recurrent joint effusions. It most commonly affects the knee. The patient may have difficulty moving the affected joint but have no other arthritic symptoms.

The cause of intermittent hydrarthrosis is unknown; it may be linked to familial tendencies, allergies, or menstruation. Onset is usually at or soon after puberty.

There is no effective treatment.

Diagnostic tests

Arthrocentesis allows the collection of a synovial fluid specimen.

Synovial fluid analysis shows gross pus or watery, cloudy fluid of decreased viscosity, typically with 50,000/μl or more white blood cells (WBCs) containing primarily neutrophils. It may also show a lower glucose level than a simultaneous 6-hour postprandial blood glucose level.

Gram stain or culture of the fluid—or a biopsy of the synovial membrane—confirms the diagnosis and identifies the causative organism.

Blood cultures may be positive and confirm the diagnosis even when the synovial culture is negative.

X-rays may be normal for several weeks and usually don't aid the diagnosis; however, radiographic changes may appear as early as a week after infection. These can include distention of the joint capsule, narrowing of the joint space (indicating cartilage damage), and erosion of bone (joint destruction).

Radioisotope joint scan may be used for less accessible joints such as spinal articulations and may help detect infection or inflammation. However, the test by itself isn't diagnostic. Joint bone scans are invariably positive but are useful only in occult sepsis (as in vertebral osteomyelitis).

Countercurrent immunoelectrophoresis measures bacterial antigens in body fluids and helps to guide treatment.

WBC count may be elevated, with many polymorphonuclear cells.

Erythrocyte sedimentation rate is increased.

C-reactive protein may be elevated.

Lactic assay can be used to distinguish septic from nonseptic arthritis.

Treatment

Parenteral antibiotic therapy should begin right away. Treatment may be modified as needed when sensitivity studies of the infecting organism become available. Penicillin G is effective against infections caused by *S. aureus*, *S. pyogenes*, *S. pneumoniae*, *S. viridans*, and *N. gonorrhoeae*. A penicillinase-resistant penicillin such as nafcillin is recommended for penicillin G-resistant strains of *S. aureus*, ampicillin for influenza, and gentamicin for gram-negative bacilli.

Treatment for septic arthritis requires monitoring of progress through frequent analysis of joint fluid cultures, synovial fluid leukocyte counts, and glucose determinations. Bioassays or bactericidal assays of synovial fluid and bioassays of blood may confirm clearing of the infection.

Codeine or propoxyphene can be given for pain, if needed. (Aspirin misleadingly reduces swelling and may mask fever, hindering accurate monitoring of progress.)

The joint may be immobilized with a splint or put into traction until the patient can tolerate movement. As the infection resolves, exercise is added to the treatment regimen to restore strength and mobility.

Needle aspiration (arthrocentesis) to remove grossly purulent joint fluid may be repeated daily until the fluid appears normal. If cultures remain positive or the WBC

count remains elevated, the patient may need arthroscopic surgical drainage to remove resistant infection. (Septic arthritis of the hip requires open surgical drainage.)

Reconstructive surgery is warranted only for severe joint damage and only after all signs of active infection disappear. This usually takes several months. The patient is likely to need arthroplasty or joint fusion. Prosthetic replacement is controversial because it may exacerbate the infection; it has been used successfully when the femoral head or acetabulum has sustained damage.

Nursing diagnoses

u Anxiety u Fear u Impaired physical mobility u Knowledge deficit u Pain u Risk for infection u Self-care deficit

Key outcomes

- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings of comfort and decreased pain.
- u The patient will maintain joint mobility and ROM.
- u The patient will perform activities of daily living within confines of the disorder.
- u The patient and family members will demonstrate mobility regimen.

Nursing interventions

- u Practice aseptic technique with all procedures. Dispose of soiled linens and dressings properly. Prevent contact between immunosuppressed patients and infected patients.
- u Watch for such signs of joint inflammation as heat, redness, swelling, pain, and drainage. Monitor vital signs and fever pattern.
- u Check splints or traction regularly. Keep the joint in proper alignment, but prevent prolonged immobilization. Start ROM exercises as soon as ordered. Begin with passive ROM and isometric exercises, and then add active ROM exercises. When acute inflammation resolves, the patient may resume weight bearing on the affected joint.
- u Monitor pain levels, and provide medication accordingly, especially before exercise. (The pain of septic arthritis tends to be underestimated.) Administer narcotics and analgesics for acute pain and heat or ice packs for moderate pain. Monitor the patient's response.
- u Carefully evaluate the patient's condition after joint aspiration.
- u Encourage the patient to perform as much self-care as his immobility and pain allow. Give him time to perform these activities at his own pace.
- u Throughout therapy, encourage the patient to express his concerns, and answer any questions he has. Offer support and encouragement when appropriate. Whenever possible, include the patient and family members in care decisions.

Patient teaching

- u Explain all treatments, tests, and procedures to the patient. Warn him that needle aspiration is painful.
- u Discuss all prescribed medications and any adverse reactions they may cause. Tell the patient to call his doctor if these symptoms occur. Explain why therapy must be closely monitored.
- u Instruct the patient and family members about the prescribed exercise regimen. Make sure they understand how to perform each exercise and the importance of rest periods to avoid tiring the patient.
- u If the patient needs surgery, explain preoperative and postoperative procedures to him and family members.
- u If the patient needs home I.V. therapy, explain the procedure to him and family members.

Bone disorders

Disorders affecting bone structure and function include hallux valgus, herniated disk, kyphosis, Legg-Calvé-Perthes disease, Osgood-Schlatter disease, osteomyelitis, osteoporosis, Paget's disease, and scoliosis.

HALLUX VALGUS

Hallux valgus is a common, painful foot condition that involves lateral deviation of the great toe at the metatarsophalangeal joint. It occurs with medial enlargement of the first metatarsal head and bunion formation (bursa and callus formation at the bony prominence). It's more common in women.

In congenital hallux valgus, abnormal bony alignment (an increased space between the first and second metatarsal known as metatarsus primus varus) causes bunion formation. In acquired hallux valgus, bony alignment is normal at the outset of the disorder.

Causes

Hallux valgus may be congenital or familial but is more often acquired from degenerative arthritis or prolonged pressure on the foot, especially from narrow-toed, high-heeled shoes, which compress the forefoot.

Complications

Deformity and pain can impair mobility.

Assessment findings

The patient may have a family history of hallux valgus, degenerative arthritis, or both. She may report prolonged pressure on the foot and chronic pain over a bunion. If she has marked hallux valgus, she may complain of pain over the second or third metatarsal heads because they bear more weight than they should.

Inspection shows a laterally deviated great toe, frequently associated with bunion formation. In an advanced stage, a flat, splayed forefoot may develop, with severely curled toes (hammertoes) and formation of a small bunion on the fifth metatarsal. (See [Hammertoe](#).)

Palpation reveals the characteristic tender bunion covered by deformed, hard, erythematous skin and palpable bursa, often distended with fluid.

Diagnostic tests

X-rays confirm the diagnosis by showing medial deviation of the first metatarsal and lateral deviation of the great toe.

Treatment

In the very early stages of acquired hallux valgus, proper shoes and foot care may eliminate the need for further treatment. Other useful measures for early management include felt pads to protect the bunion, foam pads or other devices to separate the first and second toes at night, and a supportive pad and exercises to strengthen the metatarsal arch. Early treatment is vital in patients predisposed to foot problems such as those with rheumatoid arthritis.

If the disease progresses to severe deformity with disabling pain, the patient needs a bunionectomy. After surgery, the toe is immobilized in its corrected position by a soft compression dressing (which may cover the entire foot or just the great toe and the second toe and serves as a splint) or with a short cast (such as a light slipper

spica cast).

The patient may need crutches or controlled weight bearing. Depending on the extent of the surgery, some patients walk on their heels a few days afterward; others must wait 4 to 6 weeks to bear weight on the affected foot. Supportive treatment may include physical therapy, such as warm compresses, soaks, and exercises, and analgesics to relieve pain and stiffness.

Nursing diagnoses

u Anxiety u Fear u Knowledge deficit u Pain u Risk for impaired mobility u Risk for impaired skin integrity u Self-care deficit

Key outcomes

- u The patient will exhibit adequate range of motion and joint mobility.
- u The patient will express feelings of increased comfort and decreased pain.
- u The patient will maintain adequate skin integrity.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient will express feelings of decreased anxiety and fear.

Nursing interventions

- u Encourage the patient to perform as much self-care as her immobility and pain allow. Give her time to perform these activities at her own pace.
- u Administer analgesics to relieve pain as ordered.
- u Before surgery, assess the foot's neurovascular status (temperature, color, sensation, and blanching sign).
- u After bunionectomy, apply ice to reduce swelling. Increase negative venous pressure and reduce edema by elevating the foot or supporting it with pillows.
- u Record the neurovascular status of the patient's toes, including her ability to move them (taking into account the inhibiting effect of the dressing). Perform this check every hour for the first 24 hours, then every 4 hours. Report any change in neurovascular status to the doctor immediately.
- u Prepare the patient for walking by having her dangle her foot over the bedside briefly before she gets up. This increases venous pressure gradually.
- u Encourage the patient to express her concerns about limited mobility, and offer support when appropriate. Answer any questions she has. Give her positive reinforcement for her attempts to adapt to her condition, and point out how her condition is improving. Whenever possible, include the patient in care decisions.

Patient teaching

- u If the patient needs crutches after surgery, teach her how to use them. Make sure she has a proper cast shoe or boot to protect the cast or dressing.
- u Before discharge, instruct the patient to limit activities, to rest frequently with her feet elevated—especially when she feels pain or has edema—and to wear wide-toed shoes and sandals after the dressings are removed.
- u Teach the patient proper foot care, including cleanliness and massages. Show her how to cut her toenails straight across to prevent ingrown nails and infection.
- u Demonstrate exercises the patient can do at home to strengthen her foot muscles such as standing at the edge of a step on her heel and then raising and inverting the top of her foot.
- u Stress the importance of follow-up care and prompt medical attention for painful bunions or corns.
- u If the patient needs surgery, explain all preoperative and postoperative procedures and treatments.

Hammertoe

In hammertoe, the toe assumes a clawlike position caused by hyperextension of the metatarsophalangeal joint, flexion of the proximal interphalangeal joint, and hyperextension of the distal interphalangeal joint, usually under pressure from hallux valgus displacement. This causes a painful corn on the back of the interphalangeal joint and on the bone end and a callus on the sole of the foot, both of which make walking painful. Hammertoe may be mild or severe and can affect one toe or all five.

Hammertoe can be congenital and familial or acquired from repeatedly wearing short, narrow shoes, which puts pressure on the end of the long toe. Acquired hammertoe is usually bilateral and commonly develops in children who rapidly outgrow their shoes and socks.

Treatment

In young children or adults with early deformity, repeated foot manipulation and splinting of the affected toe relieve discomfort and may correct the deformity. Other treatment includes protection of protruding joints with felt pads, corrective footwear (open-toed shoes and sandals or special shoes that conform to the shape of the foot), a metatarsal arch support, and exercises such as passive manual stretching of the proximal interphalangeal joint. Severe deformity requires surgical fusion of the proximal interphalangeal joint in a straight position.

HERNIATED DISK

A herniated disk (also known as a herniated nucleus pulposus or a slipped disk) occurs when all or part of the nucleus pulposus—an intervertebral disk's gelatinous center—extrudes through the disk's weakened or torn outer ring (anulus fibrosus). The resultant pressure on spinal nerve roots or on the spinal cord itself causes back pain and other symptoms of nerve root irritation.

About 90% of herniations affect the lumbar (L) and lumbosacral spine; 8% occur in the cervical (C) spine and 1% to 2% in the thoracic spine. The most common site for herniation is the L4-L5 disk space. Other sites include L5-S1, L2-L3, L3-L4, C6-C7, and C5-C6.

PATHOPHYSIOLOGY

**How a herniated disk develops**

A spinal disk has two parts: the soft center called the nucleus pulposus and the tough, fibrous, surrounding ring called the anulus fibrosus. The nucleus pulposus acts as a shock absorber, distributing the mechanical stress applied to the spine when the body moves.

NORMAL VERTEBRA AND INTERVERTEBRAL DISK

Physical stress—usually a twisting motion—can cause the anulus fibrosus to tear or rupture, allowing the nucleus pulposus to push through (herniate) into the spinal canal. This process allows the vertebrae to move closer together as the disk compresses. This, in turn, causes pressure on the nerve roots as they exit between the vertebrae. Pain and, possibly, sensory and motor loss follow.

A herniated disk can also occur with intervertebral joint degeneration. If the disk has begun to degenerate, minor trauma may cause herniation.

Herniation occurs in three stages: protrusion, extrusion, and sequestration.

Protrusion

The nucleus pulposus presses against the anulus fibrosus.

Extrusion and sequestration

The nucleus pulposus bulges forcefully through the anulus fibrosus, pushing against the nerve root. Then, the anulus fibrosus gives way as the core of the disk bursts through to press against the nerve root.

Lumbar herniation usually develops in people ages 20 to 45 and cervical herniation in those age 45 or older. Herniated disks affect more men than women.

Causes and pathophysiology

Herniated disks may result from severe trauma or strain, or they may be related to intervertebral joint degeneration. In an elderly person with degenerative disk changes, minor trauma may cause herniation. A person with a congenitally small lumbar spinal canal or with osteophytes along the vertebrae may be more susceptible to nerve root compression with a herniated disk. This person is also more likely to exhibit neurologic symptoms. (See [How a herniated disk develops.](#))

Complications

Neurologic deficits (most common) and bowel and bladder problems (with lumbar herniations) are complications of herniated disk.

Assessment findings

Initially, the patient may seek relief for usually unilateral, low back pain radiating to the buttocks, legs, and feet. Typically, he may report a previous traumatic injury or

back strain.

When herniation follows trauma, the patient may tell you that the pain began suddenly, subsided in a few days, and then recurred at shorter intervals and progressive intensity. He may then describe sciatic pain that began as a dull ache in the buttocks and that grows with Valsalva's maneuver, coughing, sneezing, or bending. He may also complain of accompanying muscle spasms and may add that the pain subsides with rest.

Inspection may reveal a patient with limited ability to bend forward and a posture favoring the affected side. In later stages, you may observe muscle atrophy. Palpation may disclose tenderness over the affected region.

Tissue tension assessment may reveal radicular pain from straight leg raising (with lumbar herniation) and increased pain from neck movement (with cervical herniation).

Thorough assessment of the patient's peripheral vascular status—including posterior tibial and dorsalis pedis pulses and skin temperature of the arms and legs—may help to rule out ischemic disease as the cause of leg pain or numbness. (See [Two tests for a herniated disk.](#))

Diagnostic tests

X-ray studies of the spine are essential to show degenerative changes and to rule out other abnormalities. Films may not show a herniated disk because even marked disk prolapse may show up as normal on an X-ray.

Myelography pinpoints the level of the herniation.

Computed tomography scanning shows bone and soft-tissue abnormalities. It can also show spinal canal compression that results from herniation.

ADVANCED PRACTICE

Two tests for a herniated disk

The straight-leg-raising test and its variant, Lasègue's sign, are perhaps the best tests for a herniated disk.

Straight-leg-raising test

Have the patient lie in the supine position. Place one hand on the patient's ilium to stabilize the pelvis and the other hand under the patient's ankle. Slowly raise the patient's leg. If the patient complains of posterior leg (sciatic) pain— *not back pain*— suspect a herniated disk.

Lasègue's sign

To do this test, have the patient lie supine with his thigh and knee flexed (to a 90-degree angle). Resistance and pain as well as loss of ankle or knee-jerk reflex indicate spinal root compression.

Magnetic resonance imaging defines tissues in areas usually obscured by bone on other imaging tests such as those done with X-rays.

Neuromuscular tests can be used to detect sensory and motor loss and leg muscle weakness.

Treatment

Unless neurologic impairment progresses rapidly, initial treatment is conservative, consisting of bed rest (possibly with pelvic traction) for several weeks, supportive devices (such as a brace), heat or ice applications, and exercise. Nonsteroidal anti-inflammatory drugs reduce inflammation and edema at the injury site. Steroidal drugs such as dexamethasone may be prescribed for the same purpose. Muscle relaxants (diazepam or methocarbamol) may help also.

A herniated disk that fails to respond to conservative treatment may require surgery. The most common procedure, laminectomy, involves removing a portion of the lamina and the protruding nucleus pulposus. If laminectomy doesn't alleviate pain and disability, the patient may undergo spinal fusion to stabilize the spine. Laminectomy and spinal fusion may be performed concurrently.

Chemonucleolysis—injection of the enzyme chymopapain into the herniated disk to dissolve the nucleus pulposus—is a possible alternative to a laminectomy. Microdiscectomy can also be used to remove fragments of the nucleus pulposus.

HOME CARE

Coping with a herniated disk

Follow these guidelines for a home care patient with a herniated disk.

- u Discuss all medications with the patient and his caregiver. Describe adverse reactions, especially those that require more immediate attention. If the patient must take a muscle relaxant, tell him to avoid activities that require alertness until he develops a tolerance to the drug's sedative effects.
- u Refer the patient to an occupational therapist.
- u Teach the patient relaxation techniques.
- u Encourage the patient to maintain an appropriate body weight, and discuss proper nutrition.
- u Reinforce proper body mechanics; instruct the patient to lie on his side, not his abdomen. Recommend an extra firm mattress or a bed board.
- u If the patient must wear a brace, advise him to prevent skin breakdown by not using lotions, ointments, or powders on areas where the brace touches the skin. Suggest rubbing alcohol or tincture of benzoin on these areas to toughen the skin. Tell him to keep the skin dry and clean and to wear a snug-fitting T-shirt under the brace.

Nursing diagnoses

u Activity intolerance u Anxiety u Fear u Impaired physical mobility u Pain u Risk for injury u Self-care deficit

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will demonstrate adequate joint mobility and range of motion.

- u The patient will perform activities of daily living within the confines of the disorder.
- u The patient will achieve the highest level of mobility possible within the confines of the disease.
- u The patient will demonstrate methods to prevent injury to himself.

Nursing interventions

- u Assess the patient's pain. With the patient and the doctor, plan a pain-control regimen using such methods as relaxation, transcutaneous electrical nerve stimulation, distraction, heat or ice application, traction, bracing, or positioning in addition to analgesics and muscle relaxants. Give pain medications as ordered and assess the patient's response.
- u Offer supportive care, careful patient teaching, and encouragement to help the patient cope with the discomfort and frustration of chronic back pain and impaired mobility. Include the patient and family members in all phases of his care.
- u Encourage the patient to verbalize his concerns about his disorder. Answer any questions the patient has as honestly as you can.
- u Encourage the patient to perform as much self-care as his immobility and pain allow. Provide him with adequate time to perform these activities at his own pace.
- u Help the patient identify and perform activities that promote rest and relaxation.
- u If the patient is to undergo myelography, question him carefully about allergies to iodides, iodine-containing substances, or seafood because such allergies may indicate sensitivity to a radiopaque contrast agent used in the test. Monitor intake and output. Watch for seizures and an allergic reaction.
- u If the patient is in traction, ensure that the pelvic straps are properly positioned and that the weights are suspended. Periodically remove the traction to inspect skin. Also remember to monitor for deep vein thrombosis.

ALERT During conservative treatment, watch for any deterioration in neurologic status (especially during the first 24 hours after admission), which may indicate an urgent need for surgery. Use antiembolism stockings as prescribed, and encourage the patient to move his legs as allowed. Provide high-topped sneakers or a footboard to prevent footdrop. Work closely with the physical therapy department to ensure a consistent regimen of leg- and back-strengthening exercises. Give plenty of fluids to prevent urinary stasis. Remind the patient to cough, breathe deeply, or blow into bottles or an incentive spirometer to avoid pulmonary complications. Provide thorough skin care. Assess bowel function, and provide a fracture bedpan for the patient on complete bed rest.

- u After laminectomy, microdiscectomy, or spinal fusion, enforce bed rest as ordered. If the patient has a blood drainage system (Hemovac) in use, check the tubing frequently for patency and a secure vacuum seal. Empty the system at the end of each shift as ordered, and record the amount and color of drainage. Report colorless moisture on dressings (possible cerebrospinal fluid leakage) or excessive drainage immediately. Check the neurovascular status of the patient's legs (color, motion, temperature, and sensation).
- u Monitor vital signs, and check for bowel sounds and abdominal distention. Use the logrolling technique to turn the patient. Administer analgesics as ordered, especially about 30 minutes before initial attempts to sit or walk. Assist the patient during his first attempt to walk. Provide a straight-backed chair, and allow him to sit in it briefly.

Patient teaching

- u Teach the patient about treatments, which may include bed rest and pelvic traction; heat application to the area to decrease pain; an exercise program; medications to decrease pain, inflammation, and muscle spasms; and surgery.
- u Before myelography, reinforce previous explanations of the need for this test, and tell the patient to expect some pain. Assure him that he'll receive a sedative before the test, if needed, to keep him as calm and comfortable as possible. After the test, urge the patient to remain in bed with his head elevated (especially if metrizamide was used) and to drink plenty of fluids.
- u If surgery is required, explain all preoperative and postoperative procedures and treatments to the patient and family members.
- u Prepare the patient for discharge. (See [Coping with a herniated disk.](#))

KYPHOSIS

Kyphosis is an anteroposterior spinal curve that causes the back to bow, commonly at the thoracic level but sometimes at the thoracolumbar or sacral level. It was once known as “roundback.” The normal spine has a slightly convex shape, but excessive thoracic kyphosis is abnormal. (See [Depicting kyphosis.](#))

Kyphosis occurs in children and adults. Symptomatic adolescent kyphosis affects more girls than boys and is most common between ages 12 and 16.

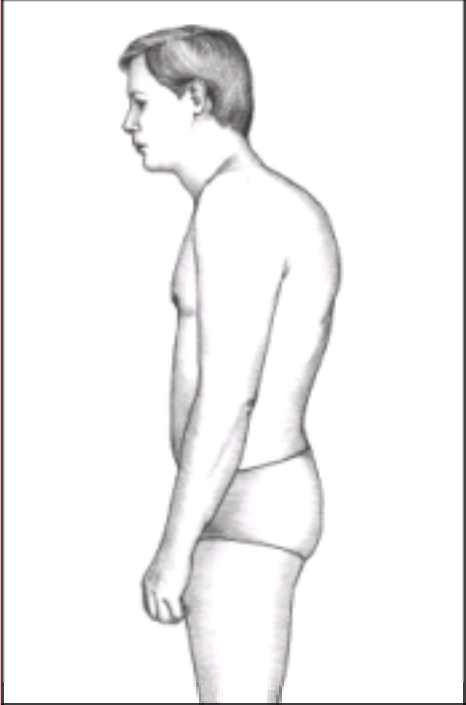

Disk lesions (Schmorl's nodes) may develop in this disorder. These small fingers of nuclear material (from the nucleus pulposus) protrude through the cartilage plates and into the spongy bone of the vertebral bodies. If the protrusion destroys the anterior portions of cartilage, bridges of new bone may form at the intervertebral space and cause ankylosis.

Causes

Adolescent kyphosis (Scheuermann's disease, juvenile kyphosis, and vertebral epiphysitis) is the most common form. No one knows what causes this disease, but some think it results from growth retardation or a vascular disturbance in the vertebral epiphysis (usually at the thoracic level) during rapid growth periods. Other suspected causes include infection, inflammation, aseptic necrosis, and disk degeneration, with subsequent stress of weight bearing on compromised vertebrae, resulting in the thoracic hump seen in adolescents with kyphosis.

Depicting kyphosis

The patient with kyphosis exhibits excessive vertebral curvature in the thoracic spine.

Adult kyphosis (adult roundback) may result from aging and associated intervertebral disk degeneration, atrophy, and vertebral collapse from osteoporosis. The condition may also result from such endocrine disorders as hyperparathyroidism and Cushing's disease or from prolonged steroidal therapy. Additional possible

causes include arthritis, Paget's disease, poliomyelitis, compression fractures of the thoracic vertebrae, metastatic tumor, plasma cell myeloma, or tuberculosis.

In both children and adults, kyphosis may result from poor posture. Rarely, congenital kyphosis occurs. This usually severe condition produces cosmetic deformity and reduces pulmonary function.

Complications

Kyphosis may result in pulmonary complications or neurologic damage, such as spastic paraparesis secondary to spinal cord compression or herniated nucleus pulposus.

Assessment findings

Adolescents with kyphosis may report a history of excessive athletic activity. Adults with kyphosis may have an associated primary condition. Patients in either group may have poor posture.

In about half of affected adolescents, kyphosis may produce mild pain at the apex of the spinal curve. Some patients complain of fatigue, tenderness, or stiffness in the involved area or along the entire spine. Adult patients may also report pain, a weak back, and fatigue.

Inspection may reveal poor posture and increased thoracic curvature when the patient stands or bends forward. You may notice varying degrees of curvature and, in some patients, compensatory lordosis. In adolescent and adult forms of kyphosis that aren't due to poor posture alone, the spinal curve doesn't straighten when the patient lies down.

During palpation, you rarely discover local tenderness in adult patients (unless the patient also has senile osteoporosis with recent compression fracture). Local tenderness is common in adolescent patients.

Diagnostic tests

Adolescent kyphosis must be distinguished from tuberculosis and other inflammatory or neoplastic diseases that cause vertebral collapse. The severe pain, bone destruction, and systemic symptoms common with these diseases help to rule out a diagnosis of kyphosis.

X-ray studies may show vertebral wedging, Schmorl's nodes, irregular end plates and, possibly, a 10- to 20-degree scoliotic curve.

Treatment

For kyphosis caused by poor posture alone, treatment may consist of therapeutic exercises, bed rest on a firm mattress (with or without traction), and a brace to correct the spinal curve until the patient stops growing.

Corrective exercises include pelvic tilt to decrease lumbar lordosis, hamstring stretch to overcome muscle contractures, and thoracic hyperextension to flatten the kyphotic curve. Exercises may be performed with or without the brace. Lateral X-rays (every 4 months) can be used to evaluate the success of correction. Gradual weaning from the brace can begin after the spine reaches full skeletal maturity and X-rays demonstrate maximum curve correction and decreased vertebral wedging.

Other treatment for adolescent and adult kyphosis includes management of the underlying disease and spinal arthrodesis to relieve symptoms. Surgery is rarely necessary unless kyphosis causes neurologic damage, a spinal curve over 60 degrees, or intractable and disabling back pain in a skeletally mature patient.

Preoperative measures may include traction. Corrective surgery may involve a posterior spinal fusion (with spinal instrumentation, iliac bone grafting, and plaster casting for immobilization) or an anterior spinal fusion (followed by casting) if kyphosis produces a spinal curve greater than 70 degrees.

Nursing diagnoses

u Anxiety u Body image disturbance u Diversional activity deficit u Pain u Risk for impaired skin integrity u Risk for injury

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will perform meaningful activity in his free time.
- u The patient will demonstrate measures to decrease injury to himself.
- u The patient will maintain adequate skin integrity.
- u The patient will express positive feelings about himself.

Nursing interventions

- u After surgery, check the patient's neurovascular status every 2 to 4 hours for the first 48 hours, and report any changes immediately. Turn the patient often, using the logroll method.
- u If patient-controlled analgesia isn't used, offer an analgesic every 3 to 4 hours.
- u Maintain fluid balance and monitor for ileus.
- u Check the patient's neurologic status every 2 hours.
- u Maintain adequate ventilation and oxygenation.
- u Encourage family support. For an adolescent patient, suggest that family members supply diversional activities. For an adult patient, arrange for alternating periods of rest and activity.
- u If the patient requires a brace, check its condition daily. Look for worn or malfunctioning parts. Carefully assess how the brace fits the patient. Keep in mind that weight changes may alter proper fit.
- u Give meticulous skin care. Check the skin at the cast edges several times daily; use heel and elbow protectors to prevent skin breakdown. Remove antiembolism stockings, if ordered, at least three times per day for at least 30 minutes. Change dressings as ordered.
- u Provide emotional support and encourage communication. Urge the patient and family members to voice their concerns, and answer their questions honestly. Expect more mood changes and depression in the adolescent patient than in the adult patient. Offer frequent encouragement and reassurance.
- u Assess the patient's readiness to make decisions, and include him in care-related decisions. If possible, include family members in all phases of patient care.
- u Assist during suture removal and new cast application (usually about 10 days after surgery). Encourage gradual ambulation (usually beginning with a tilt table in the physical therapy department). As needed, arrange for follow-up care with a social worker and a home health nurse.

Patient teaching

- u For the adolescent patient with kyphosis caused by poor posture, outline the fundamentals of good posture and demonstrate prescribed exercises. Have the patient perform a return demonstration if appropriate. Suggest bed rest to relieve severe pain. Encourage him to use a firm mattress, preferably with a bed board.
- u If the patient has a cast, provide detailed, written care instructions for the cast at discharge. Tell him to immediately report pain, burning, skin breakdown, loss of feeling, tingling, numbness, or cast odor. Urge him to drink plenty of liquids to avoid constipation and to report any illness (especially abdominal pain or vomiting) immediately. Show him how to use proper body mechanics to minimize strain on the spine. Warn him not to lie on his stomach or on his back with his legs flat.
- u If the patient is discharged with a brace, explain its purpose and tell him how and when to wear it. Make sure he understands how to check it daily for proper fit and function. Teach him to perform proper skin care. Advise against using lotions, ointments, or powders that can irritate the skin where it comes in contact with the brace. Warn that only the doctor or orthotist should adjust the brace. (See [Coping with kyphosis.](#))

Coping with kyphosis

Review the following home care tips with the patient and the family:

- u Explain how to perform therapeutic exercises, emphasizing good posture.
- u Remind the patient to use a firm mattress or bed board for support and to use bed rest when pain is severe.
- u Explain the use of the brace, and encourage compliance with the prescribed use.
- u Teach the patient good skin care to prevent skin breakdown due to the brace.
- u Caution the patient that only an orthotist should adjust the brace.

LEGG-CALVÉ-PERTHES DISEASE

Legg-Calvé-Perthes disease—also called coxa plana—is an avascular necrosis of the femoral head. Vascular interruption leads eventually to a flattened femoral head. It's typically a unilateral condition but occurs bilaterally in 15% of patients. It's most common in boys ages 4 to 10 and tends to recur in families.

The disease usually runs its four-stage course in 3 to 4 years. In the first stage, vascular interruption causes necrosis of the femoral head (usually in several months to a year). In the second stage, which may take 1 to 3 years, a new blood supply causes bone resorption and deposition of new bone cells. Deformity may result from pressure on the weakened area. In the third stage, new bone replaces necrotic bone and the femoral head gradually reforms. This process takes 1 to 3 years. The final, or residual, stage involves healing and regeneration, which fixes the joint's shape.

Causes

The cause of Legg-Calvé-Perthes disease isn't known, but metabolic, infectious, or traumatic factors may be involved.

Complications

Legg-Calvé-Perthes disease may lead to permanent disability. It may also lead to premature osteoarthritis later in life from misalignment of the acetabulum and the flattened femoral head.

Assessment findings

The patient may have a family history of the disease. Typically, he has a limp that becomes progressively worse. He may complain of persistent pain in the groin, anterior thigh, or knee that is aggravated by activity and relieved by rest. These symptoms appear during the second stage, when bone resorption and deformity begin.

Inspection may disclose muscle atrophy in the upper thigh and slight shortening of the affected leg. Palpation may reveal restricted hip abduction and internal rotation, and adductor muscle spasm in the affected hip.

Diagnostic tests

Range-of-motion(ROM) tests help to differentiate between Legg-Calvé-Perthes disease (restriction of only the abduction and rotation of the hip) and infection or arthritis (restriction of all motion).

X-rays of the hip confirm the diagnosis. Findings vary with the disease stage.

Magnetic resonance imaging and bone scan reveal classic involvement of the anterolateral portion of the femoral head and can aid early diagnosis.

Aspiration and culture of synovial fluid rule out joint sepsis.

Treatment

The goal of treatment is to retain the femoral head's normal shape. Typically, this is accomplished by containing the femoral head within the acetabulum to protect it from further stress and damage.

Methods of containing the femoral head include prolonged use of braces and casts and surgical correction. The use of braces and casts allows weight bearing while maintaining the femur in an abducted position to keep the head contained by the acetabulum. Conservative therapy lasts 2 to 4 years. Analgesics help relieve pain. Surgical containment involves osteotomy and subtrochanteric derotation, which returns the femoral head to its normal shape and full ROM. Proper placement of the epiphysis allows remodeling with ambulation. Postoperatively, the patient requires a spica cast for about 2 months.

Surgical containment requires shorter treatment periods and less emphasis on compliance compared with prolonged bracing or casting. Which containment method works best is controversial.

Nursing diagnoses

u Altered nutrition: Risk for more than body requirements u Anxiety u Diversional activity deficit u Knowledge deficit u Pain u Risk for impaired skin integrity u Self-care deficit

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will perform activities of daily living within the confines of the disease.
- u The patient will consume a nutritious diet with specified calorie intake.
- u The patient will perform meaningful activities in his spare time.
- u The patient will maintain adequate skin integrity.

Nursing interventions

- u Maintain adequate fluid balance, and provide a diet sufficient for growth. Make sure the diet doesn't cause excessive weight gain, which could make cast replacement necessary, interfering with corrective positioning.
- u Provide diversional activity for the child, alternating periods of rest and play. Arrange for tutoring for a school-age child if possible.
- u Allow the patient to perform as much self-care as his immobility and pain allow. Give him time to perform these activities at his own pace.
- u Provide thorough cast care. While the cast is still wet, turn the child every 2 to 3 hours to expose the cast to air. Use the palms of your hands rather than your fingers against the wet cast to avoid making depressions in it that could lead to pressure ulcers.

- u After the cast dries, petal it with tape or moleskin. Change the petals as they become soiled. Protect the cast with a plastic cover during each bowel movement.
- u Watch for complications. Check the child's toes for color, temperature, swelling, sensation, and motion; report dusky, cool, numb toes immediately. Check the skin under the cast with a flashlight every 4 hours while the patient is awake.
- u Follow a consistent plan of washing, drying (use alcohol), and rubbing the skin under cast or brace edges to improve circulation and prevent skin breakdown. Never use oils or powders under the cast because they encourage skin breakdown and soften the cast. Check under the cast daily for odors to detect skin breakdown or wound problems. Report persistent soreness.
- u Administer analgesics as ordered, and assess the patient's response.
- u Relieve itching by using a hair dryer (set on cool) at the cast edges. This technique also decreases dampness from perspiration. If itching becomes excessive, obtain an order for an antipruritic.
- u Provide emotional support to the child and parents, and encourage them to express their concerns. Include them in all phases of care.

Patient teaching

- u Explain all treatments, tests, and procedures to the patient and family members.
- u Make sure that the patient and family members understand the rationale for braces and know how to apply and remove them properly.
- u Teach the patient and the parents proper cast care. Tell them never to insert an object under the cast to scratch an itchy area. Discuss how to recognize signs of skin breakdown. Offer tips on ways to ease home management of the bedridden child. Tell parents which special supplies they need: pajamas and trousers a size larger than usual (opened at the side seam, with Velcro fasteners), a bedpan, adhesive tape, a moleskin and, possibly, a hospital bed.
- u After the cast is removed, show the patient and family members how to gradually debride dry, scaly skin by applying lotion after bathing.
- u Stress the need for follow-up care to monitor rehabilitation and for home tutoring and socialization to promote normal growth and development.
- u As necessary, refer the patient to an occupational therapist or a home health nurse to help him cope with activities of daily living.

OSGOOD-SCHLATTER DISEASE

Osgood-Schlatter disease—also called osteochondrosis—causes incomplete separation of the epiphysis of the tibial tubercle from the tibial shaft. A mechanical inefficiency of the extensor mechanism may result, causing tendinitis of the knee. It can affect one or both knees and is most common in active adolescent boys.

Causes

Osgood-Schlatter disease may result from traumatic avulsion of the proximal tibial tuberosity at the patellar tendon insertion. Such trauma may be a single violent action or repeated knee flexion against tight quadriceps muscle. Other causes may include locally deficient blood supply and genetic factors.

Complications

This disease can cause irregular growth and partial avascular necrosis of the proximal tibial epiphysis. Without treatment, symptoms persist until the epiphyseal line of the upper end of the tibia closes.

Assessment findings

The patient may complain of constant aching, pain, swelling, and tenderness below the kneecap that worsens during activity. On inspection, you may see obvious soft-tissue swelling, and you may palpate localized heat and tenderness. Palpation may also reveal decreased flexibility and restriction in the hamstrings, triceps surae, and quadriceps muscle.

Another assessment technique involves forcing the tibia into internal rotation while slowly extending the patient's knee from 90 degrees of flexion. At about 30 degrees, such flexion produces pain that subsides immediately after externally rotating the tibia.

Diagnostic tests

X-ray findings may be normal or may show epiphyseal separation and soft-tissue swelling for up to 6 months after onset; eventually, they may show bone fragmentation.

Treatment

Treatment initially involves ice application, nonsteroidal anti-inflammatory drugs, and avoidance of exercises that demand quadriceps contraction. In mild cases, restricting predisposing activities (such as bicycling and running) may relieve symptoms. Rehabilitation exercises reduce inflexibility and strengthen weak ankle dorsiflexion.

If the patient doesn't respond to this treatment, the affected leg may be immobilized for 6 to 8 weeks with a reinforced elastic knee support, plaster cast, or splint. The leg isn't fully immobilized unless the pain doesn't respond to more conservative treatment or the patient doesn't comply with treatment. Rarely, conservative measures fail and the patient needs surgery. Such surgery includes removal or fixation of the epiphysis or drilling holes through the tubercle to the main bone to form channels for rapid revascularization.

Nursing diagnoses

- u Altered growth and development u Fear u Impaired physical mobility u Pain u Self-care deficit u Self-esteem disturbance

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will maintain joint mobility and range of motion.
- u The patient will perform activities of daily living within the confines of the disease.
- u The patient will exhibit developmental milestones within the confines of the disease process.
- u The patient will express positive feelings about himself.

Nursing interventions

- u Assess daily for limitation of movement.
- u Administer analgesics as needed, and assess the patient's response to them.
- u Make sure the knee support or splint isn't too tight. If the patient has a cast, keep it dry and clean. Petal it to avoid skin irritation.
- u Provide the patient with crutches if needed.
- u Monitor for muscle atrophy.
- u If the patient needs surgery, monitor his circulation, sensation, and pain afterward, and watch for excessive bleeding.
- u Encourage the patient to perform as much self-care as his immobility and pain allow. Give him time to perform these activities at his own pace. Whenever possible, include the family in the patient's care.
- u Encourage the patient to express his concerns, and answer any questions. Remember that limiting normal activities is difficult for an active teenager. Reassure him that restrictions are temporary.

Patient teaching

- u Teach the patient about the prescribed exercise program, and stress the importance of following it. Make sure he understands the exercises and knows when and

- how often to do them.
- u Teach the patient to use crutches if needed.
 - u Stress the importance of protecting the injured knee by avoiding trauma and repeated flexion (from running, contact sports, and bicycling, for example).
 - u If the patient needs surgery, explain all preoperative and postoperative procedures and treatments to the patient and family members.

OSTEOMYELITIS

Osteomyelitis is a pyogenic bone infection that may be chronic or acute. The disease commonly results from combined traumatic injury—usually minor but severe enough to cause a hematoma—and acute infection originating elsewhere in the body. Osteomyelitis usually remains a local infection, but it can spread through the bone to the marrow, cortex, and periosteum.

Acute osteomyelitis is typically a blood-borne disease that most often affects rapidly growing children, particularly boys. Multiple draining sinus tracts and metastatic lesions characterize the rarer *chronic osteomyelitis*. The incidence of both types of osteomyelitis is declining, except in drug abusers.

In children, the most common disease sites include the lower end of the femur and the upper end of the tibia, humerus, and radius. In adults, the disease commonly localizes in the pelvis and vertebrae and usually results from contamination related to surgery or trauma.

The prognosis for a patient with acute osteomyelitis is good if he receives prompt treatment. The prognosis for a patient with chronic osteomyelitis (more prevalent in adults) is poor.

Causes and pathophysiology

Infection causes osteomyelitis. Bacterial pyogens are the most common agents, but the disease may also result from fungi or viruses. The most common pyogenic organism in osteomyelitis is *Staphylococcus aureus*; others include *Streptococcus pyogenes*, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Proteus vulgaris*.

Typically, these organisms find a culture site in a recent hematoma or a weakened area such as a site of local infection (as in furunculosis). From there, they spread directly to bone. As the organisms grow and produce pus within the bone, pressure builds within the rigid medullary cavity and forces the pus through the haversian canals. A subperiosteal abscess forms, depriving the bone of its blood supply and eventually causing necrosis.

In turn, necrosis stimulates the periosteum to create new bone (involucrum). The old, dead bone (sequestrum) detaches and works its way out through an abscess or the sinuses. By the time the body processes sequestrum, osteomyelitis is chronic.

Complications

Osteomyelitis may lead to chronic infection, skeletal deformities, joint deformities, disturbed bone growth (in children), differing leg lengths, and impaired mobility.

Assessment findings

The patient's history may reveal a previous injury, surgery, or primary infection. The patient may complain of a sudden, severe pain in the affected bone and related chills, nausea, and malaise. He may describe the pain as unrelieved by rest and worse with motion.

The patient's vital signs may show tachycardia and a fever. Inspection may reveal swelling and restricted movement over the infection site. The patient may refuse to use the affected area. Palpation may detect tenderness and warmth over the infection site.

Usually, chronic and acute osteomyelitis have similar clinical features, but chronic infection can persist intermittently for years, flaring up spontaneously after minor trauma. Sometimes the only sign of chronic infection is persistent pus drainage from an old pocket in a sinus tract.

Diagnostic tests

White blood cell (WBC) count shows leukocytosis if the patient has osteomyelitis and the erythrocyte sedimentation rate increases.

Blood culture can be used to identify the pathogen.

X-rays may show bone involvement only after the disease has been active for some time, usually 2 to 3 weeks.

Bone scans can be used to detect early infection. Computed tomography scanning and magnetic resonance imaging may be necessary to determine the extent of infection.

Diagnosis must rule out poliomyelitis, rheumatic fever, myositis, and bone fractures.

Treatment

To decrease internal bone pressure and prevent infarction, treatment for acute osteomyelitis begins even before confirming the diagnosis. After drawing samples for blood culture, high doses of I.V. antibiotics are typically administered; usually, a penicillinase-resistant agent, such as nafcillin or oxacillin, is administered. The infected site may be drained surgically to relieve pressure and remove sequestrum. The infected bone is usually immobilized with a cast or traction, or by complete bed rest. The patient receives analgesics and I.V. fluids as needed.

If an abscess forms, treatment includes incision and drainage, followed by a culture of the drainage. Anti-infective therapy may include systemic antibiotics; intracavitary instillation of antibiotics through closed-system continuous irrigation with low intermittent suction; limited irrigation with a blood drainage system equipped with suction such as a Hemovac; or local application of packed, wet, antibiotic-soaked dressings.

Some patients may receive hyperbaric oxygen therapy to increase the activity of naturally occurring WBCs. Additional measures include using free tissue transfers and local muscle flaps to fill in dead space and increase blood supply.

Chronic osteomyelitis may also require surgery: sequestrectomy to remove dead bone and saucerization to promote drainage and decrease pressure. The typical patient reports severe pain and requires prolonged hospitalization. Unrelieved chronic osteomyelitis in an arm or a leg may require amputation.

Nursing diagnoses

u Activity intolerance u Anxiety u Fear u Fluid volume excess u Impaired physical mobility u Impaired tissue integrity u Knowledge deficit u Pain

Key outcomes

- u The patient will experience increased comfort and decreased pain.
- u The patient will maintain joint mobility and range of motion.
- u The patient will maintain adequate fluid volume; intake will equal output.
- u The patient will maintain adequate tissue perfusion and pulses distally.
- u The patient will perform activities of daily living within the confines of the disease.

Nursing interventions

- u Focus care on controlling infection, protecting the bone from injury, and providing support.
- u Encourage the patient to verbalize his concerns about his disorder. Offer support and encouragement. Include the patient and family members in all phases of his care. Answer questions as honestly as you can.
- u Encourage the patient to perform as much self-care as his condition allows. Allow him adequate time to perform these activities at his own pace.
- u Help the patient identify care techniques and activities that promote rest and relaxation. Encourage him to perform them.
- u Use aseptic technique when changing dressings and irrigating wounds.
- u If the patient is in skeletal traction for compound fractures, cover the pin insertion points with small, dry dressings. Tell the patient not to touch the skin around the pins and wires.
- u Provide a diet high in protein and vitamin C to promote healing.
- u Assess vital signs, wound appearance, and new pain (which may indicate secondary infection) daily.
- u Carefully monitor drainage and suctioning equipment. Keep containers nearby that are filled with the irrigation solution being instilled. Monitor the amount of solution instilled and drained.
- u Support the affected limb with firm pillows. Keep it level with the body; don't let it sag.
- u Provide thorough skin care. Turn the patient gently every 2 hours, and watch for signs of developing pressure ulcers.
- u Provide complete cast care. Support the cast with firm pillows, and petal the edges with pieces of adhesive tape or moleskin to smooth rough edges. Check circulation and drainage. If a wet spot appears on the cast, circle it with a marking pen, and note the time of appearance on the cast. Be aware of how much drainage to expect. Check the circled spot at least every 4 hours. Assess increasing drainage and report as appropriate. Monitor vital signs for excessive blood loss.
- u Protect the patient from mishaps, such as jerky movements and falls, which may threaten bone integrity. Tell him to report sudden pain, unusual bone sensations and noises (crepitus), or deformity immediately. Watch for any sudden malpositioning of the limb, which may indicate fracture.
- u Assess the patient's pain pattern. Give analgesics as needed. Monitor his response.

Patient teaching

- u Explain all test and treatment procedures.
- u Review prescribed medications. Discuss possible adverse reactions to drug administration, and instruct the patient to report them to the doctor.
- u Before surgery, explain all preoperative and postoperative procedures to the patient and family members.
- u Teach the patient techniques for promoting rest and relaxation. Encourage him to perform them.
- u Before discharge, teach the patient how to protect and clean the wound site and, most importantly, how to recognize signs of recurring infection (elevated temperature, redness, localized heat, and swelling).
- u Urge the patient to schedule follow-up examinations and to seek treatment for possible sources of recurrent infection, such as blisters, boils, sties, and impetigo.
- u As necessary, refer the patient to an occupational therapist or a home health nurse to help him manage activities of daily living.

OSTEOPOROSIS

In osteoporosis, a metabolic bone disorder, the rate of bone resorption accelerates, and the rate of bone formation decelerates. The result is decreased bone mass. Bones affected by this disease lose calcium and phosphate and become porous, brittle, and abnormally vulnerable to fracture. Osteoporosis may be primary or secondary to an underlying disease.

Primary osteoporosis can be classified as idiopathic, type I, or type II. Idiopathic osteoporosis affects children and adults. Type I (or postmenopausal) osteoporosis usually affects women ages 51 to 75. Related to the loss of estrogen's protective effect on bone, type I osteoporosis results in trabecular bone loss and some cortical bone loss. Vertebral and wrist fractures are common. Type II (or senile) osteoporosis occurs most commonly between ages 70 and 85. Trabecular and cortical bone loss and consequent fractures of the proximal humerus, proximal tibia, femoral neck, and pelvis characterize type II osteoporosis.

Causes

The cause of primary osteoporosis is unknown, but clinicians suspect these contributing factors:

- u mild but prolonged negative calcium balance resulting from inadequate dietary intake
- u declining gonadal adrenal function
- u faulty protein metabolism caused by estrogen deficiency
- u a sedentary lifestyle.

Secondary osteoporosis may result from prolonged therapy with steroids or heparin, bone immobilization or disuse (as occurs with hemiplegia), alcoholism, malnutrition, rheumatoid arthritis, liver disease, malabsorption, scurvy, lactose intolerance, hyperthyroidism, osteogenesis imperfecta, and Sudeck's atrophy (localized in hands and feet, with recurring attacks).

Complications

Bone fractures are the major complication of osteoporosis. They occur most commonly in the vertebrae, femoral neck, and distal radius.

Assessment findings

The history may typically disclose a postmenopausal patient or one with a condition known to cause secondary osteoporosis. The patient (usually an elderly woman) may report that she bent down to lift something, heard a snapping sound, and felt a sudden pain in her lower back. Or she may say that the pain developed slowly over several years. If the patient has vertebral collapse, she may describe a backache and pain radiating around the trunk. Any movement or jarring aggravates the pain.

Inspection may reveal that the patient has a humped back and a markedly aged appearance. She may report a loss of height. (See [Detecting height loss.](#))

Palpation may reveal muscle spasm. The patient may also have decreased spinal movement with flexion more limited than extension.

Diagnostic tests

Differential diagnosis must exclude other causes of rarefying bone disease, especially those that affect the spine, such as metastatic carcinoma and advanced multiple myeloma.

X-ray studies show characteristic degeneration in the lower thoracolumbar vertebrae. The vertebral bodies may appear flatter and denser than usual. Loss of bone mineral appears in later disease.

Dual or single photon absorptiometry allows measurement of bone mass, which helps to assess the extremities, hips and spine

Serum calcium, phosphorus, and alkaline phosphatase levels remain within normal limits.

Parathyroid hormone levels may be elevated.

Bone biopsy shows thin, porous, but otherwise normal-looking bone.

Computed tomography scanning allows accurate assessment of spinal bone loss.

Bone scans that use a radionuclide agent display injured or diseased areas as darker portions.

Treatment

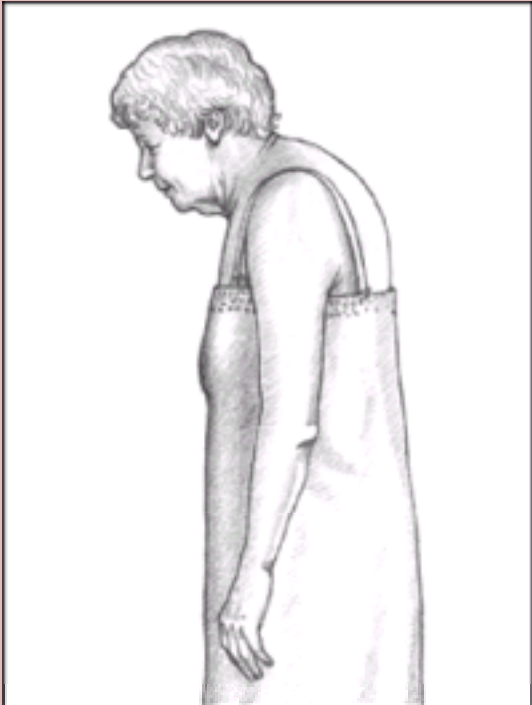

To control bone loss, prevent additional fractures, and control pain, treatment is focused on a physical therapy program of gentle exercise and activity, and drug therapy to slow disease progress. Other treatment measures include supportive devices and, possibly, surgery.

Detecting height loss

Typically, a patient with osteoporosis loses height gradually. A condition known as dowager's hump (shown below) develops when repeated vertebral fractures increase the spinal curvature. (Although a hallmark of osteoporosis, this malformation may occur apart from the disease.)

Reduced thoracic and abdominal volumes, decreased exercise tolerance, pulmonary insufficiency, and abdominal protrusion may accompany height loss.

To assess height loss, have the patient stand with her arms raised laterally and parallel to the floor. A measured difference exceeding 1 1/2 (3.8 cm) between the patient's height and the distance across the outstretched arms (from longest fingertip to longest fingertip) suggests height loss.

Estrogen may be prescribed within 3 years after menopause to decrease the rate of bone resorption. Sodium fluoride may be given to stimulate bone formation. Calcium and vitamin D supplements may help to support normal bone metabolism. Calcitonin may be used to reduce bone resorption and slow the decline in bone mass.

Weakened vertebrae should be supported, usually with a back brace. Surgery (open reduction and internal fixation) can be used to correct pathologic fractures of the femur. Colles' fracture requires reduction and immobilization (with a cast) for 4 to 10 weeks.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Body image disturbance u Impaired physical mobility u Knowledge deficit u Pain u Risk for impaired skin integrity u Risk for injury u Self-care deficit

Key outcomes

- u The patient will maintain adequate dietary intake.
- u The patient will maintain joint mobility and range of motion (ROM).
- u The patient will experience increased comfort and decreased pain.
- u The patient will exhibit intact skin integrity.
- u The patient will demonstrate measures to prevent injury.
- u The patient will perform activities of daily living within the confines of the disease.

Nursing interventions

- u Design your plan of care to consider the patient's fragility. Concentrate on careful positioning, ambulation, and prescribed exercises.
- u Provide emotional support and reassurance to help the patient cope with limited mobility. Give her opportunities to voice her feelings. If possible, arrange for her to interact with others who have similar problems.
- u Include the patient and family members in all phases of care. Answer questions as honestly as you can.
- u Encourage the patient to perform as much self-care as her immobility and pain allow. Allow her adequate time to perform these activities at her own pace.
- u Check the patient's skin daily for redness, warmth, and new sites of pain, which may indicate new fractures.
- u Provide the patient with activities that involve mild exercise; help her to walk several times daily. As appropriate, perform passive ROM exercises, or encourage her to perform active exercises. Make sure she attends scheduled physical therapy sessions.
- u Impose safety precautions. Keep bed rails up. Move the patient gently and carefully at all times. Discuss with ancillary facility personnel how easily an osteoporotic patient's bones can fracture.
- u Provide a balanced diet rich in nutrients that support skeletal metabolism: vitamin D, calcium, and protein.
- u Administer analgesics and heat to relieve pain as ordered. Assess the patient's response.

Patient teaching

- u Explain all treatments, tests, and procedures. For example, if the patient is undergoing surgery, explain all preoperative and postoperative procedures and treatments to the patient and family members.
- u Make sure the patient and family members clearly understand the prescribed drug regimen. Tell them how to recognize significant adverse reactions. Instruct them to report them immediately.
- u Teach the patient taking estrogen to perform breast self-examination. Tell her to perform this examination at least once a month and to report any lumps right away. Emphasize the need for regular gynecologic examinations. Also instruct her to report abnormal vaginal bleeding promptly.
- u If the patient takes a calcium supplement, encourage liberal fluid intake to help maintain adequate urine output and thereby avoid renal calculi, hypercalcemia, and hypercalciuria.

- u Tell the patient to report any new pain sites immediately, especially after trauma.
- u Advise the patient to sleep on a firm mattress and to avoid excessive bed rest.
- u Teach the patient how to use a back brace properly, if appropriate.
- u Thoroughly explain osteoporosis to the patient and family members. If they don't understand the disease process, they may feel needless guilt, thinking that they could have acted to prevent bone fractures.
- u Demonstrate proper body mechanics. Show the patient how to stoop before lifting anything and how to avoid twisting movements and prolonged bending.
- u Encourage the patient to install safety devices, such as grab bars and railings, at home.
- u Advise the patient to eat a diet rich in calcium. Give her a list of calcium-rich foods. Explain that type II osteoporosis may be prevented by adequate dietary calcium intake and regular exercise. Hormonal and fluoride treatments also may help prevent osteoporosis.
- u Explain that secondary osteoporosis may be prevented by effectively treating underlying disease, early mobilization after surgery or trauma, decreased alcohol consumption, careful observation for signs of malabsorption, and prompt treatment of hyperthyroidism.
- u Reinforce the patient's efforts to adapt, and show her how her condition is improving or stabilizing. As necessary, refer her to an occupational therapist or a home health nurse to help her cope with activities of daily living.

PAGET'S DISEASE

Paget's disease—also known as osteitis deformans—is a slowly progressive metabolic bone disease characterized by an initial phase of excessive bone resorption (osteoclastic phase) followed by a reactive phase of excessive abnormal bone formation (osteoblastic phase). The new bone structure, which is chaotic, fragile, and weak, causes painful deformities of the external contour and the internal structures.

Paget's disease usually affects one or several skeletal areas (most commonly the spine, pelvis, femur, and skull). Occasionally, a patient has widely distributed skeletal deformity. In about 5% of patients, the involved bone undergoes malignant changes.

The disease can be fatal, particularly when associated with heart failure (widespread disease creates a continuous need for high cardiac output), bone sarcoma, or giant cell tumors.

Causes

Although the exact cause of Paget's disease isn't known, one theory suggests that a slow or dormant viral infection (possibly mumps) causes a dormant skeletal infection, which surfaces many years later as the disease.

Complications

Involved sites may fracture easily after only minor trauma. These fractures heal slowly and usually incompletely. Vertebral collapse or vascular changes that affect the spinal cord can lead to paraplegia. Bony impingement on the cranial nerves can cause blindness and hearing loss with tinnitus and vertigo.

Other complications include osteoarthritis, sarcoma, hypertension, renal calculi, hypercalcemia, gout, heart failure, and a waddling gait (from softened pelvic bones).

Assessment findings

Clinical effects vary. The patient with early disease may be asymptomatic. As the disease progresses, he may report severe, persistent pain. If abnormal bone impinges on the spinal cord or sensory nerve root, he may complain of impaired mobility and pain increasing with weight bearing.

If the patient's head is involved, inspection may reveal characteristic cranial enlargement over the frontal and occipital areas. The patient may comment that his hat size has increased, and he may have headaches. Other deformities include kyphosis (spinal curvature caused by compression fractures of affected vertebrae) accompanied by a barrel-shaped chest and asymmetrical bowing of the tibia and femur, which typically reduces height. Palpation may disclose warmth and tenderness over affected sites.

Diagnostic tests

X-ray studies performed before overt symptoms develop show bone expansion and increased bone density.

Bone scans (more sensitive than X-rays) clearly show early pagetic lesions (the radioisotope concentrates in areas of active disease).

Bone biopsy may show bone tissue that has a characteristic mosaic pattern.

Red blood cell count indicates anemia.

Serum alkaline phosphatase level—an index of osteoblastic activity and bone formation—is elevated.

A 24-hour urinalysis demonstrates elevated hydroxyproline levels. Hydroxyproline, an amino acid excreted by the kidneys, provides an index of osteoblastic hyperactivity.

Treatment

If the patient is asymptomatic, treatment isn't needed. The patient with symptoms requires drug therapy.

The hormone calcitonin may be given subcutaneously or intramuscularly. The patient requires long-term maintenance therapy with calcitonin; noticeable improvement occurs after the first few weeks of treatment. The patient also may receive oral etidronate to retard bone resorption (and relieve bone lesions) and to reduce serum alkaline phosphatase and urinary hydroxyproline excretion. Etidronate produces improvement after 1 to 3 months.

Mithramycin (a cytotoxic antibiotic used to decrease serum calcium, urinary hydroxyproline, and serum alkaline phosphatase levels) produces remission of symptoms within 2 weeks and biochemically detectable improvement in 1 to 2 months. Mithramycin can destroy platelets or compromise renal function, so it's usually given only to patients who have severe disease, require rapid relief, or don't respond to other treatment.

Self-administration of calcitonin and etidronate helps patients with Paget's disease lead nearly normal lives. Even so, these patients may need surgery to reduce or prevent pathologic fractures, correct secondary deformities, and relieve neurologic impairment. To decrease the risk of excessive bleeding caused by hypervascular bone, drug therapy with calcitonin and etidronate or mithramycin must precede surgery. Joint replacement is difficult because polymethylmethacrylate (a glue-like bonding material) doesn't set properly on bone affected by Paget's disease. Other treatments vary according to symptoms. Aspirin, indomethacin, or ibuprofen typically controls pain.

Nursing diagnoses

- u Impaired physical mobility
- u Knowledge deficit
- u Pain
- u Risk for impaired skin integrity
- u Risk for injury

Key outcomes

- u The patient will express feelings of comfort and decreased pain.
- u The patient will perform activities of daily living within the confines of the disease.

- u The patient will maintain adequate skin integrity.
- u The patient will demonstrate measures to prevent injury to himself.
- u The patient will maintain joint mobility and range of motion.

Nursing interventions

- u Assess the patient's pain level daily to evaluate the effectiveness of analgesic therapy. Watch for new areas of pain or newly restricted movements—which may indicate new fracture sites—and sensory or motor disturbances, such as difficulty in hearing, seeing, or walking.
- u Monitor serum calcium and alkaline phosphatase levels.
- u If bed rest confines the patient for prolonged periods, prevent pressure ulcers with meticulous skin care. Reposition the patient frequently, and use a flotation mattress. Provide high-topped sneakers or a footboard to manage footdrop.
- u Monitor intake and output. Encourage adequate fluid intake to minimize renal calculi formation.

Patient teaching

- u Help the patient adjust to lifestyle changes imposed by Paget's disease. Teach him to pace activities and, if necessary, to use assistive devices.
- u Encourage the patient to follow a recommended exercise program. Urge him to avoid both immobilization and excessive activity.
- u Suggest a firm mattress or a bed board to minimize spinal deformities.
- u Explain all medications to the patient. Instruct him to use analgesic medications cautiously.
- u To prevent falls at home, urge the patient to remove throw rugs and small obstacles from the floor.
- u Emphasize the importance of regular checkups, including the eyes and ears, to assess for complications.
- u Demonstrate how to inject calcitonin properly and how to rotate injection sites. Caution the patient that adverse reactions may occur (including nausea, vomiting, local inflammatory reaction at the injection site, facial flushing, itchy hands, and fever). Reassure him that these reactions are usually mild and occur infrequently.
- u Tell the patient receiving etidronate to take this medication with fruit juice 2 hours before or after meals (milk or other calcium-rich fluids impair absorption), divide the daily dosage to minimize adverse reactions, and watch for and report stomach cramps, diarrhea, fractures, and new or increasing bone pain.
- u Instruct the patient receiving plicamycin to watch for signs of infection, easy bruising, bleeding, and temperature elevation. Urge him to schedule and report for regular follow-up laboratory tests.
- u Refer the patient and family members to community support resources, such as a home health care agency and the Paget's Disease Foundation.

SCOLIOSIS

In scoliosis, a lateral curvature of the spine, the vertebrae rotate into the convex part of the curve. This rotation causes rib prominence along the thoracic spine and waistline asymmetry in the lumbar spine. Scoliosis can affect the spine at any level, but right thoracic curves are most common.

Idiopathic scoliosis affects less than 1% of school-age children and is most common during the growth spurt between ages 10 and 13. It affects boys and girls equally, but spinal curve progression is more common in girls.

This disorder can be classified as nonstructural or structural. In *nonstructural scoliosis*, the spinal curve appears flexible, straightening temporarily when the patient leans sideways. In contrast, *structural scoliosis* is a fixed deformity that doesn't correct itself when the patient leans sideways.

Scoliosis is also classified by age of onset as infantile, juvenile, or adolescent. *Infantile scoliosis* is most common in boys ages 1 to 3. It may resolve spontaneously or it may progress and require treatment. *Juvenile scoliosis* equally affects boys and girls ages 3 to 10. This disorder usually requires long-term follow-up and treatment during the peak growing years. *Adolescent scoliosis* occurs after age 10 and during adolescence.

Causes

Nonstructural scoliosis is commonly related to leg-length discrepancies, poor posture, paraspinal inflammation, or acute disk disease.

Structural scoliosis has no known cause, but it may stem from a congenital or a neuromuscular problem. The disorder affects otherwise healthy children for no known reason.

In congenital structural scoliosis, the vertebrae or the rib cage develops abnormally before birth, making the spine more likely to curve. Common abnormalities include wedge-shaped and block (unseparated) vertebrae. Spinal abnormalities can occur separately or together to cause abnormal curvature. Sometimes multiple spinal abnormalities balance each other, making treatment unnecessary.

Neuromuscular scoliosis may be caused by spinal muscles weakened by Duchenne's muscular dystrophy (marked by a long C-shaped spinal curve), polio, cerebral palsy, or spinal muscular atrophy.

Some types of scoliosis fit no specific category such as that resulting from neurofibromatosis (Recklinghausen's disease). Traumatic scoliosis may derive from vertebral fractures or disk disease. Degenerative scoliosis may develop in older patients with osteoporosis and degenerative joint disease of the spine.

Complications

Untreated or inadequately treated extreme spinal curvature can eventually result in debilitating back pain and severe deformity. Thoracic curves exceeding 60 degrees may reduce pulmonary function. Thoracic curves exceeding 80 degrees heighten the patient's risk for cor pulmonale in middle age.

Assessment findings

The patient history may reveal a family history of scoliosis. Typically, the disorder is detected during a community or school scoliosis screening program or as part of a routine checkup. A parent may notice that the child's hemlines look uneven, pant legs appear unequal in length, or one hip rises higher than the other. Scoliosis rarely produces symptoms until it's well established; then symptoms include backache, fatigue, and dyspnea.

Inspection may reveal signs of scoliosis. For example, to assess thoracic (or trunk) alignment, hold a plumb line (a string with an attached weight) while the patient stands with her back toward you. The plumb line should fall perpendicularly from the center of her head to the cervical spine at C7, through the coccyx (between the gluteal folds), to an area between the feet. Any other angle suggests scoliosis. (See [Testing for scoliosis](#).)

Diagnostic tests

Spinal X-ray studies, including anterior, posterior, and lateral views taken with the patient standing upright and bending, confirm scoliosis and help determine the degree of curvature and flexibility of the spine. X-rays also help determine skeletal maturity, predict remaining bone growth, and show whether the patient has nonstructural or structural scoliosis.

Bone growth studies, though not diagnostic, may help to determine skeletal maturity.

Treatment

The severity of the deformity and potential spine growth determine appropriate treatment, which may include close observation, exercise, a brace, surgery, or a combination of these. Therapy should begin early, while spinal deformity remains subtle. A mild curve of less than 25 degrees should be monitored through X-ray studies and an examination every 3 months. If the curve progresses between 5 degrees and 10 degrees and if the patient is still growing, the doctor may recommend

a brace. An exercise program that includes pelvic tilts, spine hyperextension, push-ups, and breathing exercises may strengthen torso muscles.

A 30- to 50-degree curve requires management with spinal exercises and a brace to prevent the curve from progressing. Transcutaneous electrical nerve stimulation may be used as an alternative in which the spinal muscles are stimulated while the patient sleeps. Electrodes lead to a battery pack, and the device stimulates the paraspinal muscles with a mild electrical charge. The current “pulls” muscles away from the curve, theoretically preventing the curve progression.

ADVANCED PRACTICE

Testing for scoliosis

When assessing your patient for an abnormal spinal curve, use this screening test for scoliosis. Have the patient remove her shirt and stand as straight as she can with her back to you. Instruct her to distribute her weight evenly on each foot. While the patient does this, observe both sides of her back from neck to buttocks. Look for these signs:

- uneven shoulder height and shoulder blade prominence
- unequal distance between the arms and body
- asymmetrical waistline
- uneven hip height
- a sideways lean.

With the patient's back still facing you, ask the patient to do the “forward-bend” test. In this test the patient places her palms together and slowly bends forward, remembering to keep her head down. As she complies, check for these signs:

- asymmetrical thoracic spine or prominent rib cage (rib hump) on either side
- asymmetrical waistline.

Usually, a brace halts progression in most patients but doesn't reverse the established curvature. Such devices passively strengthen the patient's spine by applying asymmetrical pressure to skin, muscles, and ribs. Braces can be adjusted as the patient grows and can be worn until bone growth is complete.

A curve of 40 degrees or more requires surgery (spinal fusion with instrumentation) because such a lateral curve continues to progress at the rate of 1 degree per year even after the patient reaches skeletal maturity.

Surgery is used to correct lateral curvature by posterior spinal fusion and internal stabilization with various rods and spinal hardware, depending on the patient's condition and the preferred surgery.

After spinal fusion, the patient may need to wear a brace until the spine heals and stabilizes. Periodic follow-up examinations are needed for several months.

Nursing diagnoses

- Anxiety
- Body image disturbance
- Fear
- Impaired physical mobility
- Knowledge deficit
- Pain
- Risk for injury

Key outcomes

- The patient will experience feelings of increased comfort and decreased pain.
- The patient will maintain joint mobility and range of motion (ROM) within the confines of the disease.
- The patient will achieve the highest level of mobility possible within the confines of the disease.
- The patient will express positive feelings about herself.
- The patient will demonstrate measures to prevent injury to herself.

Nursing interventions

- Provide emotional support, along with meticulous skin and cast care and patient teaching.
- Encourage the patient to verbalize her concerns about the disorder, and answer her questions honestly. Include the patient and family members in all phases of care.
- Encourage the patient to perform as much self-care as her immobility and pain allow. Provide her with adequate time to perform these activities at her own pace.
- If the patient needs a brace, enlist the help of a physical therapist, a social worker, and an orthotist.
- If the patient needs a body cast, remember that its application can be traumatic because it's done on a special frame with the patient's head and face covered throughout the procedure.
- Check the skin around the cast edge daily. Keep the cast clean and dry. Petal the edges of the cast.
- After corrective surgery, provide the patient with pain medications as ordered, and assess the patient's response to them.
- Check sensation, movement, color, and blood supply in all extremities every 2 to 4 hours for the first 48 hours and then several times per day to detect neurovascular deficit (a serious complication following spinal surgery). Logroll the patient often.
- Measure intake, output, and urine specific gravity to monitor effects of blood loss, which may be substantial.
- Monitor abdominal distention and bowel sounds.
- Encourage deep-breathing exercises to avoid pulmonary complications.
- Promote active ROM arm exercises to help maintain muscle strength. Any exercise, even brushing the hair or teeth, is helpful. Encourage the patient to perform quadriceps-setting, calf-pumping, and active ROM exercises with the feet.

- u Watch for skin breakdown and signs and symptoms of cast syndrome (nausea, abdominal pressure, and vague abdominal pain), which may result from hyperextension of the spine.
- u Remove antiembolism stockings for 30 minutes daily.
- u To help prevent depression that may result from altered body image and immobility, encourage the patient to wear her own clothes, wash her hair, and use makeup.
- u If the patient underwent surgery with spinal instrumentation (such as a Harrington rod), if she's discharged in a cast, or if she must have bed rest, arrange for a social worker and a home health nurse to provide home care.
- u If you work in a school, screen children routinely for scoliosis during physical examinations.

Patient teaching

- u If the patient needs a brace, explain what it does and how to care for it (for example, how to check the screws for tightness and pad the uprights to prevent excessive wear on clothing). Suggest loose-fitting, oversized clothes for greater comfort.
- u Instruct the patient to wear the brace 23 hours per day and to remove it only for bathing and exercise.
- u To prevent skin breakdown, advise the patient not to use lotions, ointments, or powders on areas where the brace contacts the skin. Instead, suggest rubbing alcohol or tincture of benzoin to toughen the skin. Tell her to keep the skin dry and clean and to wear a snug T-shirt under the brace.
- u Advise the patient to increase activities gradually and avoid vigorous sports. Emphasize the importance of conscientiously performing prescribed exercises. Recommend swimming during the 1 hour out of the brace, but strongly warn against diving.
- u Instruct the patient to turn her whole body instead of just her head when looking to the side. To make reading easier, suggest holding a book so she can look straight ahead at it instead of down. If she finds this difficult, help her obtain prism glasses.
- u If the patient has a cast, make sure she and her family members understand proper cast care. Explain cast syndrome. Warn the patient not to insert or let anything get under the cast and to immediately report cracks in the cast, pain, burning, skin breakdown, numbness, or odor.
- u If the patient is having surgery, explain preoperative and postoperative procedures. After surgery, make sure she knows how to recognize complications and measures to take to prevent them. Before discharge, check with the surgeon about activity limitations and make sure the patient understands them.
- u Discuss all prescribed medications with the patient and any adverse reactions. Advise the patient to notify the doctor if these reactions persist.
- u Teach the patient relaxation techniques to promote rest and relaxation, and encourage her to perform them.

Muscle and connective tissue disorders

Diseases that affect the skeletal muscles and connective tissues invariably cause discomfort and restrict movement. Common among these disorders are Achilles tendon contracture, carpal tunnel syndrome, tendinitis and bursitis, and torticollis.

ACHILLES TENDON CONTRACTURE

Achilles tendon contracture, a shortening of the Achilles tendon also known as the tendo calcaneus or heel cord, causes foot pain and strain, with limited ankle dorsiflexion.

Causes

Achilles tendon contracture may reflect a congenital structural anomaly or a muscular reaction to chronic poor posture, especially in women who wear high-heeled shoes or joggers who land on the balls of their feet instead of their heels. Other causes include paralytic conditions, such as poliomyelitis or cerebral palsy.

Complications

Untreated Achilles tendon contracture can produce increasing pain and immobility.

Assessment findings

The patient history may reveal that the patient has a paralytic condition affecting the legs or that he's a runner. He may complain of foot pain, which he describes as spasmodic and most pronounced during dorsiflexion of the foot. If the patient has footdrop (fixed equinus), he may be unable to place his heel on the ground. (This condition is caused by contracture of the flexor foot muscle.)

A simple test confirms Achilles tendon contracture: Have the patient keep his knee flexed as you position his foot in dorsiflexion. With Achilles tendon contracture, gradual knee extension forces the foot into plantar flexion.

Diagnostic tests

A physical examination and patient history suggest Achilles tendon contracture.

Treatment

Conservative measures may help correct Achilles tendon contracture. Among them are raising the inside heel of the shoe in the reflex type of contracture; gradually lowering the heels of shoes (sudden lowering can aggravate the problem) and stretching exercises if the cause is high-heeled shoes; or using support braces or casting to prevent footdrop in a paralyzed patient. Alternatives include using wedged plaster casts or stretching the tendon by manipulation. Analgesics may relieve pain.

With fixed footdrop, treatment may include surgery (tenotomy) to cut the tendon and allow further stretching. After surgery, a short leg cast maintains the foot in 90-degree dorsiflexion for 6 weeks. Some patients begin partial weight bearing after 2 weeks.

Nursing diagnoses

- u Altered tissue perfusion (peripheral) u Impaired physical mobility u Pain u Risk for impaired skin integrity u Risk for injury

Key outcomes

- u The patient will express feelings of comfort and relief of pain.
- u The patient will maintain joint mobility and range of motion.
- u The patient will achieve the highest level of mobility possible within the confines of the disease.
- u The patient will demonstrate actions that prevent injury.
- u The patient will maintain tissue perfusion and circulation.

Nursing interventions

- u After surgery to lengthen the Achilles tendon, elevate the casted foot to decrease venous pressure and edema. Raise the foot of the bed or support the foot with pillows.
- u Check and document the neurovascular status of the toes (temperature, color, sensation, capillary refill time, toe mobility) every hour for the first 24 hours and then every 4 hours. If you detect any changes, increase the elevation of the patient's legs and notify the surgeon immediately.
- u Prepare the patient for ambulation by having him dangle his foot over the side of the bed briefly (5 to 15 minutes) before he gets out of bed. This lets venous pressure increase gradually. Assist the patient in walking as ordered (usually within 24 hours of surgery) using crutches and a non-weight-bearing or touch-down gait.
- u Protect the patient's skin with moleskin or by petaling the edges of the cast.

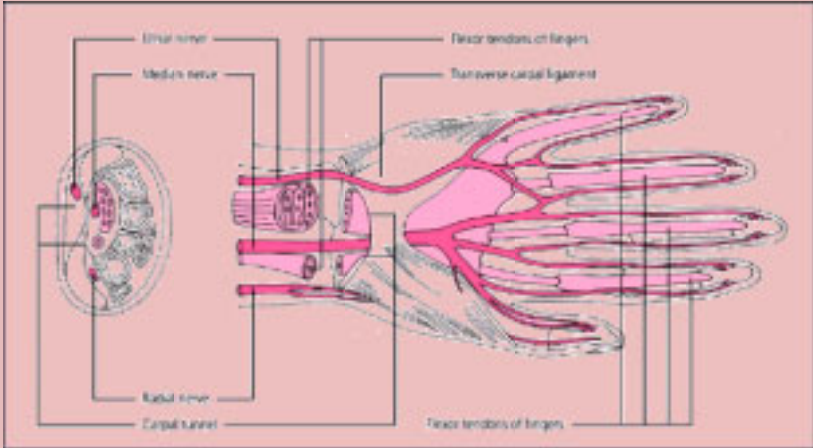

- u To prevent Achilles tendon contracture in paralyzed patients, apply support braces, universal splints, casts, or high-topped sneakers. Make sure the weight of the sheets doesn't keep paralyzed feet in plantar flexion.
- u Administer analgesics as ordered for pain.

Patient teaching

- u Before discharge, teach the patient how to care for the cast. Advise him to elevate his foot regularly when sitting or whenever the foot throbs or swells.
- u Make sure he understands exercise and walking recommendations.
- u Teach meticulous foot care, and urge the patient to seek immediate medical care for foot problems. Warn women against wearing high-heeled shoes constantly, and suggest regular foot (dorsiflexion) exercises.
- u Teach the patient about prescribed analgesics and reportable adverse effects.

Locating the carpal tunnel

The carpal tunnel lies between the longitudinal tendons of the hand-flexing forearm muscles (not shown) and the transverse carpal filament. Note the median nerve and flexor tendons passing through the tunnel on their way from the forearm to the hand.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is the most common nerve entrapment syndrome. It results from compression of the median nerve in the wrist, where it passes through the carpal tunnel. (See [Locating the carpal tunnel.](#))

The median nerve controls motions in the forearm, wrist, and hand, such as turning the wrist toward the body, flexing the index and middle fingers, and many thumb movements. It also supplies sensation to the index, middle, and ring fingers. Compression of this nerve causes loss of movement and sensation in the wrist, hand, and fingers. Carpal tunnel syndrome usually occurs in women between ages 30 and 60 and may pose a serious occupational health problem. It may also occur in people who move their wrists continuously, such as butchers, computer operators, and concert pianists. Any strenuous use of the hands—sustained grasping, twisting, or flexing—aggravates the condition.

Causes

The exact cause of carpal tunnel syndrome is unknown. It may result from amyloidosis or from an edema-producing condition, such as diabetes, rheumatoid arthritis, pregnancy, premenstrual fluid retention, renal failure, and heart failure. (See [Amyloidosis.](#))

Repetitive wrist motions involving excessive flexion or extension also cause the carpal tunnel structures (tendons, for example) to swell and press the median nerve against the transverse carpal ligament. Dislocation or an acute sprain may damage the median nerve. Some experts think that a vitamin B₆ deficiency contributes to carpal tunnel syndrome.

Complications

Continued use of the affected wrist may increase tendon inflammation, compression, and neural ischemia, causing a decrease in wrist function. Untreated carpal tunnel syndrome can produce permanent nerve damage with loss of movement and sensation.

Amyloidosis

Amyloidosis is a rare, chronic disease in which an abnormal fibrillar scleroprotein (amyloid) infiltrates body organs and soft tissues, possibly causing permanent or life-threatening organ damage.

Amyloidosis may be familial, especially with Portuguese ancestry. It's frequently associated with carpal tunnel syndrome or may occur with multiple myeloma or chronic infections, tuberculosis, osteomyelitis, long-term hemodialysis, chronic inflammatory conditions, aging, or Alzheimer's disease.

Assessment may disclose decreased sensations and sweating, macroglossia, dyspnea, coughing, lightheadedness, palpitations, increased clotting time, and distant heart sounds, crackles, or murmurs. Check for abdominal pain, constipation, diarrhea, GI bleeding, malnourishment, decreased bowel sounds, and an enlarged liver. Note morning stiffness and fatigue, decreased muscle strength, and small joint nodules. Raised skin lesions may occur in the axillary, inguinal, or anal regions or on the face, neck, ear, or tongue. Edema may be evident.

Definitive diagnosis requires tissue biopsy to identify amyloid deposits. Rectal mucosa biopsy and abdominal fat pad aspiration are less hazardous than kidney or liver biopsy. Electrocardiography or echocardiography aids diagnosis. Liver function studies are usually normal except for slightly elevated serum alkaline phosphatase levels.

Treatment options include drugs to decrease amyloid deposits, transplantation for renal failure, measures to prevent arrhythmias, total parenteral nutrition for malnutrition, vitamin K for coagulopathy, analgesics for pain, and tracheostomy for macroglossia.

Assessment findings

The history may disclose that the patient's occupation or hobby requires strenuous or repetitive use of the hands. It may reveal a hormonal condition, wrist injury, rheumatoid arthritis, or another condition that causes swelling in carpal tunnel structures.

The patient may complain of weakness, pain, burning, numbness, or tingling in one or both hands. Paresthesia may affect the thumb, forefinger, middle finger, and half of the ring finger. She may report that the paresthesia worsens at night and in the morning (because of vasodilation and venous stasis). She may also report that the pain spreads to the forearm and, in severe cases, as far as the shoulder. She can usually relieve the pain by shaking her hands vigorously or dangling her arms at her sides. Inspection and palpation may show that the patient can't make a fist; her fingernails may be atrophied, with surrounding dry, shiny skin. (See [Eliciting signs](#)

[of carpal tunnel syndrome.\)](#)

Diagnostic tests

Electromyography detects a median nerve motor conduction delay of more than 5 milliseconds.

Digital electrical stimulation discloses median nerve compression by measuring the length and intensity of stimulation from the fingers to the median nerve in the wrist.

A compression test supports the diagnosis. A blood pressure cuff inflated above systolic pressure on the forearm for 1 to 2 minutes provokes pain and paresthesia along the distribution of the median nerve.

Treatment

Treatment is initially conservative: splinting the wrist for 1 to 2 weeks, possible occupational changes, and correction of any underlying disorder. Medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) taken orally and corticosteroids given by injection are the most commonly prescribed agents. NSAIDs, such as indomethacin, mefenamic acid, phenylbutazone, or piroxicam, typically accompany corticosteroid and splinting therapy. They help control pain and reduce inflammation. Corticosteroid injections reduce inflammation almost immediately but only temporarily. If the doctor suspects a vitamin B₆ deficiency, he may prescribe pyridoxine.

When conservative treatment fails, the only alternative is surgical decompression of the nerve by sectioning the entire transverse carpal tunnel ligament. Neurolysis (freeing the nerve fibers) may also be necessary.

Nursing diagnoses

u Altered role performance u Anxiety u Impaired physical mobility u Pain u Self-care deficit

Key outcomes

- u The patient will express feelings of comfort and relief of pain.
- u The patient will maintain muscle strength.
- u The patient will maintain joint mobility and range of motion (ROM).
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient will perform roles within the confines of the disease process.

Nursing interventions

- u Encourage the patient to express her concerns. Listen and offer your support and encouragement.
- u Have her perform as much self-care as her immobility and pain allow. Provide her with adequate time to perform these activities at her own pace.
- u Administer mild analgesics as needed. Encourage the patient to use her hands as much as possible; if the condition has impaired her dominant hand, you may have to help her eat and bathe.
- u After surgery, monitor vital signs, and regularly check the color, sensation, and motion of the affected hand.

Patient teaching

- u Teach the patient how to apply a splint. Advise her not to make it too tight. Show her how to remove the splint to perform gentle ROM exercises (which should be done daily).
- u Advise the patient who's about to be discharged to occasionally exercise her hands in warm water. If she's using a sling, tell her to remove it several times a day to exercise her elbow and shoulder.
- u If the patient requires surgery, explain preoperative and postoperative care procedures.
- u Suggest occupational counseling for the patient who has to change jobs because of carpal tunnel syndrome.
- u Review the prescribed medication regimen. Emphasize that drug therapy may require 2 to 4 weeks before maximum effectiveness is achieved. If the regimen includes indomethacin, mefenamic acid, phenylbutazone, or piroxicam, advise taking the drug with foods or antacids to avoid stomach upset. List possible adverse reactions. Instruct the patient regarding which adverse reactions require immediate medical attention.
- u If the patient is pregnant, advise her to avoid NSAIDs because their effects on the fetus aren't known.

TENDINITIS AND BURSITIS

In tendinitis, inflammation affects the tendons and tendon-muscle attachments to bone, usually in the shoulder rotator cuff, hip, Achilles tendon, hamstring, or elbow. (See [Understanding epicondylitis.](#))

Tendinitis is more common in older people, but it can afflict anyone who performs an activity that overstresses a tendon or repeatedly stresses a joint. (See [Anatomy of tendons and bursae.](#)) The disorder causes localized pain around the affected area and restricts joint movement. Initially, swelling results from fluid accumulation. As the disorder progresses, calcium deposits form in and around the tendon, causing further swelling and immobility.

ADVANCED PRACTICE

Eliciting signs of carpal tunnel syndrome

Two simple tests—for Tinel's sign and Phalen's sign— may confirm carpal tunnel syndrome. The tests prove that certain wrist movements compress the median nerve, causing pain, burning, numbness, or tingling in the hand and fingers.

Tinel's sign

Lightly percuss the transverse carpal ligament over the median nerve where the patient's palm and wrist meet. If this action produces discomfort, such as numbness or tingling, shooting into the palm and fingers, the patient has Tinel's sign.

Phalen's sign

If flexing the patient's wrist for about 30 seconds causes the patient to feel subsequent pain or numbness in her hand or fingers, she has Phalen's sign. The more severe the carpal tunnel syndrome, the more rapidly the symptoms develop.

ADVANCED PRACTICE

Understanding epicondylitis

Epicondylitis (also called tennis elbow) is one of several activity-related joint disorders. It occurs when the forearm extensor supinator tendon fibers become inflamed at their common attachment to the lateral humeral epicondyle.

Epicondylitis may produce acute or subacute pain. It probably begins as a partial tear and is common among tennis players or people whose activities require a forceful grasp, wrist extension against resistance, or frequent forearm rotation.

Signs and symptoms

The patient may initially have elbow pain that gradually increases, radiating to the forearm and back of the hand whenever he grasps an object or twists his elbow. Rarely, the elbow is red, swollen, warm, or restricted in range of motion. The patient may have tenderness over the involved lateral or medial epicondyle or over the head of the radius.

Selective tissue tension assessment may reproduce the pain by wrist extension and supination with lateral involvement or by flexion and pronation with medial epicondyle involvement. Neuromuscular test results may reveal a weak grasp.

Treatment

The patient may receive a local injection of a corticosteroid and anesthetic and systemic nonsteroidal antiinflammatory drugs, such as aspirin or ibuprofen, to relieve pain. Supportive treatment includes:

- ▮ immobilization with a splint from the distal forearm to the elbow, which may relieve pain in 2 to 3 weeks
- ▮ heat therapy with warm compresses, short wave diathermy, or ultrasound (alone or with diathermy)
- ▮ physical therapy to detach the tendon from the chronically inflamed periosteum
- ▮ a “tennis elbow strap” wrapped snugly around the forearm about 1” (2.5 cm) below the epicondyle to relieve the strain on affected forearm muscles and tendons.

If medical and supportive measures fail, surgical release of the tendon at the epicondyle may be necessary.

Bursitis is a painful inflammation of one or more bursae. These closed sacs hold lubricating synovial fluid and facilitate the movement of muscles and tendons over bony prominences. Bursitis causes sudden or gradual pain and limits joint motion. Usually, the disorder occurs in the subdeltoid, subacromial, olecranon, trochanteric, calcaneal, or prepatellar bursae. It may be septic, calcific, acute, or chronic.

Causes

Tendinitis commonly results from trauma (such as strain during a sports activity), another musculoskeletal disorder (rheumatic diseases, congenital defects), postural malalignment, abnormal body development, or hypermobility. In calcific tendinitis, calcium deposits in the tendon cause proximal weakness and, if calcium erodes into adjacent bursae, acute calcific bursitis.

Bursitis usually results from recurring trauma that stresses or pressures a joint or from an inflammatory joint disease, such as rheumatoid arthritis or gout. Chronic bursitis follows attacks of acute bursitis or repeated trauma and infection. Common stressors include repetitive kneeling, such as that done by carpet layers (knee), jogging in worn-out shoes on hard asphalt surfaces (ankle or foot), and prolonged sitting with crossed legs on hard surfaces (hip). Septic bursitis may result from wound infection or from bacterial invasion of the skin over the bursa.

Complications

Untreated tendinitis can produce scar tissue and subsequent disability. As calcium erodes into adjacent tissue, acute calcific bursitis may flare up. Untreated bursitis can cause extreme pain and restricted joint movement.

Assessment findings

In *tendinitis*, the patient history may reveal traumatic injury or strain associated with athletic activity, or the patient may report a concurrent musculoskeletal disorder. The patient with tendinitis may report palpable tenderness over the affected site, referred tenderness in the related segment, or both.

In tendinitis of the *shoulder*, the patient history may disclose restricted shoulder movement (especially abduction) and localized pain that is most severe at night and often interferes with sleep. Significantly, the patient with this disorder may report that heat aggravates shoulder pain rather than provides relief. In tendinitis of the *elbow* (epicondylitis), the patient usually complains of tenderness over the lateral epicondyle and pain when grasping objects or twisting the elbow. In tendinitis of the *hamstring*, the patient may have pain in the posterolateral aspect of the knee and palpable tenderness when he flexes his knee at a 90-degree angle. In tendinitis of the *foot*, the patient may complain of pain over the Achilles tendon and on dorsiflexion. Palpation may reveal crepitus when the patient moves his foot.

In *bursitis*, the patient typically recalls an unusual strain or injury 2 to 3 days before his pain began. The pain, which can develop suddenly or gradually, may limit movement. The patient's work or leisure activity may involve a repetitive action. Usually you can palpate tenderness over the site and, in severe bursitis, swelling.

Other symptoms vary according to the affected site and may include impaired arm abduction (subdeltoid bursitis) or pain when attempting to climb stairs (prepatellar bursitis).

Diagnostic tests

X-rays may appear normal at first in tendinitis but, later, bony fragments, osteophyte sclerosis, or calcium deposits may appear. In early bursitis, X-rays also usually appear normal, except in calcific bursitis, where films show calcium deposits in the joint.

Arthrography results are usually normal in tendinitis with minor irregularities on the tendon undersurface.

Arthrocentesis detects microorganisms and other causes of inflammation if joint infection is suspected.

Additionally, various blood tests and urinalysis may be performed to rule out other disorders.

Treatment

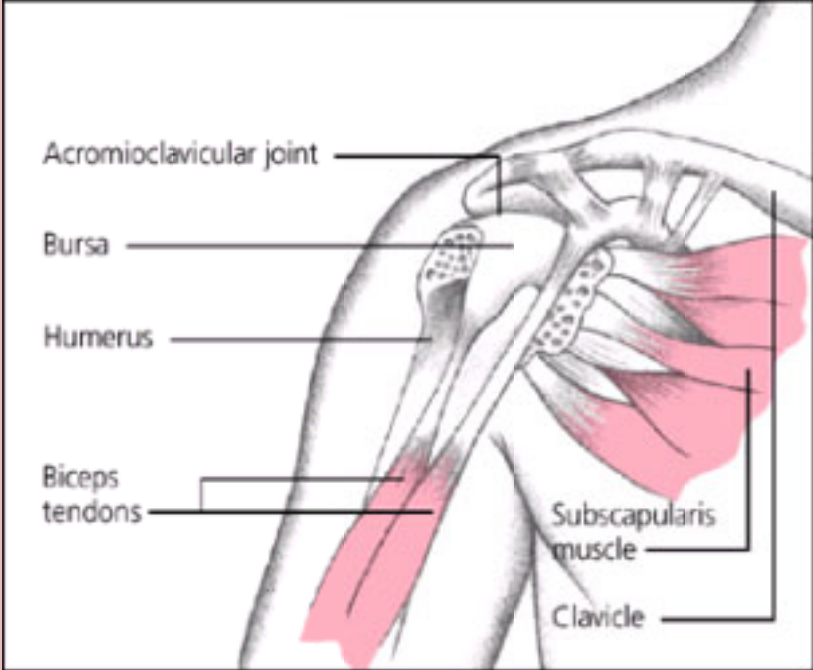

To relieve pain, treatment involves resting the joint (by immobilization); nonsteroidal anti-inflammatory drugs; cold, heat, or ultrasound applications; possible injection of a local anesthetic (such as lidocaine) and corticosteroids for immediate relief; and extended-release corticosteroids, such as triamcinolone or prednisolone, for longer relief.

Until the patient can perform range-of-motion (ROM) exercises easily, treatment also includes oral anti-inflammatory agents and short-term analgesics. Supplementary measures involve fluid removal by aspiration, physical therapy to preserve motion and prevent frozen joints, and heat and cold therapies. Rarely, calcific tendinitis requires surgical removal of calcium deposits. Long-term control of chronic bursitis and tendinitis may require lifestyle changes.

Anatomy of tendons and bursae

Tendons, like stiff rubber bands, hold the muscles in place and enable them to move the bones. Bursae are located at friction points around joints and between tendons, cartilage, or bone. Bursae keep these body parts lubricated so they move freely.

SHOULDER JOINT

The diagram illustrates the anatomical structures of the shoulder joint. Labels include: Acromioclavicular joint, Bursa, Humerus, Biceps tendons, Subscapularis muscle, and Clavicle. The biceps tendons and subscapularis muscle are highlighted in pink.

Nursing diagnoses

u Anxiety u Impaired physical mobility u Knowledge deficit u Pain u Self-care deficit

Key outcomes

u The patient will express decreased pain and increased comfort.

- u The patient will maintain joint mobility and ROM.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient will verbalize understanding of the treatment regimen and disease process.
- u The patient will develop adequate coping mechanisms and decreased anxiety.

Nursing interventions

- u Assess the severity of the patient's pain. Also assess ROM in the affected joint to determine the effectiveness of the treatment.
- u Encourage the patient to verbalize his concerns about his disorder. Listen, answer his questions, and offer support and encouragement. Include the patient and family members in all phases of his care.
- u Encourage the patient to perform as much self-care as his immobility and pain allow. Provide him with adequate time to perform these activities at his own pace.
- u Give medications as ordered, and assess the patient's response to them.
- u Before injecting corticosteroids or local anesthetics, ask the patient if he has any drug allergies.
- u Assist with intra-articular injection. Scrub the patient's skin thoroughly with povidone-iodine (or a comparable solution), and shave the injection site if necessary. After the injection, massage the area to ensure penetration through the tissue and joint space. Apply ice intermittently for about 4 hours to minimize pain. Avoid applying heat to the area for 2 days.

Patient teaching

- u Instruct the patient to take anti-inflammatory agents with milk to minimize GI distress. Direct him to report any signs or symptoms of GI distress immediately.
- u Help the patient identify and perform activities that promote rest and relaxation.
- u Teach the patient how to perform strengthening exercises, and encourage him to follow the prescribed exercise regimen. To maintain joint mobility and prevent muscle atrophy, urge him to perform exercises or physical therapy regularly when he is free from pain.
- u Advise the patient to wear a sling during the first few days of an attack of subdeltoid bursitis or tendinitis to support the arm and protect the shoulder, particularly at night. Demonstrate how to apply and wear the sling to relieve weight on the shoulder. To protect the shoulder during sleep, a splint may be worn instead of a sling. Instruct the patient to remove the splint during the day.
- u Tell the patient with sports-related bursitis or tendinitis to evaluate his sports equipment, shoes, and playing surfaces.
- u If the patient has Achilles tendinitis, recommend that he wear cushioned shoes, lose excess weight, and choose non-weight-bearing activities such as swimming.
- u If the patient needs cold treatments to relieve swelling and pain, show him how to use a commercial cold pack or how to make an ice pack. If he needs heat applications, show him how to apply dry and moist heat. With either therapy, caution him to limit treatments to 20 minutes to prevent skin damage.
- u To prevent recurrence, teach the patient to use proper body mechanics to minimize joint stress.

TORTICOLLIS

In torticollis, a neck deformity also known as wryneck, spastic or shortened sternocleidomastoid neck muscles cause the head to tilt to the affected side and the chin to rotate to the opposite side. The disorder may be congenital or acquired. Congenital (muscular) torticollis mostly affects infants after difficult delivery (breech presentation), firstborn infants, and girls. Acquired torticollis usually develops either before age 10 or after age 40. It may be acute, spasmodic, or hysterical.

Causes

Possible causes of *congenital torticollis* include malposition of the head in utero, prenatal injury, fibroma, interrupted blood supply, or fibrotic rupture of the sternocleidomastoid muscle with hematoma and scar formation. *Acute torticollis* results from muscular damage caused by inflammatory diseases, such as myositis, lymphadenitis, and tuberculosis, and from cervical spinal injuries that produce scar tissue contractures. *Spasmodic torticollis* results from rhythmic muscle spasms caused by an organic central nervous system (CNS) disorder (probably irritation of the nerve root by arthritis or osteomyelitis). *Hysterical torticollis* results from a psychogenic inability to control the neck muscles.

Complications

Permanent contracture may complicate torticollis.

Assessment findings

In acquired torticollis, the patient history usually reveals gradual onset of painful neck deformity. It may disclose an organic CNS disorder or an inflammatory disorder that causes muscle damage. The patient may complain of recurring and unilateral neck muscle stiffness and pain followed by a drawing sensation and a momentary twitching or contraction that pulls the head to the side.

If the patient is an infant with suspected congenital torticollis, inspection may reveal an enlarged sternocleidomastoid muscle visible at birth and for several weeks afterward. The muscle slowly shrinks (or regresses) over 6 months, although incomplete regression can cause permanent contracture. In severe deformity, the infant's face and head flatten from sleeping on the affected side; this asymmetry gradually worsens.

Palpation reveals an enlarged, firm, and tender sternocleidomastoid muscle in both congenital and acquired torticollis.

Diagnostic tests

X-rays of the cervical spine don't reveal bone or joint disease but may be used to detect an associated disorder.

Treatment

In congenital torticollis, the goal of treatment is to stretch the shortened neck muscle. Nonsurgical treatment for an infant includes passive neck stretching and proper positioning during sleep. For an older child, treatment involves active stretching exercises. Surgical correction should be done during preschool years and only if other therapies fail.

Treatment for acquired torticollis is done to correct the underlying condition. In the acute form, application of heat, cervical traction, and gentle massage may relieve pain. Stretching exercises and a neck brace may relieve symptoms of the spasmodic and hysterical forms.

In elderly patients with acquired torticollis, treatment may include carbidopa-levodopa, carbamazepine, and haloperidol.

Nursing diagnoses

u Anxiety u Body image disturbance u Fear u Impaired mobility u Impaired skin integrity u Pain u Self-care deficit

Key outcomes

- u The patient will express feelings of comfort and relief of pain.
- u The patient will exhibit adequate skin integrity.
- u The patient will perform activities of daily living within the confines of the disease.
- u The patient will perform joint mobility and ROM without difficulty.
- u The patient will express positive feelings about himself.

Nursing interventions

- u To aid early diagnosis of congenital torticollis, observe the infant for limited neck movement. Thoroughly assess his degree of discomfort.
- u Prepare the patient for surgery, if necessary, by shaving his neck to the hairline on the affected side. Also prepare him for possible immobilization with a brace.
- u After corrective surgery, monitor the patient closely for nausea or signs of respiratory complications, especially if he's in cervical traction. Keep suction equipment available to manage possible aspiration.
- u If the patient has an immobilization device such as a brace, monitor circulation, sensation, and color around the device. Inspect the skin around the device for signs of breakdown.
- u Provide emotional support for the patient and family to relieve their anxiety caused by fear, pain, an altered body image, and limitations imposed by treatments.
- u Help the patient begin stretching exercises as ordered as soon he can tolerate them.

Patient teaching

- u Teach parents how to perform stretching exercises with the child. Suggest placing toys or hanging mobiles on the side of the crib opposite the affected side of the child's neck. This encourages the child to move his head and stretch his neck in that direction.
- u Before discharge, emphasize to the patient or his parents the importance of continuing daily heat applications, massages, and stretching exercises as prescribed.
- u Explain that physical therapy is essential to recovery.

INTRODUCTION

Renal and urologic disorders affect more than 8 million Americans, so you're bound to encounter such patients often. To give them the best possible care, you need to know about normal anatomy and physiology. (See [Reviewing renal and urologic anatomy](#).) You also need to know the causes, complications, and typical assessment findings for specific renal and urologic disorders. Your familiarity with diagnostic tests and treatments enables you to explain them to the patient and answer his questions.

Kidneys and homeostasis

By producing and eliminating urine, the kidneys maintain homeostasis. These vital organs regulate the volume, electrolyte concentration, and acid-base balance of body fluids; detoxify the blood and eliminate wastes; regulate blood pressure; and aid in erythropoiesis.

The kidneys eliminate wastes from the body through urine formation (by glomerular filtration, tubular reabsorption, and tubular secretion) and excretion. Glomerular filtration, the process of filtering the blood flowing through the kidneys, depends on the permeability of the capillary walls, vascular pressure, and filtration pressure. The normal glomerular filtration rate (GFR) is about 120 ml/minute.

Clearance measures function

Clearance, the volume of plasma that can be cleared of a substance per unit of time, depends on how renal tubular cells handle a substance that has been filtered by the glomerulus.

- u If the tubules don't reabsorb or secrete the substance, clearance equals the GFR.
- u If the tubules reabsorb it, clearance is less than the GFR.
- u If the tubules secrete it, clearance exceeds the GFR.
- u If the tubules reabsorb and secrete it, clearance is less than, equal to, or greater than the GFR.

The most accurate measure of glomerular function is creatinine clearance. That is because creatinine is only filtered by the glomerulus and not reabsorbed by the tubules.

The transport of filtered substances in tubular reabsorption or secretion may be active (requiring energy expenditure) or passive (requiring no expenditure). For example, energy is required to move sodium across tubular cells (active transport), but none is required to move urea (passive transport). The amount of reabsorption or secretion of a substance depends on the maximum tubular transport capacity for that substance: the greatest amount of a substance that can be reabsorbed or secreted in a minute without saturating the system.

Fluid and acid-base balance

Hormones partially control water regulation by the kidneys. Hormonal control depends on the response of osmoreceptors to changes in osmolality. The two hormones involved are antidiuretic hormone (ADH), produced by the pituitary gland, and aldosterone, produced by the adrenal cortex. ADH alters the collecting tubules' permeability to water. When plasma concentration of ADH is high, the tubules are most permeable to water, so a greater amount of water is reabsorbed, creating a high concentration but small volume of urine. The reverse is true if ADH concentration is low.

Aldosterone regulates sodium and water reabsorption from the distal tubules. A high plasma aldosterone concentration promotes sodium and water reabsorption from the tubules and decreases sodium and water excretion in the urine; a low plasma aldosterone concentration promotes sodium and water excretion.

Aldosterone also helps control the distal tubular secretion of potassium. Other factors that determine potassium secretion include the amount of potassium ingested, the number of hydrogen ions secreted, the level of intracellular potassium, the amount of sodium in the distal tubule, and the GFR.

The countercurrent mechanism is the method by which the kidneys concentrate urine. This mechanism is composed of a multiplication system and an exchange system, which occur in the renal medulla by way of the limbs of the loop of Henle and the vasa recta. It achieves active transport of sodium and chloride between the

loop of Henle and the medullary interstitial fluid. Failure of this mechanism produces polyuria and nocturia.

To regulate acid-base balance, the kidneys secrete hydrogen ions, reabsorb sodium and bicarbonate ions, acidify phosphate salts, and synthesize ammonia, all of which keep the blood at its normal pH of 7.37 to 7.43.

Blood pressure regulation

The kidneys help regulate blood pressure by synthesizing and secreting renin in response to an actual or perceived decline in the volume of extracellular fluid. Renin, in turn, acts on a substrate to form angiotensin I, which is converted to the more potent angiotensin II. Angiotensin II increases arterial blood pressure by peripheral vasoconstriction and stimulation of aldosterone secretion. The resulting increase in the aldosterone level promotes the reabsorption of sodium and water to correct the fluid deficit and renal ischemia.

Reviewing renal and urologic anatomy
<p>The kidneys are located retroperitoneally in the lumbar area, with the right kidney a little lower than the left because of the liver mass above it. The left kidney is slightly longer than the right and closer to the midline. The kidneys assume different locations with changes in body position. The coverings of the kidneys consist of the fibrous (or true) capsule, perirenal fat, renal fascia, and pararenal fat.</p>
<p>Structure of the kidney</p> <p>The gross structure of each kidney includes the lateral and medial margins, the hilus, the renal sinus, and renal parenchyma. The hilus, located at the medial margin, is the indentation where the blood and lymph vessels enter the kidney and the ureter emerges. The hilus leads to the renal sinus, a spacious cavity filled with adipose tissue, branches of the renal vessels, calyces, the renal pelvis, and the ureter. The renal sinus is surrounded by parenchyma, which consists of a cortex and a medulla.</p> <p>The cortex, or outermost layer of the kidney, contains the glomeruli (parts of the nephron), cortical arches (areas that separate the medullary pyramids from the renal surface), columns of Bertin (areas that separate the pyramids from one another), and medullary rays of Ferrein (long, delicate processes from the bases of the pyramids that mix with the cortex).</p> <p>The medulla contains the pyramids (cone-shaped structures of parenchymal tissue), papillae (apical ends of the pyramids through which urine oozes into the minor calyces), and Bellini's ducts (collecting ducts in the pyramids that empty into the papillae).</p> <p>The ureters are a pair of retroperitoneally located, mucosa-lined, fibromuscular tubes that transport urine from the renal pelvis to the urinary bladder. Although the ureters have no sphincters, their oblique entrance into the bladder creates a mucosal fold that produces a sphincterlike action during bladder contraction.</p>
<p>Structure of the bladder</p> <p>The gross structure of the bladder includes the fundus (large, central, posterosuperior portion of the bladder), the apex (anterosuperior region), the body posteroinferior region (containing the ureteral orifices), and the urethral orifice, or neck (most inferior portion of the bladder). The three orifices compose a triangular area called the trigone.</p> <p>The adult urinary bladder is a spherical, muscular sac, with a normal capacity of 300 to 500 ml. It's located anterior and inferior to the peritoneal cavity and posterior to the pubic bones.</p>
<p>Functional units</p> <p>The functional units of each kidney are its 1 million to 3 million nephrons. Each nephron consists of the renal corpuscle and the tubular system.</p> <p>The renal corpuscle includes the glomerulus (a network of minute blood vessels) and Bowman's capsule (an epithelial sac surrounding the glomerulus that is part of the tubular system). The renal corpuscle has a vascular pole, where the afferent arteriole enters and the efferent arteriole emerges, and a urinary pole that narrows to form the beginning of the tubular system.</p> <p>The tubular system includes the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule. The last portion of the nephron consists of the collecting duct.</p>
<p>Vasculature</p> <p>Renal arteries branch into five segmental arteries that supply different areas of the kidneys. The segmental arteries then branch into several divisions from which the afferent arterioles and vasa recta arise. Renal veins follow a similar branching pattern, characterized by stellate vessels and segmental branches, and empty into the inferior vena cava. The tubular system receives its blood supply from a peritubular capillary network of vessels.</p> <p>The ureters receive their blood supply from the renal, vesical, gonadal, and iliac arteries and the abdominal aorta. The ureteral veins follow the arteries and drain into the renal vein. The bladder receives blood through vesical arteries. Vesical veins unite to form the pudendal plexus, which empties into the iliac veins. A rich lymphatic system drains the renal cortex, kidneys, ureters, and bladder.</p>
<p>Innervation</p> <p>The kidneys are innervated by sympathetic branches from the celiac plexus, upper lumbar splanchnic and thoracic nerves, and intermesenteric and superior hypogastric plexuses, which form a plexus around the kidneys. Similar numbers of sympathetic and parasympathetic nerves from the renal plexus, superior hypogastric plexus, and intermesenteric plexus innervate the ureters. Nerves that arise from the inferior hypogastric plexus innervate the bladder. The parasympathetic nerve supply to the bladder controls urination.</p>

Other renal functions

The kidneys secrete erythropoietin in response to decreased oxygen tension in the renal blood supply. Erythropoietin then acts on the bone marrow to increase the production of red blood cells. Renal tubular cells synthesize active vitamin D and help regulate calcium balance and bone metabolism.

ADVANCED PRACTICE

<div></div> <div>Causes of common renal and urologic symptoms</div>	
SYMPTOM	POSSIBLE CAUSE
Dribbling	Prostatic enlargement, urethral strictures, ectopic ureter
Dysuria	Infection
Edema	Nephrotic syndrome, renal failure
Frequency	Infection, diabetes mellitus, excess fluid intake
Hematuria	Glomerular diseases, renal or urologic trauma, neoplasms, renal calculi
Hesitancy	Prostatic enlargement, sphincter dyssynergia
Incontinence	Infection, renal or urologic neoplasms, prolapsed uterus, neurogenic bladder, excess fluid intake
Nocturia	Infection, cardiovascular fluid shift when prone
Oliguria	Renal failure, renal or urologic neoplasms, vascular insufficiency
Proteinuria	Glomerular diseases, infection
Pyuria	Infection
Renal colic	Thrombi, emboli, renal calculi
Urgency	Infection, prostatic disease

Assessment

Assessment requires an accurate patient history, a thorough physical examination, and certain laboratory data.

Patient history

Ask the patient about symptoms that pertain specifically to renal or urologic problems, such as urinary frequency or urgency. (See [Causes of common renal and urologic symptoms](#).) Also ask about any systemic diseases that can produce renal or urologic dysfunction, such as hypertension, diabetes mellitus, or bladder infections. Family history may suggest a genetic predisposition to certain renal diseases such as polycystic kidney disease. Finally, ask which medications the patient has been taking; abuse of analgesics or antibiotics can cause nephrotoxicity.

Physical examination

Carefully observe the patient's overall appearance. Examine the skin for color, turgor, intactness, and texture; mucous membranes for color, secretions, odor, and intactness; eyes for periorbital edema and vision; general activity for motion, gait, and posture; muscle movement for motor function and general strength; and mental status for level of consciousness, orientation, and response to stimuli.

Next, assess the patient for distinctive changes in vital signs that renal disease can cause: hypertension from fluid and electrolyte imbalances and renin-angiotensin system hyperactivity; a strong, fast, irregular pulse due to fluid and electrolyte imbalances; hyperventilation to compensate for metabolic acidosis; and increased susceptibility to infection from decreased resistance. Palpation and percussion may reveal little because, unless the kidneys and bladder are enlarged, they may be hard to palpate, especially if the patient is obese or in pain.

Diagnostic tests

If the patient needs invasive tests, such as cystoscopy, excretory urography, and renal angiography, explain each procedure to allay his anxiety and encourage cooperation. (See [Invasive diagnostic tests in renal and urologic disorders](#).) Afterward, observe the patient closely for complications, such as hypersensitivity to the contrast medium and hemorrhage, and document your findings. Monitor vital signs, intake and output, and general status.

Various laboratory tests show serum levels of chemical substances, such as uric acid, creatinine, and blood urea nitrogen. Tests also reveal urine characteristics, including the presence of red blood cells, white blood cells, casts, and bacteria; specific gravity and pH; and physical properties, such as clarity, color, and odor.

Noninvasive renal and urologic monitoring includes:

- u **Intake and output assessment.** Intake and output measurement is used to assess the patient's hydration status but isn't a valid evaluation of renal function because urine output varies with different types of renal disorders. To provide the most useful and accurate information, use calibrated containers, establish baseline values for the patient, compare measurement patterns, and validate intake and output measurements by weighing the patient daily. Monitor all fluid losses, including blood, emesis, diarrhea, and wound and stoma drainage.

Invasive diagnostic tests in renal and urologic disorders

Invasive diagnostic tests allow the assessment of renal and urologic disorders. Below you'll find the purpose for invasive tests your patient may undergo, with nursing considerations for each test.

Cystoscopy

In cystoscopy, the doctor visualizes the inside of the bladder with a fiber-optic scope to diagnose and sometimes treat a urologic disorder.

Before the procedure, give a sedative or apply a local anesthetic (such as lidocaine gel) as ordered. Afterward, offer increased fluids and administer analgesics. Watch for hematuria and signs of perforation, hemorrhage, and infection.

Cystometry

In cystometry, sterile water or carbon dioxide is used to evaluate intravesical pressure, sensation, and capacity in response to filling.

Before the procedure, observe the patient's voiding and catheterize him for residual urine. During the procedure, document the patient's verbalized sensations and signs of media leakage, and ask him to cough to increase abdominal pressure and determine the effect on intravesical pressure. Afterward, remove the catheter. Again observe the patient's voiding, and catheterize him for residual urine.

Excretory urography

In excretory urography, X-rays and a contrast medium are used to allow visualization of the renal parenchyma, renal pelves, ureters, and bladder.

Before the procedure, ask the patient about previous reactions to contrast media and allergies to shellfish or iodine. Adequately hydrate him. Afterward, watch for signs of a hypersensitivity reaction (chills, dyspnea, fever, increased pulse rate, pruritus, and urticaria). Also watch for hematomas at the injection site.

Nephrotomography

After I.V. injection of a contrast medium, nephrotomography is used to visualize the parenchyma, calyces, and pelvis in layers.

Before the test, ask the patient about previous reactions to contrast media and allergies to shellfish or iodine. Adequately hydrate him. After the test, watch for signs of a hypersensitivity reaction.

Renal angiography

Renal angiography calls for the injection of a contrast medium into a catheter in the femoral artery or vein, allowing the visualization of the arterial tree, capillaries, and venous drainage of the kidneys.

Before the procedure, ask the patient about previous reactions to contrast media and allergies to shellfish or iodine. Adequately hydrate him. Afterward, offer increased fluids, and watch for signs of a hypersensitivity reaction. Watch for hematomas and hemorrhage at the injection site as well as for nephrotoxicity.

Renal scan

A renal scan exhibits renal function by showing the appearance and disappearance of radioisotopes within the kidneys.

Before the procedure, ask the patient about previous reactions to contrast media and allergies to shellfish or iodine. Adequately hydrate him. After the procedure, offer increased fluids, and watch for signs of a hypersensitivity reaction. Dispose of urine following facility guidelines.

Renal biopsy

During renal biopsy, a specimen is obtained to develop a histologic diagnosis and determine therapy and the prognosis.

Before the procedure, make sure the patient's clotting times, prothrombin times, and platelet count are recorded on his chart and that he has undergone excretory urography. Place him in the prone position with his side slightly elevated on a towel or pillow, and clean the skin over the biopsy site.

During the procedure, help the patient maintain the correct position. Tell him to lie still and hold his breath if the biopsy is done at the bedside. In many cases, it's done in the operating room.

Afterward, instruct the patient to breathe normally. Apply gentle pressure to the bandage site. Watch for hemorrhage and hematoma at the biopsy site; also watch for hematuria. Enforce bed rest for 24 hours after the procedure, and offer increased fluids.

Voiding cystourethrography

In voiding cystourethrography, X-rays and a contrast medium are used to determine the size and shape of the bladder and urethra.

Before the procedure, ask the patient about previous reactions to contrast media and allergies to shellfish or iodine. Adequately hydrate him. Catheterize him during the procedure. Afterward, offer him increased fluids, and watch for signs of a hypersensitivity reaction.

Videourodynamic studies

Before the procedure, ask the patient about previous reactions to contrast media and allergies to shellfish or iodine. Adequately hydrate him. Catheterize him during the procedure. Afterward, offer him increased fluids, and watch for signs of a hypersensitivity reaction.
Videourodynamic studies
A videourodynamic study is a combination of fluoroscopy and complex cystometry. It's used to document voiding dysfunction.
Follow the nursing procedures described above for cystometry and voiding cystourethrography.

▫ *Specimen collection.* Meticulous collection is vital for valid laboratory data. If the patient collects the specimen, explain how to clean the meatal orifice properly.

The culture specimen should be caught midstream in a sterile container; a urinalysis specimen should be collected in a clean container, preferably at the first voiding of the day. Begin a 24-hour specimen collection after discarding the first voiding; such specimens commonly require special handling or preservatives. When obtaining a urine specimen from a catheterized patient, don't take the specimen from the collection bag; instead, aspirate a sample through the collection port in the catheter using a sterile needle and a syringe.

Send all urine specimens to the laboratory as soon as possible to avoid degradation and altered values. Unless contraindicated and whenever possible, refrigerate urine until testing can be done.

- *X-rays.* A plain film of the abdomen discloses the size, shape, and position of the kidneys, ureters, and bladder and possible areas of calcification.
- *Ultrasonography.* This safe, painless procedure allows visualization of the renal parenchyma, calyces, pelvis, ureters, and bladder. Because the test doesn't depend on renal function, it's useful in patients with renal failure and in detecting complications after kidney transplantation.

Treatment

Intractable renal or urologic dysfunction may require urinary diversion, dialysis, or kidney transplantation.

Urinary diversion is the creation of an abnormal outlet for excreting urine. Several methods of urinary diversion may be performed: ileal conduit, cutaneous ureterostomy, ureterosigmoidostomy, continent diversions, and bladder augmentation or substitution procedures.

In dialysis, a semipermeable membrane, osmosis, and diffusion imitate normal kidney function by eliminating excess body fluids, maintaining or restoring plasma electrolyte and acid-base balances, and removing waste products and dialyzable toxins from the blood. Dialysis is most often used for patients with acute or chronic renal failure. The most common types are peritoneal dialysis and hemodialysis.

In peritoneal dialysis, a dialysis solution (dialysate) is infused into the peritoneal cavity. Substances then diffuse through the peritoneal membrane. Waste products remain in the solution and are removed.

Hemodialysis separates solutes in an external receptacle by differential diffusion through a cellophane membrane placed between the blood and the dialysate. Because the blood must actually pass out of the body into a dialysis machine, hemodialysis requires an access route to the blood supply by an arteriovenous fistula or cannula or by a bovine or synthetic graft. When caring for a patient with such vascular access routes, monitor the patency of the access route, prevent infection, and promote safety and adequate function. After dialysis, watch for complications, which may include headache, vomiting, agitation, and twitching.

Patients with end-stage renal disease may benefit from kidney transplantation, despite its limitations: a shortage of donor kidneys, the chance of transplant rejection, and the lifelong need for medications and follow-up care. After transplantation, maintain the patient's fluid and electrolyte balance, prevent infection, monitor for rejection, and promote psychological well being.

Congenital renal disorders

Congenital renal disorders are present at birth but may not cause signs and symptoms until much later in life. These disorders include medullary sponge kidney and polycystic kidney disease.

MEDULLARY SPONGE KIDNEY

In medullary sponge kidney, the collecting ducts in the renal pyramids dilate, and cavities, clefts, and cysts form in the medulla. Medullary sponge kidney may affect only a single pyramid in one kidney or all pyramids in both kidneys. An affected kidney may be normal in size, but it's usually somewhat enlarged and spongy.

Because this disorder is usually asymptomatic and benign, it's commonly overlooked until the patient reaches adulthood. Although found in both sexes and in all age-groups, it's usually diagnosed in adolescents and adults ages 30 to 50. The prognosis usually is good.

This disorder is unrelated to medullary polycystic disease, a hereditary disorder. These conditions are similar only in the presence and location of the cysts.

Causes

Medullary sponge kidney may be transmitted as an autosomal dominant trait (but sometimes as a recessive trait). It's generally considered a congenital abnormality.

Complications

In 50% to 60% of patients, complications include formation of calcium oxalate calculi, which lodge in the dilated cystic collecting ducts or pass through a ureter, and infection from duct dilation (in 20% to 30% of patients). Hypertension and renal failure seldom occur, except in patients with severe infection or nephrolithiasis. Secondary impairment of renal function from obstruction and infection occurs in about 10% of patients.

Assessment findings

Clinical features usually appear only as a result of complications and seldom occur before young adulthood. The patient may complain of severe colic, hematuria, burning on urination, urgency, and frequency—all signs and symptoms of a lower urinary tract infection (UTI). He also may report signs and symptoms of pyelonephritis—sudden onset of chills, fever, dull flank pain, and costovertebral angle tenderness.

Diagnostic tests

Excretory urography—usually the key to diagnosis—typically reveals a characteristic flowerlike appearance of the pyramidal cavities when they fill with contrast material. It also may show renal calculi.

Urinalysis is normal unless complications develop, such as an increased white blood cell count and casts with infection, and an increased red blood cell count with hematuria. It may show hypercalciuria or a slight reduction in concentrating ability.

Diagnosis must distinguish medullary sponge kidney from renal tuberculosis, renal tubular acidosis, and healed papillary necrosis. If infection is suspected, calculi should be evaluated.

Treatment

Treatment is focused on preventing or treating complications caused by calculi and infection. Specific measures include increasing fluid intake and monitoring renal

function and urine output. If new symptoms develop, the patient needs immediate evaluation.

Because medullary sponge kidney is benign, surgery is seldom necessary except to remove calculi during acute obstruction. Only serious, uncontrollable infection or hemorrhage necessitates nephrectomy.

Nursing diagnoses

u Altered tissue perfusion (renal) u Altered urinary elimination u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain urine specific gravity within designated limits.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient will maintain hemodynamic stability.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Limit the patient's dietary calcium intake to prevent calculus formation.
- u When the patient is hospitalized for calculi, strain all urine, and give analgesics to relieve pain.
- u Before diagnostic tests that use a contrast medium, ask about previous allergic reaction to shellfish, iodine, or contrast media. If the patient has had such a reaction, the doctor may cancel the test, do a limited study without a contrast medium, or pretreat the patient with antihistamines or steroids.
- u If infection occurs, administer the prescribed antibiotic either I.V. or by mouth.
- u Provide at least 2 L (2.1 qt) of fluids daily by mouth (or parenterally if the patient has difficulty swallowing).

Patient teaching

- u Explain the disorder to the patient and family members. Stress that the condition is benign and the prognosis is good, but warn them to watch for and report any signs of calculus passage or UTI.
- u Explain all tests and demonstrate how to collect a clean-catch urine specimen for culture and sensitivity tests.
- u To prevent UTI, instruct the patient to bathe often and use proper toilet hygiene.

POLYCYSTIC KIDNEY DISEASE

Polycystic kidney disease is an inherited disorder characterized by multiple, bilateral, grapelike clusters of fluid-filled cysts that enlarge the kidneys, compressing and eventually replacing functioning renal tissue. (See [Polycystic kidney](#).) The disease affects males and females equally and appears in two distinct forms. The rare infantile form causes stillbirth or early neonatal death. The adult form has an insidious onset but usually becomes obvious between ages 30 and 50; rarely, it may not cause symptoms until the patient is in his 70s. Renal deterioration is more gradual in adults than in infants, but in both age-groups the disease progresses relentlessly to fatal uremia.

The prognosis in adults varies widely. Progression may be slow, even after symptoms of renal insufficiency appear. When uremic symptoms develop, polycystic disease usually is fatal within 4 years unless the patient receives dialysis.

Causes

Although both types of polycystic kidney disease are genetically transmitted, the incidence in two distinct age groups and the different inheritance patterns suggest two unrelated disorders. The infantile type appears to be inherited as an autosomal recessive trait; the adult type, as an autosomal dominant trait.

Complications

A few infants with this disease survive for 2 years and then die of hepatic complications or renal, respiratory, or heart failure. In adults, this disease can cause recurrent hematuria, life-threatening retroperitoneal bleeding from cyst rupture, proteinuria, and colicky abdominal pain from the ureteral passage of clots or calculi. In most cases, about 10 years after symptoms appear, progressive compression of kidney structures by the enlarging mass produces renal failure.

Assessment findings

Inspection of the neonate with infantile polycystic kidney disease reveals pronounced epicanthal folds, a pointed nose, a small chin, and floppy, low-set ears (Potter facies). The infant also exhibits huge, bilateral, symmetrical masses on his flanks that are tense and can't be transilluminated.

Characteristically, the infant also shows signs of respiratory distress, heart failure and, eventually, uremia and renal failure. Accompanying hepatic fibrosis and intrahepatic bile duct abnormalities may cause portal hypertension and bleeding varices.

The patient with adult polycystic kidney disease commonly is asymptomatic in his 30s and 40s, but he may report polyuria, urinary tract infections (UTIs), and other nonspecific symptoms. Your assessment frequently shows hypertension.

Later assessment reveals overt symptoms caused by the enlarging kidney mass, such as lumbar pain, widening girth, and a swollen or tender abdomen. The patient states that abdominal pain is usually worsened by exertion and relieved by lying down. In advanced stages, palpation easily reveals grossly enlarged kidneys.

ALERT A severe headache with or without a neurologic deficit should be considered a sign of a berry aneurysm. This type of cyst can lead to spontaneous rupture of the vasculature in the brain.

Diagnostic tests

In a patient with polycystic disease, excretory or retrograde urography typically reveals enlarged kidneys, with elongation of the pelvis, flattening of the calyces, and indentations caused by cysts. Excretory urography of the neonate shows poor excretion of contrast medium.

Ultrasonography, tomography, and radioisotopic scans show kidney enlargement and cysts; tomography, computed tomography, and magnetic resonance imaging show multiple areas of cystic damage.

Urinalysis and creatinine clearance tests—nonspecific tests that evaluate renal function—indicate abnormalities.

Diagnosis must rule out renal tumors.

Treatment

Polycystic kidney disease can't be cured. The primary goal of treatment is to preserve renal parenchyma and prevent pyelonephritis. Progressive renal failure requires

treatment similar to that for other types of renal disease, including dialysis or, rarely, kidney transplantation.

When adult polycystic kidney disease is discovered in the asymptomatic stage, careful monitoring is required, including urine cultures and creatinine clearance tests every 6 months. When urine culture reveals infection, the patient needs prompt and vigorous antibiotic treatment even if he has no symptoms.

As renal impairment progresses, selected patients may undergo dialysis, transplantation, or both. Cystic abscess or retroperitoneal bleeding may necessitate surgical drainage; intractable pain (an uncommon symptom) may require surgery. Nephrectomy usually isn't recommended because this disease occurs bilaterally and the infection could recur in the remaining kidney.

Nursing diagnoses

- u Altered family processes
- u Altered tissue perfusion (renal)
- u Fatigue
- u Fluid volume deficit
- u Ineffective individual coping
- u Pain
- u Risk for infection
- u Risk for injury
- u Self-care deficit

Key outcomes

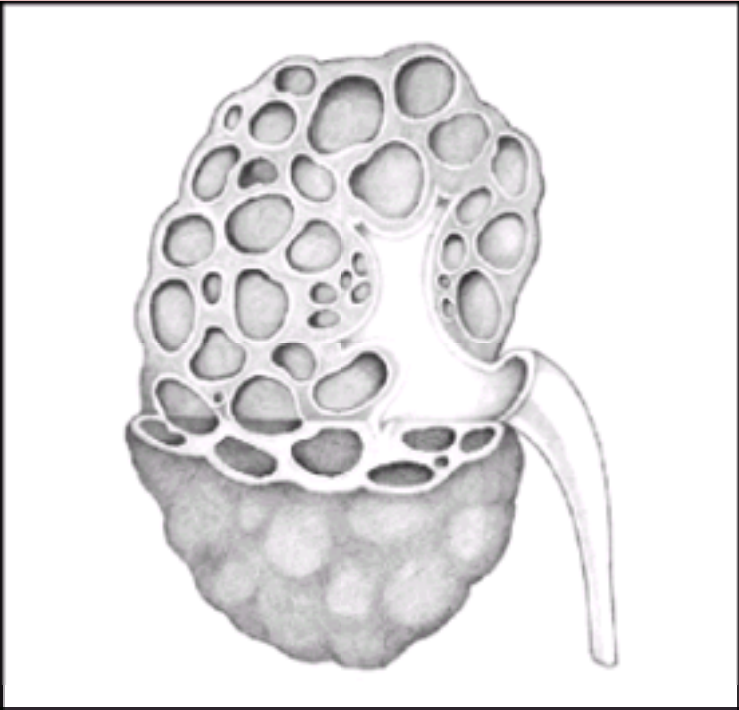

- u The patient will maintain fluid balance.
- u The patient will maintain urine specific gravity within the designated limits.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient will maintain hemodynamic stability.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Provide supportive care to minimize any associated symptoms.
- u Carefully assess the patient's lifestyle and physical and mental state. Determine how rapidly the disease is progressing. Use this information to plan individualized patient care.
- u Encourage the patient to rest, and help with activities of daily living when the patient has abdominal pain. Offer analgesics as needed.
- u Acquaint yourself with all aspects of end-stage renal disease, including dialysis and transplantation, so that you can provide appropriate care and patient teaching as the disease progresses.

Polycystic kidney

The kidney in the cross section below has multicystic damage. Each indentation represents a cyst.

- u Administer antibiotics, as ordered, for UTI. Provide adequate hydration during antibiotic therapy.
- u Screen urine for blood, cloudiness, and calculi or granules. Report any of these findings immediately.
- u Use universal precautions when handling all blood and body fluids.
- u Before beginning excretory urography and other procedures that use an iodine-based contrast medium, ask the patient if he's ever had an allergic reaction to iodine or shellfish. Even if he says no, watch for a possible allergic reaction after the procedures.
- u If the patient requires peritoneal dialysis, position him carefully, elevating the head of the bed to reduce pressure on the diaphragm and aid in respiration. Be alert for signs of infection, such as cloudy drainage, elevated temperature and, rarely, bleeding. If pain occurs, reduce the amount of dialysate. Periodically monitor the diabetic patient's blood glucose levels, and administer insulin as ordered. Watch for complications, such as peritonitis, atelectasis, hypokalemia, pneumonia, and shock.
- u If the patient requires hemodialysis, check the blood access site (arteriovenous fistula or subclavian or femoral catheter) every 2 hours for patency and signs of clotting. Don't use the arm with the shunt or fistula for measuring blood pressure or drawing blood. Weigh the patient before beginning dialysis.

HOME CARE

Coping with polycystic kidney disease

Review the following home care tips with your patient and the family, as applicable:

- u Notify the doctor if daily systolic or diastolic blood pressure readings increase 20 mm Hg above baseline.
- u Limit sodium to help control blood pressure and fluid retention.
- u Tell the patient to weigh himself daily, at the same time, with the same scale, and wearing the same amount of clothes. If weight gain is sudden, or if 5 lb (2.3 kg) are gained in 1 week or less, the doctor should be notified.
- u Review signs of fluid retention to report: peripheral edema, difficulty breathing, abdominal fullness.
- u If urine output suddenly decreases, blood or pus is in the urine, flank pain occurs, urinary pattern changes, or urine is darker or more concentrated, tell the patient to notify the doctor.
- u Fever, nausea, vomiting, weight loss, headaches (unresolved), visual problems, or excessive itching should also be reported.

- u During hemodialysis, monitor vital signs, clotting times, blood flow, vascular access site function, and arterial and venous pressures. Watch for complications, such as septicemia, embolism, hepatitis, and rapid fluid and electrolyte losses.
- u After hemodialysis, monitor vital signs and check the vascular access site. Weigh the patient and watch for signs of fluid and electrolyte imbalances.
- u Allow the patient to verbalize his fears and concerns about the progressive disorder.

Patient teaching

- u Discuss the patient's prognosis, including possible treatments, such as dialysis or transplantation. Answer all questions. (See [Coping with polycystic kidney disease.](#))
- u Explain all diagnostic procedures to the patient or to family members if he's an infant. Review treatments such as dialysis.
- u Discuss prescribed medications and their possible adverse effects. Stress the need to take medications exactly as prescribed, even if symptoms are minimal or absent.
- u Refer the young adult patient or the parents of an infant with polycystic kidney disease for genetic counseling. Parents usually have questions about the risk to other offspring.

Acute renal disorders

Acute renal disorders have a sudden onset. They include acute poststreptococcal glomerulonephritis, acute pyelonephritis, acute renal failure, acute tubular necrosis, renal calculi, and renal vein thrombosis.

ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Acute poststreptococcal glomerulonephritis (also called acute glomerulonephritis) is relatively common. This disorder, a bilateral inflammation of the glomeruli, follows a streptococcal infection of the respiratory tract or, less often, a skin infection such as impetigo. It's most common in boys ages 3 to 7 but can occur at any age. Up to 95% of children and 70% of adults recover fully; the rest, especially elderly patients, may progress to chronic renal failure within months.

Causes and pathophysiology

Acute poststreptococcal glomerulonephritis follows untreated streptococcal infection, especially of the respiratory tract. It results from the entrapment and collection of antigen-antibody complexes (produced as an immunologic mechanism in response to a group A beta-hemolytic streptococcus) in the glomerular capillary membranes, inducing inflammatory damage and impeding glomerular function. Sometimes the immune complement further damages the glomerular membrane. The damaged and inflamed glomeruli lose the ability to be selectively permeable, allowing red blood cells and proteins to filter through as the glomerular filtration rate (GFR) decreases. Uremic poisoning may result.

Complications

Children usually have few complications, but renal function progressively deteriorates in 33% to 50% of adults who contract sporadic acute poststreptococcal glomerulonephritis, often in the form of glomerulosclerosis accompanied by hypertension. The more severe the disorder, the more likely that complications will follow.

Assessment findings

In most cases, acute poststreptococcal glomerulonephritis begins within 1 to 3 weeks after an untreated streptococcal infection in the respiratory tract. The patient or the patient's parents may report decreased urination, smoky or coffee-colored urine, and fatigue. The patient also may experience shortness of breath, dyspnea, and orthopnea. These symptoms of pulmonary edema point to heart failure resulting from hypervolemia.

Assessment findings may show oliguria (with output less than 400 ml/24 hours) and mild to moderate periorbital edema. Findings also may reveal mild to severe hypertension resulting from either sodium or water retention (caused by decreased GFR) or inappropriate renin release.

An elderly patient may complain of vague, nonspecific symptoms, such as nausea, malaise, and arthralgia. Auscultation reveals bibasilar crackles if heart failure is present.

Diagnostic tests

Abnormal blood values (elevated electrolyte, blood urea nitrogen [BUN], and creatinine levels and decreased serum protein levels) and the presence of red blood cells, white blood cells, mixed cell casts, and protein in the urine indicate renal failure. (The proteinuria in an elderly patient usually isn't as pronounced.) Urine frequently contains high levels of fibrin-degradation products and C3 protein.

Elevated antistreptolysin-O titers (in 80% of patients), streptozyme and anti-DNase B titers, and low serum complement levels verify recent streptococcal infection. A throat culture may show group A beta-hemolytic streptococci.

Kidney-ureter-bladder X-rays show bilateral kidney enlargement. A renal biopsy may be necessary to confirm the diagnosis or assess renal tissue status.

Treatment

The goal of treatment in poststreptococcal glomerulonephritis is to eliminate the streptococcal infection with antibiotics and provide supportive therapy until symptoms resolve. The goal of therapy is to relieve symptoms and prevent complications. Vigorous supportive care includes bed rest, fluid and dietary sodium restrictions, and correction of electrolyte imbalances (possibly with dialysis, but this is seldom necessary).

Treatment may include loop diuretics, such as metolazone or furosemide, to reduce extracellular fluid overload, and vasodilators, such as hydralazine or nifedipine. If the patient has a documented staphylococcal infection, antibiotics are recommended for 7 to 10 days; otherwise, their use is controversial.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered role performance u Decreased cardiac output u Fatigue u Fluid volume excess u Impaired gas exchange u Impaired physical mobility u Pain u Risk for infection u Risk for injury u Self-care deficit

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain urine specific gravity within the designated limits.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate the condition and modify his lifestyle accordingly.
- u The patient will maintain hemodynamic stability.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Because acute poststreptococcal glomerulonephritis usually resolves within 2 weeks, nursing care primarily is supportive.

- u Provide bed rest during the acute phase. Perform passive range-of-motion exercises for the patient on bed rest. Allow the patient to resume normal activities gradually as symptoms subside.
- u Check the patient's vital signs and electrolyte values. Assess renal function daily through serum creatinine and BUN levels and urine creatinine clearance tests. Immediately report signs of acute renal failure (oliguria, azotemia, and acidosis).
- u Monitor intake and output and daily weight. Report peripheral edema or the formation of ascites.
- u Consult the dietitian about a diet high in calories and low in protein, sodium, potassium, and fluids.
- u Protect the debilitated patient against secondary infection by providing good nutrition and hygienic technique and by preventing contact with infected people.
- u Provide emotional support for the patient and family members. Encourage the patient to verbalize concerns about the inability to perform in expected roles. Assure them that the activity restrictions are temporary.

Patient teaching

- u Stress to the patient or parents, if the patient is a child, that follow-up examinations are necessary to detect chronic renal failure. Emphasize the need for regular blood pressure, urine protein, and renal function assessments during the convalescent months to detect recurrence. Explain that after acute poststreptococcal glomerulonephritis, gross hematuria may recur during nonspecific viral infections and abnormal urinary findings may persist for years.
- u If the patient is scheduled for dialysis, explain the procedure fully.
- u Advise a patient with a history of chronic upper respiratory tract infections to report signs and symptoms of infection, such as fever and sore throat, immediately.
- u Encourage a pregnant patient with a history of acute poststreptococcal glomerulonephritis to have frequent medical evaluations because pregnancy further stresses the kidneys and increases the risk of chronic renal failure.
- u Explain to a patient taking diuretics that he may experience orthostatic hypotension and dizziness when he changes positions quickly.

ACUTE PYELONEPHRITIS

Acute pyelonephritis (also called acute infective tubulointerstitial nephritis) is one of the most common renal diseases. In this disorder, sudden inflammation is caused by bacterial invasion. It occurs mainly in the interstitial tissue and the renal pelvis, and occasionally in the renal tubules. It may affect one or both kidneys. With treatment and continued follow-up care, the prognosis is good and extensive permanent damage is rare.

Pyelonephritis occurs more often in women than in men, probably because the shorter urethra and the proximity of the urinary meatus to the vagina and rectum allow bacteria to reach the bladder more easily. Women also lack the antibacterial prostatic secretions that men produce.

Typically, the infection spreads from the bladder to the ureters and then to the kidneys, commonly through vesicoureteral reflux. Vesicoureteral reflux may result from congenital weakness at the junction of the ureter and the bladder. Bacteria refluxed to intrarenal tissues may create colonies of infection within 24 to 48 hours.

Causes

Acute pyelonephritis results from bacterial infection of the kidneys. Infecting bacteria usually are normal intestinal and fecal flora that grow readily in urine. The most common causative organism is *Escherichia coli*, but *Proteus*, *Pseudomonas*, *Staphylococcus aureus*, and *Streptococcus faecalis* (enterococcus) can also cause such infections.

Infection may result from procedures that involve the use of instruments (such as catheterization, cystoscopy, and urologic surgery) or from a hematogenic infection (such as septicemia and endocarditis).

Pyelonephritis may result from an inability to empty the bladder (for example, in patients with neurogenic bladder), urinary stasis, or urinary obstruction caused by tumors, strictures, or benign prostatic hyperplasia. Incidence increases with age and is higher in the following groups:

- u *Sexually active women.* Intercourse increases the risk of bacterial contamination.
- u *Pregnant women.* About 5% of pregnant women develop asymptomatic bacteriuria; if untreated, about 40% of these women develop pyelonephritis.
- u *People with obstructive diseases.* Resulting hydronephrosis increases the risk of urinary tract infection (UTI), which can lead to pyelonephritis.
- u *People with neurogenic bladder.* Seen in patients with diabetes, spinal cord injury, multiple sclerosis, and tabes dorsalis, neurogenic bladder causes incomplete emptying and urinary stasis. Frequent catheterization increases the risk of introducing bacteria. Glycosuria may support bacterial growth in urine.
- u *People with other renal diseases.* Compromised renal function increases susceptibility to acute pyelonephritis.

Complications

Associated complications include secondary arteriosclerosis, calculus formation, further renal damage, renal abscesses with possible metastasis to other organs, septic shock, and chronic pyelonephritis. (See [Chronic pyelonephritis](#).)

Assessment findings

A patient with acute pyelonephritis commonly looks ill. She usually complains of pain over one or both kidneys, urinary urgency and frequency, burning during urination, dysuria, nocturia, and hematuria (usually microscopic but possibly gross). Palpating the flank area may increase pain. Urine may appear cloudy and have an ammonia-like or fishy odor. Other common symptoms include a temperature of 102° F (38.9° C) or higher, chills, anorexia, and general fatigue.

The patient usually reports that symptoms developed rapidly over a few hours or a few days. Although these symptoms may disappear within days, even without treatment, residual bacterial infection is likely and can cause recurrence of symptoms.

Diagnostic tests

Diagnosis requires a urinalysis and culture and sensitivity testing. Typical findings include:

- u pyuria. Urine sediment reveals leukocytes singly, in clumps, and in casts and, possibly, a few red blood cells.
- u significant bacteriuria. Urine culture reveals more than 100,000 organisms/μl of urine.
- u low specific gravity and osmolality. These findings result from a temporarily decreased ability to concentrate urine.
- u slightly alkaline urine pH.
- u proteinuria, glycosuria, and ketonuria. These conditions occur less frequently.

Blood tests and X-rays also help in the evaluation of acute pyelonephritis. A complete blood count shows an elevated white blood cell count (up to 40,000/μl) and an elevated neutrophil count. The erythrocyte sedimentation rate is also elevated.

Kidney-ureter-bladder radiography may reveal calculi, tumors, or cysts in the kidneys and the urinary tract. Excretory urography may show asymmetrical kidneys, possibly indicating a high frequency of infection.

Treatment

Treatment centers on antibiotic therapy appropriate to the specific infecting organism after identification by urine culture and sensitivity studies. For example, *Enterococcus* requires treatment with ampicillin, penicillin G, or vancomycin. *Staphylococcus* requires penicillin G or, if the bacterium is resistant, a semisynthetic penicillin such as nafcillin, or a cephalosporin. *Escherichia coli* may be treated with sulfisoxazole, nalidixic acid, or nitrofurantoin; *Proteus*, with ampicillin, sulfisoxazole, nalidixic acid, or a cephalosporin; and *Pseudomonas*, with gentamicin, tobramycin, or carbenicillin.

When the infecting organism can't be identified, therapy usually consists of a broad-spectrum antibiotic, such as ampicillin or cephalexin. Antibiotics must be

prescribed cautiously for elderly patients because of the combined effects of aging and pyelonephritis on renal function. Antibiotics also are used with caution in pregnant patients. In these patients, urinary analgesics such as phenazopyridine can help relieve pain.

ADVANCED PRACTICE

Chronic pyelonephritis

Chronic pyelonephritis is a persistent kidney inflammation that can scar the kidneys and lead to chronic renal failure. Its etiology may be bacterial, metastatic, or urogenous. This disease most frequently occurs in patients who are predisposed to recurrent acute pyelonephritis, such as those with urinary obstructions or vesicoureteral reflux.

Assessment and diagnosis

Patients with chronic pyelonephritis may have a childhood history of unexplained fevers or enuresis. Clinical signs and symptoms include flank pain, anemia, low urine specific gravity, proteinuria, leukocytes in urine, and hypertension. Uremia seldom develops unless structural abnormalities exist in the excretory system. Intermittent bacteriuria may occur.

When no bacteria are found in the urine, diagnosis depends on excretory urography (the patient's renal pelvis may appear small and flattened) and renal biopsy.

Treatment

Effective treatment of chronic pyelonephritis requires control of hypertension, elimination of the obstruction (when possible), and long-term antimicrobial therapy.

Symptoms may disappear after several days of antibiotic therapy. Although urine usually becomes sterile within 48 to 72 hours, the course of such therapy ranges from 10 to 14 days. Follow-up treatment includes reculturing urine 1 week after drug therapy stops and then periodically for the next year to detect residual or recurring infection. A patient with an uncomplicated infection usually responds well to therapy and doesn't suffer reinfection.

If infection results from obstruction or vesicoureteral reflux, antibiotics may be less effective and surgery may be necessary to relieve the obstruction or correct the anomaly. A patient at high risk for recurring urinary tract and kidney infections—for example, a patient with a long-term indwelling catheter or on maintenance antibiotic therapy—requires lengthy follow-up care.

Nursing diagnoses

- u Altered tissue perfusion (renal)
- u Altered urinary elimination
- u Fatigue
- u Fluid volume excess
- u Impaired physical mobility
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain urine specific gravity within the designated limits.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify her lifestyle appropriately.
- u The patient will report increased comfort.
- u The patient will maintain hemodynamic stability.

Nursing interventions

- u Administer antipyretics for fever.
- u Force fluids to achieve a urine output of more than 2,000 ml/24 hours. This helps empty the bladder of contaminated urine and is the best way to prevent calculus formation. Don't encourage intake of more than 2 to 3 L (2.1 to 3.2 qt) because this can decrease the effectiveness of the antibiotics.
- u Provide an acid-ash diet to prevent calculus formation.
- u Observe aseptic technique during catheter insertion and care.
- u Be sure to refrigerate or culture a urine specimen within 30 minutes of collection to prevent overgrowth of bacteria.

Patient teaching

- u Instruct a female patient to avoid bacterial contamination by wiping the perineum from front to back after bowel movements.
- u Teach proper technique for collecting a clean-catch urine specimen.
- u Stress the need to complete the prescribed antibiotic regimen, even after symptoms subside. Encourage long-term follow-up care for a high-risk patient.
- u Advise routine checkups for a patient with a history of UTI. Teach her to recognize signs and symptoms of infection, such as cloudy urine, burning on urination, and urinary urgency and frequency, especially when accompanied by a low-grade fever and back pain.

ACUTE RENAL FAILURE

About 5% of all hospitalized patients develop acute renal failure, the sudden interruption of renal function resulting from obstruction, reduced circulation, or renal parenchymal disease. This condition is classified as *prerenal*, *intrarenal*, or *postrenal* and normally passes through three distinct phases: *oliguric*, *diuretic*, and *recovery*. It's usually reversible with medical treatment. If not treated, it may progress to end-stage renal disease, uremia, and death.

Causes

The three types of acute renal failure each have separate causes. Prerenal failure results from conditions that diminish blood flow to the kidneys. Between 40% and 80% of all cases of acute renal failure are caused by prerenal azotemia. Intrarenal failure (also called intrinsic or parenchymal renal failure) results from damage to the kidneys themselves, usually from acute tubular necrosis. Postrenal failure results from bilateral obstruction of urine outflow. (See [Causes of acute renal failure.](#))

Complications

Ischemic acute tubular necrosis can lead to renal shutdown. Electrolyte imbalance, metabolic acidosis, and other severe effects follow as the patient becomes increasingly uremic and renal dysfunction disrupts other body systems. If left untreated, the patient dies. Even with treatment, an elderly patient is particularly susceptible to volume overload, precipitating acute pulmonary edema, hypertensive crisis, hyperkalemia, and infection.

Assessment findings

The patient's history may include a disorder that can cause renal failure, and he may have a recent history of fever, chills, central nervous system (CNS) problems such as headache, and GI problems, such as anorexia, nausea, vomiting, diarrhea, and constipation.

The patient may appear irritable, drowsy, and confused or demonstrate other alterations in his level of consciousness. In advanced stages, seizures and coma may occur. Depending on the stage of renal failure, his urine output may be oliguric (less than 400 ml/24 hours) or anuric (less than 100 ml/24 hours). (See [Stages of](#)

[acute renal failure.](#))

Inspection may uncover evidence of bleeding abnormalities, such as petechiae and ecchymoses. Hematemesis may occur. The skin may be dry and pruritic and, rarely, you may note uremic frost. Mucous membranes may be dry, and the patient's breath may have a uremic odor. If the patient has hyperkalemia, muscle weakness may occur.

Causes of acute renal failure		
Acute renal failure can be classified as prerenal, intrarenal, or postrenal. All conditions that lead to prerenal failure impair renal perfusion, resulting in decreased glomerular filtration rate and increased proximal tubular reabsorption of sodium and water. Intrarenal failure results from damage to the kidneys themselves; postrenal failure, from obstruction of urine flow.

Auscultation may reveal tachycardia and, possibly, an irregular rhythm. Bibasilar crackles may be heard if the patient has heart failure.

Palpation and percussion may reveal abdominal pain if pancreatitis or peritonitis occurs and may reveal peripheral edema if the patient has heart failure.

Diagnostic tests

Blood test results indicating acute intrarenal failure include elevated blood urea nitrogen, serum creatinine, and potassium levels, and low blood pH, bicarbonate, hematocrit, and hemoglobin levels.

Urine specimens show casts, cellular debris, decreased specific gravity and, in glomerular diseases, proteinuria and urine osmolality close to serum osmolality. The urine sodium level is less than 20 mEq/L if oliguria results from decreased perfusion and more than 40 mEq/L if it results from an intrarenal problem. A creatinine clearance test measures the glomerular filtration rate and allows for an estimate of the number of remaining functioning nephrons.

ADVANCED PRACTICE

<div></div> <div>Stages of acute renal failure</div>		
Before assessing a patient with renal failure, review the stages of the condition, described in the table below.		
STAGE	CHARACTERISTICS	NURSING INTERVENTIONS

Onset (hours to several days)	<p>Begins with the precipitating event, which is often recognized in retrospect. Nitrogenous waste products (blood urea nitrogen [BUN] and creatinine) begin to accumulate in serum.</p> <p>Urine output is 100 to 400 ml/24 hours. Serum shows increasing levels of BUN, creatinine, potassium phosphate, and magnesium and decreasing levels of calcium and bicarbonate. Sodium is increased but is diluted by water retention.</p>	<ul style="list-style-type: none"> None needed.
Oliguric* (usually 1 to 2 weeks)	<p>Kidneys lose ability to concentrate urine; urine is diluted with output of 3,000 to 10,000 ml/24 hours. BUN and creatinine levels begin to decrease. A return to normal BUN and creatinine levels signals the end of this stage. Normal renal tubular function is reestablished unless some residual damage remains.</p> <p>Renal function and electrolyte levels return to normal unless irreversible renal damage has occurred.</p>	<ul style="list-style-type: none"> Monitor the patient closely for fluid overload and electrolyte imbalances. Keep the patient on bed rest to prevent further catabolic metabolism. Give the patient nutritional support in the form of total parenteral nutrition, as ordered. Assess the patient for fluid deficits. Closely monitor electrolyte levels. Gradually increase the patient's activity level. Provide the patient with a high-carbohydrate diet; restrict potassium and protein as needed.
Diuretic (2 to 6 weeks)		<ul style="list-style-type: none"> Continue to monitor the patient's blood levels on an outpatient basis. Instruct the patient to gradually resume his former activities, but inform him that he's still vulnerable to fatigue and renal damage.
Recovery (up to 1 year)		
<p><i>*Note:</i> Some patients don't experience the oliguric phase of acute renal failure.</p>		

An electrocardiogram (ECG) shows tall, peaked T waves; a widening QRS complex; and disappearing P waves if hyperkalemia is present.

Other studies used to determine the cause of renal failure include kidney ultrasonography, plain films of the abdomen, kidney-ureter-bladder radiography, excretory urography renal scan, retrograde pyelography, computed tomography scans, and nephrotomography.

Treatment

Supportive measures include a diet high in calories and low in protein, sodium, and potassium, with supplemental vitamins and restricted fluids. Meticulous electrolyte monitoring is essential to detect hyperkalemia. If hyperkalemia occurs, acute therapy may include hypertonic glucose-and-insulin infusions and sodium bicarbonate—all administered I.V.—and sodium polystyrene sulfonate (Kayexalate) by mouth or enema to remove potassium from the body.

If measures fail to control uremic symptoms, the patient may require hemodialysis or peritoneal dialysis. Early initiation of diuretic therapy during the oliguric phase may benefit the patient. (See [Preventing acute renal failure.](#))

Nursing diagnoses

- Activity intolerance
- Altered family processes
- Altered nutrition: Less than body requirements
- Altered oral mucous membrane
- Decreased cardiac output
- Fatigue
- Fear
- Fluid volume deficit
- Fluid volume excess
- Impaired skin integrity
- Risk for infection
- Risk for injury

Key outcomes

- The patient will maintain fluid balance.
- The patient will maintain urine specific gravity within the designated limits.
- The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- The patient will maintain hemodynamic stability.
- The patient and family members will demonstrate skill in managing the urinary elimination problems.
- The patient will avoid or minimize complications.

Nursing interventions

- Measure and record intake and output of all fluids, including wound drainage, nasogastric tube output, and diarrhea.
- Follow universal precautions during care because the patient with acute renal failure is highly susceptible to infection. Don't allow staff members or visitors with upper respiratory tract infections to come into contact with the patient. Use standard precautions when handling blood and body fluids.
- Be sure to weigh the patient daily. You may need to measure abdominal girth every day. Mark the skin with indelible ink so that measurements can be taken in the same place.

ALERT Evaluate all drugs the patient is taking to identify those that may affect or be affected by renal function.

- Assess hematocrit and hemoglobin level and replace blood components as ordered. Don't use whole blood if the patient is prone to heart failure and can't tolerate extra fluid volume. Packed red blood cells deliver the necessary blood components without added volume.
- Monitor vital signs. Watch for and report signs of pericarditis (pleuritic chest pain, tachycardia, and pericardial friction rub), inadequate renal perfusion (hypotension), and acidosis.

PREVENTION

Preventing acute renal failure

Because there are no specific therapies for the treatment of acute renal failure due to ischemia or nephrotoxicity, identifying high-risk groups and taking preventive measures are important. After major surgery or trauma, aggressive restoration of fluid volume can help reduce acute renal failure. This is also important in cases of burns or infection such as cholera. Careful and prudent administration of drug dosages can help prevent nephrotoxicity. Monitoring blood levels and adjusting medication dosages accordingly is helpful in limiting injury. Allopurinol and forced diuresis may be helpful in individuals at high risk such as those undergoing cancer chemotherapy.

- u Maintain proper electrolyte balance. Strictly monitor potassium levels. Watch for symptoms of hyperkalemia (malaise, anorexia, paresthesia, muscle weakness, and ECG changes), and report them immediately. Avoid administering medications that contain potassium.
- u Assess the patient frequently, especially during emergency treatment to lower potassium levels. If he receives hypertonic glucose-and-insulin infusions, monitor potassium and glucose levels. If you give sodium polystyrene sulfonate rectally, make sure the patient doesn't retain it and become constipated. This can lead to bowel perforation.
- u Maintain nutritional status. Provide a diet high in calories and low in protein, sodium, and potassium, with vitamin supplements. Give the anorexic patient small, frequent meals.
- u Prevent complications of immobility by encouraging frequent coughing and deep breathing and by performing passive range-of-motion exercises. Help the patient walk as soon as possible. Add lubricating lotion to his bath water to combat skin dryness.
- u Provide mouth care frequently to lubricate dry mucous membranes. If stomatitis occurs, use an antibiotic solution, if ordered, and have the patient swish it around in the mouth before swallowing.
- u Monitor for GI bleeding by testing all stools for occult blood using the guaiac test. Administer medications carefully, especially antacids and stool softeners.
- u Provide meticulous perineal care to reduce the risk of ascending urinary tract infection in women and to protect skin integrity caused by frequent loose, irritating stools, particularly when sodium polystyrene sulfonate is used.
- u Use appropriate safety measures, such as bed rails and restraints, because the patient with CNS involvement may become dizzy or confused.
- u If the patient requires hemodialysis, check the blood access site (arteriovenous fistula or subclavian or femoral catheter) every 2 hours for patency and signs of clotting. Don't use the arm with the shunt or fistula for measuring blood pressure or drawing blood. Weigh the patient before beginning dialysis.
- u During hemodialysis, monitor vital signs, clotting times, blood flow, vascular access site function, and arterial and venous pressures. Watch for complications, such as septicemia, embolism, hepatitis, and rapid fluid and electrolyte losses.
- u After hemodialysis, monitor vital signs, check the vascular access site, weigh the patient, and watch for signs of fluid and electrolyte imbalances.
- u If the patient requires peritoneal dialysis, position him carefully, elevating the head of the bed to reduce pressure on the diaphragm and aid respiration. Be alert for signs of infection, such as cloudy drainage, elevated temperature and, rarely, bleeding. If pain occurs, reduce the amount of dialysate. Periodically monitor the diabetic patient's blood glucose levels, and administer insulin as ordered. Watch for complications, such as peritonitis, atelectasis, hypokalemia, pneumonia, and shock.
- u Provide emotional support to the patient and family members.
- u Administer any prescribed medications after hemodialysis is completed. Many medications are removed from the blood during treatment.
- u Assess the patient's ability to resume normal activities of daily living, and plan for gradually resuming activity.

Patient teaching

- u Reassure the patient and family members by clearly explaining all diagnostic tests, treatments, and procedures.
- u Tell the patient about his prescribed medications, and stress the importance of complying with the regimen.
- u Stress the importance of following the prescribed diet and fluid allowance.
- u Instruct the patient to weigh himself daily and report changes of 3 lb (1.4 kg) or more immediately.
- u Advise the patient against overexertion. If he becomes dyspneic or short of breath during normal activity, tell him to report it to his doctor.
- u Teach the patient how to recognize edema, and tell him to report this finding to the doctor.

ACUTE TUBULAR NECROSIS

Acute tubular necrosis (also called acute tubulointerstitial nephritis) is the most common cause of acute renal failure in critically ill patients. It accounts for about 75% of all cases of acute renal failure. This disorder injures the tubular segment of the nephron, causing renal failure and uremic syndrome. Mortality can be as high as 70%, depending on complications from underlying diseases. Patients with nonoliguric forms of acute tubular necrosis have a better prognosis.

Causes and pathophysiology

Acute tubular necrosis results from ischemic or nephrotoxic injury, most commonly in debilitated patients, such as the critically ill or those who have undergone extensive surgery. In ischemic injury, disruption of blood flow to the kidneys may result from circulatory collapse, severe hypotension, trauma, hemorrhage, dehydration, cardiogenic or septic shock, surgery, anesthetics, or transfusion reactions. Nephrotoxic injury may follow ingestion or inhalation of certain chemicals, such as aminoglycoside antibiotics and radiographic contrast agents, or it may result from a hypersensitivity reaction of the kidneys.

Specifically, acute tubular necrosis can result from any of the following:

- u diseased tubular epithelium that allows leakage of glomerular filtrate across the membranes and reabsorption of filtrate into the blood
- u obstructed urine flow from the collection of damaged cells, casts, red blood cells (RBCs), and other cellular debris within the tubular walls
- u ischemic injury to glomerular epithelial cells, resulting in cellular collapse and decreased glomerular capillary permeability
- u ischemic injury to vascular endothelium, eventually resulting in cellular swelling, sludging, and tubular obstruction.

Complications

Nephrotoxic acute tubular necrosis doesn't damage the basement membrane of the nephron, so it's potentially reversible. However, ischemic acute tubular necrosis can damage the epithelial and basement membranes and can cause lesions in the renal interstitium. Infections (frequently septicemia) can complicate up to 70% of all cases and are the leading cause of death. GI hemorrhage, fluid and electrolyte imbalance, and cardiovascular dysfunction may occur during the acute phase or not until the recovery phase. Neurologic complications occur commonly in elderly patients and occasionally in younger patients. Hypercalcemia may occur during the recovery phase.

Assessment findings

The patient's history may include an ischemic or a nephrotoxic injury that can cause acute tubular necrosis. The signs of acute tubular necrosis may be obscured by the patient's primary disease.

You may first note that the patient's urine output may be oliguric (less than 400 ml/24 hours); occasionally, in severe cases, urine output may be less than 100 ml/24 hours for several days.

Inspection may reveal evidence of bleeding abnormalities such as petechiae and ecchymoses. Hematemesis may occur. The skin may be dry and pruritic and, rarely, a uremic frost may be present. Mucous membranes also may be dry, and the breath may have a uremic odor. If hyperkalemia is present, muscle weakness may occur.

The patient may exhibit evidence of central nervous system involvement, such as lethargy, somnolence, confusion, disorientation, asterixis, agitation, myoclonic muscle twitching and, possibly, seizures.

Auscultation may reveal tachycardia and, possibly, an irregular rhythm. Rarely, a pericardial friction rub can be heard, indicating pericarditis. Bibasilar crackles may occur if heart failure is present.

Palpation and percussion may reveal abdominal pain if pancreatitis or peritonitis occurs and may reveal peripheral edema if heart failure is present. Fever and chills

can signal the onset of infection.

Diagnostic tests

Diagnosis usually doesn't occur until the condition reaches an advanced stage. The most significant laboratory test findings are urine sediment, containing RBCs and casts, and diluted urine with a low specific gravity (1.010), low osmolality (less than 400 mOsm/kg), and high sodium level (40 to 60 mEq/L).

Blood studies reveal elevated blood urea nitrogen and serum creatinine levels, decreased serum protein levels, anemia, defects in platelet adherence, metabolic acidosis, and hyperkalemia.

An electrocardiogram may show arrhythmias (from electrolyte imbalances). With hyperkalemia, it also may show a widening QRS complex, disappearing P waves, and tall, peaked T waves.

Treatment

Acute tubular necrosis requires vigorous supportive measures during the acute phase until normal renal function resumes. Initial treatment may include administration of diuretics and infusion of a large volume of fluids to flush tubules of cellular casts and debris and to replace fluid loss. This treatment carries a risk of fluid overload. Long-term fluid management requires daily replacement of projected and calculated losses (including insensible loss).

Other appropriate measures to control complications include transfusion of packed RBCs for anemia and administration of antibiotics for infection. A patient with hyperkalemia may require emergency I.V. administration of 50% glucose, regular insulin, and sodium bicarbonate. Sodium polystyrene sulfonate may be given by mouth or by enema to reduce extracellular potassium levels. Peritoneal dialysis or hemodialysis may be needed for a catabolic patient.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered role performance
- u Altered tissue perfusion (renal)
- u Decreased cardiac output
- u Fatigue
- u Fluid volume excess
- u Impaired gas exchange
- u Pain
- u Risk for infection
- u Risk for injury
- u Self-care deficit

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain urine specific gravity within the designated limits.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient will maintain hemodynamic stability.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Maintain fluid balance and watch for fluid overload, a common complication of therapy. Accurately record intake and output, including wound drainage, nasogastric tube output, and peritoneal dialysis and hemodialysis balances. Weigh the patient at the same time every day.

PREVENTION

Preventing acute tubular necrosis

Patients at risk for acute tubular necrosis need to be identified. Because it occurs predominantly in elderly hospitalized patients, be aware of contributing causes. These include aminoglycoside therapy and exposure to industrial chemicals, heavy metals, and contrast media. Patients who've been exposed must receive adequate hydration; monitor their urinary output closely.

To prevent acute tubular necrosis, make sure every patient is well hydrated before surgery or after X-rays that use a contrast medium. Administer mannitol, as ordered, to a high-risk patient before and during these procedures. Carefully monitor a patient receiving a blood transfusion, and discontinue the transfusion immediately if early signs of transfusion reaction (fever, rash, and chills) occur.

- u Monitor hemoglobin and hematocrit levels, and administer blood products as needed. Use fresh packed cells instead of whole blood, especially in an elderly patient, to prevent fluid overload and heart failure.
- u Maintain electrolyte balance. Monitor laboratory test results and report imbalances. Restrict foods that contain sodium and potassium, such as bananas, prunes, orange juice, and baked potatoes. Check for potassium content in prescribed medications (for example, potassium penicillin).
- u Provide adequate calories and essential amino acids while restricting protein intake to maintain an anabolic state. Total parenteral nutrition (TPN) may be indicated for a severely debilitated or catabolic patient. If the patient is receiving TPN, keep his skin meticulously clean.
- u Use aseptic technique, particularly when handling catheters, because the debilitated patient is vulnerable to infection. Immediately report fever, chills, delayed wound healing, or flank pain if the patient has an indwelling catheter.
- u Watch for complications. If anemia worsens, causing pallor, weakness, or lethargy with decreased hemoglobin, administer RBCs as ordered. For acidosis, give sodium bicarbonate or assist with dialysis in severe cases as ordered. Watch for hypotension, which diminishes renal perfusion and decreases urine output.
- u Perform passive range-of-motion exercises. Provide good skin care, and apply lotion or bath oil to prevent dry skin. Help the patient walk as soon as possible, but make sure he doesn't become exhausted. (See [Preventing acute tubular necrosis](#).)
- u Provide emotional support to the patient and family members. Encourage the patient to verbalize concerns about his inability to perform in expected roles. Assure him that activity restrictions are temporary.

Patient teaching

- u Teach the patient the signs of infection, and tell him to report them to the doctor immediately. Remind him to stay away from crowds and any infected person.
- u Review the prescribed diet, including dietary restrictions, and stress the importance of adhering to it.
- u Teach the patient how to cough and perform deep breathing to prevent pulmonary complications.
- u Fully explain each procedure to the patient and family members as often as necessary, and help them set goals that are realistic for the patient's prognosis.

RENAL CALCULI

Renal calculi can form anywhere in the urinary tract, but they most commonly develop in the renal pelvis or calyces. Calculi form when substances that normally are dissolved in the urine (such as calcium oxalate and calcium phosphate) precipitate. Renal calculi vary in size and may be solitary or multiple. (See [Variations in renal calculi](#).)

About 1 in 1,000 Americans require hospitalization for renal calculi. They're more common in men than women and are rare in blacks and children.

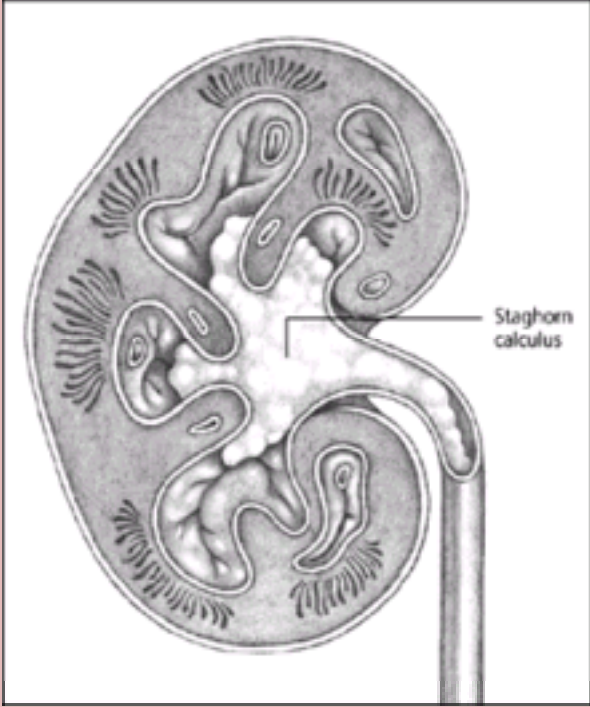

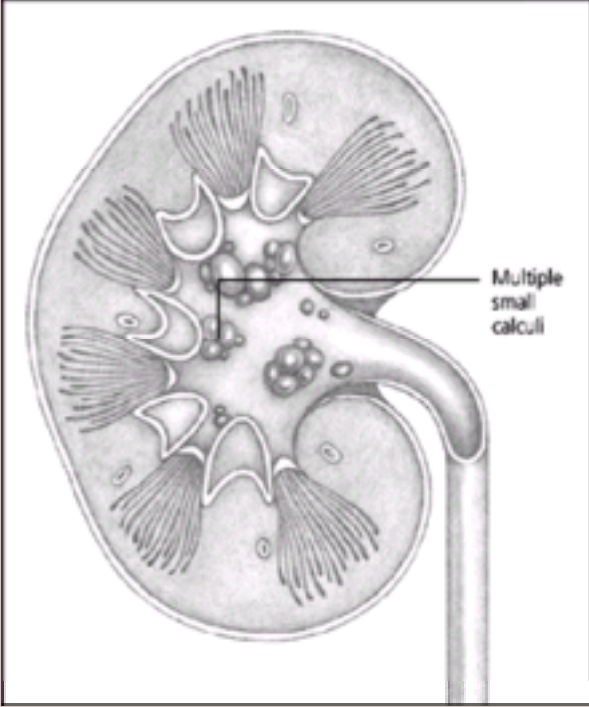

Causes

The exact cause of renal calculi is unknown, but predisposing factors include:

- u *Dehydration.* Decreased water excretion concentrates calculus-forming substances.
- u *Infection.* Infected, scarred tissue may be a site for calculus development. In addition, infected calculi (usually magnesium ammonium phosphate or staghorn calculi) may develop if bacteria serve as the nucleus in calculus formation. Struvite calculus formation commonly results from *Proteus* infections, which may lead to destruction of renal parenchyma.

Variations in renal calculi

Renal calculi vary in size and type. Small calculi may remain in the renal pelvis or pass down the ureter. A staghorn calculus (a cast of the calyceal and pelvic collecting system) may develop from a stone that stays in the kidney.

- u *Changes in urine pH.* Consistently acidic or alkaline urine may provide a favorable medium for calculus formation, especially for magnesium ammonium phosphate or calcium phosphate calculi.
- u *Obstruction.* Urinary stasis allows calculus constituents to collect and adhere, forming calculi. Obstruction also encourages infection, which compounds the obstruction.
- u *Immobilization.* Immobility from spinal cord injury or other disorders allows calcium to be released into the circulation and, eventually, to be filtered by the kidneys.
- u *Metabolic factors.* Hyperparathyroidism, renal tubular acidosis, elevated uric acid (usually with gout), defective metabolism of oxalate, a genetically caused defect in metabolism of cystine, and excessive intake of vitamin D or dietary calcium may predispose a person to renal calculi.

CULTURAL TIP Renal calculi are prevalent in certain geographic areas such as the southeastern United States (called the “stone belt”), possibly because a hot climate promotes dehydration and concentrates calculus-forming substances or because of regional dietary habits.

Other possible causes of renal calculi include multiple myeloma, Paget's disease, bone cancer, Cushing's disease or syndrome (loss of bone calcium), and milk-alkali syndrome.

Complications

Calculi either remain in the renal pelvis and damage or destroy renal parenchyma, or they enter the ureter; large calculi in the kidneys cause pressure necrosis. Calculi in some sites cause obstruction, with resultant hydronephrosis, and tend to recur. Intractable pain and serious bleeding also can result from calculi and the damage they cause.

Assessment findings

Typically, assessment findings vary with the size, location, and cause of the calculi. The key symptom of renal calculi is severe pain, which usually results from obstruction—large, rough calculi occlude the opening to the ureteropelvic junction and increase the frequency and force of peristaltic contractions. The patient usually reports that the pain travels from the costovertebral angle to the flank and then to the suprapubic region and external genitalia (classic renal colic pain). Pain intensity fluctuates and may be excruciating at its peak.

The patient with calculi in the renal pelvis and calyces may complain of more constant, dull pain. He also may report back pain (from calculi causing obstruction within a kidney) and severe abdominal pain (from calculi traveling down a ureter). The patient with severe pain also typically complains of nausea, vomiting and, possibly, fever and chills.

You may note hematuria (when calculi abrade a ureter), abdominal distention and, rarely, anuria (from bilateral obstruction or, in the patient with one kidney, unilateral obstruction).

Diagnostic tests

Diagnosis is based on clinical features and the results of various tests. For example, kidney-ureter-bladder (KUB) radiography reveals most renal calculi, and excretory urography helps confirm the diagnosis and determine the size and location of calculi.

Kidney ultrasonography is easily performed, noninvasive, and nontoxic. It's used to detect obstructive changes, such as unilateral or bilateral hydronephrosis and radiolucent calculi not seen on the KUB radiography.

Urine culture of a midstream specimen may indicate pyuria, a sign of urinary tract infection. A 24-hour urine collection is evaluated for calcium oxalate, phosphorus, and uric acid excretion levels; three separate collections, along with blood samples, are needed for accurate testing.

Calculus analysis shows mineral content.

Other diagnostic test results may suggest the cause of calculus formation:

- u Serial blood calcium and phosphorus levels indicate hyperparathyroidism and show an increased calcium level in proportion to normal serum protein levels.
- u Blood protein levels are used to determine the level of free calcium unbound to protein.

u Increased blood uric acid levels may indicate gout.

Appendicitis, cholecystitis, peptic ulcer, and pancreatitis must be ruled out as sources of pain before the diagnosis can be confirmed.

Treatment

Because 90% of renal calculi are smaller than 5 mm in diameter, treatment usually involves encouraging their natural passage through vigorous hydration (more than 3 L [3.2 qt]/24 hours). Other treatment measures include administration of antimicrobial agents for infection (varying with the cultured organism); analgesics, such as meperidine or morphine, for pain; and diuretics to prevent urinary stasis and further calculus formation (thiazides decrease calcium excretion into the urine). Methenamine mandelate is given to suppress calculus formation when infection is present.

Measures to prevent recurrence include a diet of adequate calcium intake, often combined with oxalate-binding cholestyramine, for absorptive hypercalciuria; parathyroidectomy for hyperparathyroidism; administration of allopurinol for uric acid calculi; and daily oral doses of ascorbic acid to acidify the urine. High-risk groups should be identified and monitored closely. Other preventive measures include adequate hydration (2.5 to 3 L [2.6 to 3.2 qt]/24 hours), early mobilization of patients, repositioning, and exercise for immobilized or patients with inadequate mobility.

Calculi too large for natural passage may require removal. A calculus lodged in the ureter may be removed by inserting a cystoscope through the urethra and then manipulating the calculus with catheters or retrieval instruments. Extraction of calculi from other areas, such as the kidney calyx or renal pelvis, may necessitate a flank or lower abdominal approach. Two other methods, percutaneous ultrasonic lithotripsy and extracorporeal shock wave lithotripsy, shatter the calculus into fragments for removal by suction or natural passage.

Cystine calculi are difficult to treat without surgical intervention or an invasive procedure. If electrohydraulic ultrasound isn't effective, the calculi are surgically removed.

Nursing diagnoses

u Altered fluid balance u Altered tissue perfusion (renal) u Altered urinary elimination u Knowledge deficit u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate tissue perfusion and modify his lifestyle accordingly.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u To aid diagnosis, maintain a 24- to 48-hour record of urine pH using nitrazine pH paper. Strain all urine through gauze or a tea strainer, and save all solid material recovered for analysis.
- u To facilitate spontaneous passage of calculi, encourage the patient to walk, if possible. Also force fluids to maintain a urine output of 3,000 to 4,000 ml/24 hours (urine should be very dilute and colorless).
- u If the patient can't drink the required amount of fluid, give supplemental I.V. fluids.
- u Record intake and output and daily weight to assess fluid status and renal function.
- u Medicate the patient generously for pain when he's passing a calculus.
- u To help acidify urine, offer fruit juices, especially cranberry juice.
- u If the patient had calculi surgically removed, he probably has an indwelling catheter or a nephrostomy tube. Unless one of his kidneys was removed, expect bloody drainage from the catheter. Never irrigate the catheter without a doctor's order. Check dressings regularly for bloody drainage, and know how much drainage to expect. Immediately report excessive drainage or a rising pulse rate, symptoms of hemorrhage. Use aseptic technique when changing dressings or providing catheter care.
- u Watch for signs of infection, such as a rising fever or chills, and give antibiotics as ordered.

Patient teaching

- u Encourage increased fluid intake. If appropriate, show the patient how to check his urine pH, and instruct him to keep a daily record. Tell him to immediately report symptoms of acute obstruction, such as pain or an inability to void.
- u Urge the patient to follow a prescribed diet and comply with drug therapy to prevent recurrence of calculi. For example, if a hyperuricemic condition caused the patient's calculi, teach him which foods are high in purine.
- u If surgery is necessary, supplement and reinforce the doctor's teaching. The patient is apt to be fearful, especially if he needs a kidney removed, so emphasize that the body can adapt well to one kidney. If he's having an abdominal or flank incision, teach deep-breathing and coughing exercises.

RENAL VEIN THROMBOSIS

Clotting in the renal vein, or renal vein thrombosis, produces renal congestion, engorgement and, sometimes, infarction. Thrombosis may affect both kidneys and occurs in an acute or a chronic form.

Chronic thrombosis usually impairs renal function, causing nephrotic syndrome. If thrombosis affects both kidneys, the prognosis is poor. Thrombosis that affects only one kidney, or gradual progression that allows development of collateral circulation, may preserve partial renal function. The disorder occurs in people of all ages, including infants.

The acute form usually can be recognized and treated before nephrotic syndrome occurs.

Causes

Renal vein thrombosis often results from a tumor that obstructs the renal vein (usually hypernephroma). Other causes include thrombophlebitis of the inferior vena cava (which may result from abdominal trauma) or blood vessels of the legs, heart failure, periarteritis, and pregnancy or retroperitoneal fibrosis that causes increased venous compression.

Oral contraceptives and cancers that cause hypercoagulability heighten the risk of renal vein thrombosis. In infants, thrombosis usually follows diarrhea that causes severe dehydration.

Chronic renal vein thrombosis often is a complication of other glomerulopathic diseases, such as amyloidosis, diabetic nephropathy, and membranoproliferative glomerulonephritis.

Complications

Thrombosis that occurs abruptly and causes extensive damage may precipitate rapidly fatal renal infarction (see [Renal infarction](#)). Disseminated intravascular coagulation also may occur.

Assessment findings

Symptoms vary depending on the severity and abruptness of occlusion. A patient with a rapid onset of venous obstruction may report severe lumbar pain and tenderness in the epigastric region and the costovertebral angle. You may note fever, chills, nausea, vomiting, hematuria, ipsilateral lower leg edema, and oliguria when the obstruction is bilateral. The kidneys enlarge and become easily palpable. Hypertension occasionally develops.

When onset is gradual, as often occurs in elderly patients, the patient may have a history of recurrent pulmonary emboli. He may also have newly developed or worsening hypertension. He usually complains of nausea and vomiting. Peripheral edema, usually without pain—a sign of venous congestion—may be palpable.

Renal infarction

Renal infarction is a coagulated, necrotic area in one or both kidneys. Infarction commonly results from renal artery embolism and occlusion secondary to mitral stenosis, infective endocarditis, atrial fibrillation, microthrombi in the left ventricle, rheumatic valvular disease, or myocardial infarction.

The patient history usually includes acute hypertension with severe upper abdominal or flank pain or tenderness, fever, anorexia, nausea, vomiting and, possibly, muscle weakness or tetany and increased urine output. A bruit may be auscultated in the epigastrium. The affected kidney is small and not palpable; the other may feel enlarged.

A positive diagnosis requires urinalysis that reveals proteinuria and hematuria and elevated urine and serum enzyme levels. Blood studies may reveal leukocytosis and increased erythrocyte sedimentation rate. A captopril test may differentiate this form of hypertension from essential hypertension. Excretory urography or isotopic renal scan indicates vascular occlusion. Renal arteriography reveals existing infarction but is a high-risk test. Computed tomography pinpoints areas of occlusion and the extent of infarction.

Infection or significant hypertension may necessitate surgical removal of the occlusion or nephrectomy. Persistent hypertension may respond to antihypertensives and a low-sodium diet. Other treatments may include early administration of intra-arterial streptokinase, catheter embolectomy, and heparin therapy.

Diagnostic tests

Excretory urography provides reliable diagnostic evidence. In acute renal vein thrombosis, the kidneys appear enlarged and excretory function diminishes or is absent in the affected kidney. Contrast medium seems to “smudge” necrotic renal tissue. In chronic renal thrombosis, the test may show ureteral indentations that result from collateral venous channels.

Renal arteriography and biopsy may confirm the diagnosis.

Venography confirms the presence of the occluding thrombosis.

Urinalysis reveals hematuria, oliguria, proteinuria (more than 2 g/24 hours in chronic disease), and casts.

Blood studies show leukocytosis, hypoalbuminemia, hyperlipidemia, and thrombocytopenia.

Treatment

Gradual thrombosis that affects only one kidney may be treated effectively with anticoagulant therapy (heparin or warfarin), particularly if it's long term and if the thrombus extends into the vena cava. Thrombolytic therapy, using streptokinase or alteplase, also is effective.

Surgery must be performed within 24 hours of thrombosis, but even then it has limited success because thrombi may extend into the small veins. Extensive intrarenal bleeding and severe hypertension in an atrophic kidney may necessitate nephrectomy.

A patient who survives abrupt thrombosis with extensive renal damage develops nephrotic syndrome and requires treatment for renal failure, such as dialysis and, possibly, transplantation. An infant with renal vein thrombosis may either recover completely after rehydration and heparin therapy or surgery, or may suffer irreversible kidney damage. Bilateral damage can be fatal.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (renal)
- u Decreased cardiac output
- u Fluid volume deficit
- u Pain
- u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient will maintain hemodynamic stability.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Give analgesics to relieve pain and promote comfort.
- u Assess renal function regularly. Monitor vital signs, intake and output, daily weight, and electrolyte levels.
- u Administer diuretics for edema as ordered, and enforce dietary restrictions on sodium and potassium intake.
- u Monitor the patient closely for signs of pulmonary emboli, such as bibasilar crackles and dyspnea.
- u If you give heparin by continuous I.V. infusion, frequently monitor partial thromboplastin time to determine the patient's response to the drug. Follow protocols for heparin infusion, and watch for infiltration to avoid tissue damage and a drop in heparin's therapeutic blood levels.
- u During anticoagulant or thrombolytic therapy, watch for and report signs of internal bleeding, such as tachycardia, hypotension, hematuria, bleeding from the nose or gums, ecchymoses, petechiae, and tarry stools.

Patient teaching

- u Teach the patient about any medications he's taking. If he's on maintenance warfarin therapy, caution him to avoid trauma and to use an electric razor and a soft toothbrush.
- u Warn the patient to avoid aspirin and aspirin-containing products because they aggravate bleeding tendencies.
- u Instruct the patient to plan his diet to maintain a consistent amount of vitamin K because varying levels can interfere with effective anticoagulation. Teach him how to reduce sodium and potassium in his diet.
- u Teach the patient the signs of bleeding, and tell him to immediately report any findings to the doctor.

Chronic renal disorders develop slowly and persist for a long time. They include chronic glomerulonephritis, chronic renal failure, cystinuria, hydronephrosis, nephrotic syndrome, renal tubular acidosis, and renovascular hypertension.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis is a slowly progressive disease characterized by inflammation of the glomeruli, which results in sclerosis, scarring and, eventually, renal failure. This condition normally remains subclinical until the progressive phase begins. By the time it produces symptoms, chronic glomerulonephritis is usually irreversible.

Causes

Common causes of chronic glomerulonephritis include primary renal disorders, such as membranoproliferative glomerulonephritis, membranous glomerulopathy, focal segmental glomerulosclerosis, rapidly progressive glomerulonephritis and, less often, poststreptococcal glomerulonephritis. Systemic disorders that may cause chronic glomerulonephritis include systemic lupus erythematosus, Goodpasture's syndrome, and hemolytic-uremic syndrome.

Complications

Chronic glomerulonephritis can cause contracted, granular kidneys and lead to end-stage renal failure. It also can produce severe hypertension, leading to cardiovascular complications, including cardiac hypertrophy and heart failure, which may speed the development of advanced renal failure, eventually necessitating dialysis or kidney transplantation.

Assessment findings

This disorder usually develops insidiously and without symptoms, often over many years. But when it becomes suddenly progressive, your assessment may reveal edema and hypertension.

In late stages, the patient may complain of nausea, vomiting, pruritus, dyspnea, malaise, fatigue, and mild to severe edema. Your assessment may show severe hypertension and associated cardiac complications.

Diagnostic tests

The following findings support a diagnosis of chronic glomerulonephritis:

- u Urinalysis shows proteinuria, hematuria, cylindruria, and red blood cell casts.
- u Blood studies reveal rising blood urea nitrogen and serum creatinine levels in advanced renal insufficiency as well as a decrease in hemoglobin.
- u X-rays exhibit symmetrically contracted kidneys with normal pelves and calyces.
- u Renal biopsy establishes the underlying disease and provides data to plan therapy.

Treatment

Appropriate treatment is essentially nonspecific and symptomatic. Goals include controlling hypertension with antihypertensives and a sodium-restricted diet, correcting fluid and electrolyte imbalances through restrictions and replacement, reducing edema with loop diuretics such as furosemide, and preventing heart failure. Treatment also may include antibiotics for symptomatic urinary tract infections (UTIs), dialysis, or kidney transplantation.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (renal)
- u Fatigue
- u Fluid volume excess
- u Impaired skin integrity
- u Risk for infection

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient will maintain hemodynamic stability.
- u The patient will avoid or minimize complications.
- u The patient will experience increased energy and decreased fatigue.

Nursing interventions

- u Monitor vital signs, intake and output, and daily weight to evaluate fluid retention. Observe for signs of fluid, electrolyte, and acid-base imbalances.
- u Ask the dietitian to help the patient plan low-sodium, high-calorie meals with adequate protein.
- u Provide good skin care to help prevent complications of pruritus, edema, and friability.
- u Help the patient adjust to his illness by encouraging him to express his feelings and ask questions.

Patient teaching

- u Instruct the patient to take prescribed antihypertensives and diuretics as scheduled, even if he feels better. Advise him to take diuretics in the morning so that his sleep won't be disturbed.
- u Teach the patient the signs of infection, particularly those of UTI, and warn him to report them immediately. Tell him to avoid contact with people who have communicable illnesses.
- u Urge compliance with the prescribed diet.
- u Stress the importance of keeping all follow-up examinations to assess renal function.

CHRONIC RENAL FAILURE

Chronic renal failure is usually the end result of a gradually progressive loss of renal function. It also occasionally results from a rapidly progressive disease of sudden onset that gradually destroys the nephrons and eventually causes irreversible renal damage. Few symptoms develop until after more than 75% of glomerular filtration is lost. Then, the remaining normal parenchyma deteriorates progressively and symptoms worsen as renal function decreases.

Chronic renal failure may progress through the following stages:

- u reduced renal reserve (glomerular filtration rate [GFR] 5% to 50% of normal)
- u renal insufficiency (GFR 20% to 35% of normal)
- u renal failure (GFR 20% to 25% of normal)
- u end-stage renal disease (GFR less than 20% of normal).

This syndrome is fatal without treatment, but maintenance dialysis or a kidney transplant can sustain life.

Causes

Chronic renal failure may result from

- u *chronic glomerular disease*, such as glomerulonephritis
- u *chronic infections*, such as chronic pyelonephritis or tuberculosis
- u *congenital anomalies*, such as polycystic kidney disease
- u *vascular diseases*, such as renal nephrosclerosis or hypertension
- u *obstructive processes*, such as calculi
- u *collagen diseases*, such as systemic lupus erythematosus
- u *nephrotoxic agents*, such as long-term aminoglycoside therapy
- u *endocrine diseases*, such as diabetic neuropathy.

Complications

If this condition continues unchecked, uremic toxins accumulate and produce potentially fatal physiologic changes in all major organ systems.

Even if the patient can tolerate life-sustaining maintenance dialysis or a kidney transplant, he may still have anemia, peripheral neuropathy, cardiopulmonary and GI complications, sexual dysfunction, and skeletal defects.

Assessment findings

The patient's history may include a disease or condition that can cause renal failure, but he may not have any symptoms for a long time. Symptoms usually occur by the time the GFR is 20% to 35% of normal, and almost all body systems are affected. Assessment findings reflect involvement of each system; many findings reflect involvement of more than one system.

- u *Renal*. In certain fluid and electrolyte imbalances, the kidneys can't retain salt, and hyponatremias occur. The patient may complain of dry mouth, fatigue, and nausea. You may note hypotension, loss of skin turgor, and listlessness that may progress to somnolence and confusion. Later, as the number of functioning nephrons decreases, so does the kidneys' capacity to excrete sodium and potassium. Urine output decreases, and the urine is very dilute, with casts and crystals present. Accumulation of potassium causes muscle irritability and then muscle weakness, irregular pulses, and life-threatening cardiac arrhythmias as serum potassium levels increase. Sodium retention causes fluid overload, and edema is palpable. Metabolic acidosis also occurs.
- u *Cardiovascular*. When the cardiovascular system is involved, hypertension and an irregular pulse are noted. Life-threatening cardiac arrhythmias can occur. With pericardial involvement, you may auscultate a pericardial friction rub. Uremic toxins cause the pericardial sac to become inflamed and irritated. Heart sounds may be distant if pericardial effusion is present. Bibasilar crackles may be auscultated, and peripheral edema may be palpated if heart failure occurs.
- u *Respiratory*. Pulmonary changes include reduced pulmonary macrophage activity with increased susceptibility to infection. If pneumonia is present, lung sounds may be decreased over areas of consolidation. Bibasilar crackles indicate pulmonary edema. With pleural involvement, the patient may complain of pleuritic pain, and you may auscultate a pleural friction rub. Kussmaul's respirations occur with metabolic acidosis.
- u *GI*. With inflammation and ulceration of GI mucosa, inspection of the mouth may reveal gum ulceration and bleeding and, possibly, parotitis. The patient may complain of hiccups, a metallic taste in the mouth, anorexia, nausea, and vomiting caused by esophageal, stomach, or bowel involvement. You may note a uremic fetor (ammonia smell) to the breath. Abdominal palpation and percussion may elicit pain.
- u *Skin*. Inspection of the skin typically reveals a pallid, yellowish bronze color. The skin is dry and scaly with purpura, ecchymoses, petechiae, uremic frost (most often in critically ill or terminal patients), and thin, brittle fingernails with characteristic lines. The hair is dry and brittle and may change color and fall out easily. The patient usually complains of severe itching.
- u *Neurologic*. You may note that the patient has alterations in level of consciousness that may progress from mild behavior changes, shortened memory and attention span, apathy, drowsiness, and irritability to confusion, coma, and seizures. The patient may complain of hiccups, muscle cramps, fasciculations, and twitching, which are caused by muscle irritability. He may also complain of restless leg syndrome. One of the first signs of peripheral neuropathy, restless leg syndrome causes pain, burning, and itching in the legs and feet that may be relieved by voluntarily shaking, moving, or rocking them. This condition eventually progresses to paresthesia, motor nerve dysfunction (usually bilateral footdrop) and, unless dialysis is initiated, flaccid paralysis.
- u *Endocrine*. Children with chronic renal failure exhibit growth retardation, even with elevated growth hormone levels. Adults may have a history of infertility, decreased libido, amenorrhea in women, and impotence in men.
- u *Hematologic*. Inspection may reveal purpura, GI bleeding and hemorrhage from body orifices, easy bruising, ecchymoses, and petechiae caused by thrombocytopenia and platelet defects.
- u *Musculoskeletal*. The patient may have a history of pathologic fractures and complain of bone and muscle pain caused by calcium-phosphorus imbalance and consequent parathyroid hormone imbalances. You may note gait abnormalities or, possibly, an inability to ambulate. Children may have impaired bone growth and bowed legs from rickets.

Diagnostic tests

Various laboratory findings aid in the diagnosis and monitoring of chronic renal failure. For example, blood studies show elevated blood urea nitrogen, serum creatinine, sodium, and potassium levels; decreased arterial pH and bicarbonate levels; low hematocrit and hemoglobin levels; decreased red blood cell (RBC) survival time; mild thrombocytopenia; platelet defects; and metabolic acidosis. They also show increased aldosterone secretion (related to increased renin production) and increased blood glucose levels similar to those that occur in diabetes mellitus (a sign of impaired carbohydrate metabolism). Hypertriglyceridemia and decreased high-density lipoprotein levels are common.

Arterial blood gas analysis reveals metabolic acidosis.

Urine specific gravity becomes fixed at 1.010; urinalysis may show proteinuria, glycosuria, RBCs, leukocytes, and casts and crystals, depending on the cause.

X-ray studies, including kidney-ureter-bladder radiography, excretory urography, nephrotomography, renal scan, and renal arteriography show reduced kidney size.

Renal biopsy allows histologic identification of the underlying pathology.

EEG shows changes that indicate metabolic encephalopathy.

Treatment

The goal of conservative treatment is to correct specific symptoms. A low-protein diet reduces the production of end products of protein metabolism that the kidneys can't excrete. (A patient receiving continuous peritoneal dialysis should have a high-protein diet.) A high-calorie diet prevents ketoacidosis and the negative nitrogen balance that results in catabolism and tissue atrophy. The diet should restrict sodium, phosphorus, and potassium.

Maintaining fluid balance requires careful monitoring of vital signs, weight changes, and urine volume (if not anuric). Fluid retention can be reduced with loop diuretics such as furosemide (if some renal function remains) and with fluid restriction. Digitalis glycosides in small doses may be used to mobilize the fluids causing the edema; antihypertensives may be used to control blood pressure and associated edema.

Antiemetics taken before meals may relieve nausea and vomiting, and cimetidine or ranitidine may decrease gastric irritation. Methylcellulose or docusate can help prevent constipation.

Anemia necessitates iron and folate supplements; severe anemia requires infusion of fresh frozen packed cells or washed packed cells. Transfusions relieve anemia only temporarily. Synthetic erythropoietin (epoetin alfa) stimulates the division and differentiation of cells within the bone marrow to produce RBCs.

Drug therapy commonly relieves associated symptoms. An antipruritic, such as trimeprazine or diphenhydramine, can relieve itching, and aluminum hydroxide gel can lower serum phosphate levels. The patient also may benefit from supplementary vitamins (particularly vitamins B and D) and essential amino acids.

ALERT Careful monitoring of serum potassium levels is necessary to detect hyperkalemia. Emergency treatment for severe hyperkalemia includes dialysis therapy and administration of 50% hypertonic glucose I.V., regular insulin, calcium gluconate I.V., sodium bicarbonate I.V., and cation exchange resins such as sodium polystyrene sulfonate. Cardiac tamponade resulting from pericardial effusion may require emergency pericardial tap or surgery.

Calcium and phosphorus imbalances may be treated with phosphate binding agents, calcium supplements, and reduction of phosphorus in the diet. If hyperparathyroidism develops secondary to low serum calcium levels, a parathyroidectomy may be performed.

Intensive dialysis and thoracentesis can relieve pulmonary edema and pleural effusion.

Hemodialysis or peritoneal dialysis (particularly the newer techniques, such as continuous ambulatory peritoneal dialysis and continuous cyclic peritoneal dialysis) can help control most manifestations of end-stage renal disease. Altering the dialysate can correct fluid and electrolyte disturbances. However, maintenance dialysis itself may produce complications, including serum hepatitis (hepatitis B) from numerous blood transfusions, protein wasting, refractory ascites, and dialysis dementia.

Nursing diagnoses

u Altered family processes u Altered nutrition: Less than body requirements u Altered oral mucous membrane u Altered sexuality patterns u Altered thought processes u Altered tissue perfusion (renal) u Decreased cardiac output u Fluid volume excess u Impaired gas exchange u Impaired tissue integrity u Ineffective family coping: Disabling u Pain u Powerlessness u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain urine specific gravity within designated limits.
- u The patient will report increased comfort.
- u The patient will maintain hemodynamic status
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will perform activities of daily living within the confines of the disease.

Nursing interventions

The widespread clinical effects of chronic renal failure require meticulous and carefully coordinated supportive care.

- u Provide good skin care. Bathe the patient daily, using superfatted soaps, oatmeal baths, and skin lotion to ease pruritus. Give good perineal care, using mild soap and water. Pad the bed rails to guard against ecchymoses. Turn the patient often, and use a convoluted foam or low-pressure mattress to prevent skin breakdown.
- u Provide good oral hygiene. Brush the patient's teeth often with a soft brush or sponge tip to reduce breath odor. Hard candy and mouthwash minimize metallic taste in the mouth and alleviate thirst.
- u Offer small, palatable, nutritious meals. Try to provide favorite foods within dietary restrictions, and encourage intake of high-calorie foods.
- u Monitor the patient for hyperkalemia. Watch for cramping of the legs and abdomen and for diarrhea. As potassium levels increase, watch for muscle irritability and a weak pulse rate. Monitor the electrocardiogram for tall, peaked T waves; widening QRS complex; prolonged PR interval; and disappearance of P waves, indicating hyperkalemia.
- u Carefully assess the patient's hydration status. Check for jugular vein distention, and auscultate the lungs for crackles. Carefully measure daily intake and output, including all drainage, emesis, diarrhea, and blood loss. Record daily weight, presence or absence of thirst, axillary sweat, tongue dryness, hypertension, and peripheral edema.
- u Monitor for bone or joint complications. Prevent pathologic fractures by turning the patient carefully and ensuring his safety. Perform passive range-of-motion exercises for the bedridden patient.
- u Encourage the patient to perform deep-breathing and coughing exercises to prevent pulmonary congestion. Auscultate for crackles, rhonchi, and decreased breath sounds. Be alert for clinical signs of pulmonary edema (such as dyspnea and restlessness). Administer diuretics and other medications as ordered.
- u Maintain aseptic technique. Use a micropore filter during I.V. therapy, watch for signs of infection (listlessness, high fever, and leukocytosis), and warn the patient to avoid contact with infected people during the cold and flu season.
- u Carefully observe and document seizure activity. Infuse sodium bicarbonate for acidosis and sedatives or anticonvulsants for seizures as ordered. Pad the bed rails, and keep an oral airway and suction setup at the bedside. Periodically assess neurologic status, and check for Chvostek's and Trousseau's signs, indicators of low serum calcium levels.
- u Observe for signs of bleeding. Watch for prolonged bleeding at puncture sites and at the vascular access site used for hemodialysis. Monitor hematocrit and hemoglobin level, and check stool, urine, and vomitus for blood.
- u Report signs of pericarditis, such as a pericardial friction rub and chest pain. Also watch for the disappearance of friction rub, with a decrease of 15 to 20 mm Hg in blood pressure during inspiration (paradoxical pulse), an early sign of pericardial tamponade.
- u Schedule medication administration carefully. Give iron before meals, aluminum hydroxide gels after meals, and antiemetics (as necessary) a half hour before meals. Administer antihypertensives at appropriate intervals. If the patient requires a rectal infusion of sodium polystyrene sulfonate for dangerously high potassium levels, apply an emollient to soothe the perianal area. Be sure the sodium polystyrene sulfonate enema is expelled; otherwise, it causes constipation and doesn't lower potassium levels. Recommend antacid cookies as an alternative to aluminum hydroxide gels needed to bind GI phosphate. Don't give magnesium products because poor renal excretion can lead to toxic levels.
- u If the patient requires dialysis, check the vascular access site every 2 hours for patency and the arm used for adequate blood supply and intact nerve function (check temperature, pulse rate, capillary refill, and sensation). If a fistula is present, feel for a thrill and listen for a bruit. Use a gentle touch to avoid occluding the fistula. Report signs of possible clotting. Don't use the arm with the vascular access site to take blood pressure readings, draw blood, or give injections because these procedures may rupture the fistula or occlude blood flow.
- u Withhold the morning dose of antihypertensive on the day of dialysis, and instruct the patient to do the same.
- u Check the patient's hepatitis antigen status. If he's a carrier of hepatitis B, use universal precautions.
- u After dialysis, check for disequilibrium syndrome, a result of sudden correction of blood chemistry abnormalities. Symptoms range from a headache to seizures. Also check for excessive bleeding from the dialysis site, and apply a pressure dressing or an absorbable gelatin sponge as indicated. Monitor blood pressure carefully after dialysis.

Patient teaching

- u Teach the patient how to take his medications and what adverse effects to watch for. Suggest taking diuretics in the morning so that sleep isn't disturbed.
- u Instruct the anemic patient to conserve energy by resting frequently.
- u Tell the patient to report leg cramps or excessive muscle twitching. Stress the importance of keeping follow-up appointments to have his electrolyte levels monitored.
- u Tell the patient to avoid high-sodium and high-potassium foods. Encourage adherence to fluid and protein restrictions. To prevent constipation, stress the need for exercise and sufficient dietary fiber.
- u If the patient requires dialysis, remember that he and family members are under extreme stress. The facility probably offers a course on dialysis; if not, you need to teach the patient and family members. Topics to cover include reason for the procedure; complications; signs and symptoms of the related disease; how to check for bleeding, electrolyte imbalance, and changes in blood pressure; diet; exercise; and the use of equipment.
- u Refer the patient and family members for counseling if they need help coping with chronic renal failure.
- u Demonstrate how to care for the shunt, fistula, or other vascular access device and how to perform meticulous skin care. Discourage activity that might cause the

patient to bump or irritate the access site.

- u Suggest that the patient wear a medical identification bracelet or carry pertinent information with him.

CYSTINURIA

Cystinuria is an inborn error of amino acid transport in the kidneys and intestine that allows excessive urinary excretion of cystine and other dibasic amino acids. This results in recurrent cystine renal calculus formation.

Cystinuria occurs in about 1 in 15,000 live births. It's the most common defect of amino acid transport. Onset of symptoms commonly occurs between ages 10 and 30 (although it can occur in infants as young as age 1 or in adults well into their 30s). With proper treatment, the prognosis is good.

Causes and pathophysiology

Cystinuria is inherited as an autosomal recessive trait. It affects both sexes but is more severe in males. For some unknown reason, it's more common in people of short stature.

The condition arises when impaired renal tubular reabsorption of dibasic amino acids (cystine, lysine, arginine, and ornithine) causes excessive amino acid concentration and excretion in the urine. When cystine concentration exceeds its solubility, cystine precipitates and forms crystals, precursors of cystine calculi. Excessive excretion of the other three amino acids produces no ill effects.

Complications

Cystine calculi can obstruct and destroy the tissue in the kidneys and ureters. Although infections occur frequently, treatment almost always prevents long-lasting effects.

Assessment findings

A patient with cystine calculi typically complains of dull flank pain from renal parenchymal and capsular distention; nausea, vomiting, and abdominal distention from acute renal colic (caused by smooth-muscle spasm and hyperperistalsis or paralytic ileus); hematuria; and tenderness at the costovertebral angle.

Renal calculi may cause urinary tract obstruction, with resultant secondary infection. A patient reports chills, fever, burning, itching, dysuria, urinary frequency, and foul-smelling urine. In prolonged ureteral obstruction, assessment shows a visible or palpable flank mass.

Diagnostic tests

Various diagnostic tests confirm cystinuria. For example, chemical analysis of calculi shows cystine crystals with a variable amount of calcium. Pure cystine calculi are radiolucent on X-ray, but most contain some calcium. These calculi are light yellow or brownish yellow and granular and may be large.

Blood studies may show an elevated white blood cell count, especially if the patient has a urinary tract infection (UTI), and elevated clearance of cystine, lysine, arginine, and ornithine.

Urinalysis with amino acid chromatography indicates aminoaciduria, consisting of cystine, lysine, arginine, and ornithine. Urine pH normally is less than 5.0.

Microscopic examination of urine shows hexagonal, flat cystine crystals. When glacial acetic acid is added to chilled urine, cystine crystals resemble benzene rings.

An oxide-nitroprusside test result is positive. In cystinuria, a urine specimen made alkaline by adding ammonia turns magenta when nitroprusside is added.

Confirming tests also include excretory urography to determine renal function and kidney-ureter-bladder radiography to detect the size and location of calculi. Because cystine calculi are translucent, these tests can only confirm a diagnosis if other minerals are deposited on the calculus or if an obstruction is present.

Treatment

No effective treatment exists to decrease cystine excretion. Increasing fluid intake to maintain a minimum 24-hour urine volume of 3,000 ml and reduce urine cystine concentration is the primary means of diluting excess cystine and preventing cystine calculus formation.

Sodium bicarbonate and an alkaline-ash diet (high in vegetables and fruit and low in protein) alkalinize urine, thereby increasing cystine solubility. However, this therapy may provide a favorable environment for formation of calcium phosphate calculi.

Penicillamine also can increase cystine solubility, but it should be used with caution because of its toxicity and the high incidence of allergic reactions.

Dissolving cystine calculi may take up to 12 months (in 40% of patients). Irrigating agents, such as tromethamine or acetylcysteine, have been effective. Electrohydraulic ultrasonography may be used to break the calculi into fragments that can be passed.

Treatment also may include surgical removal of calculi, when necessary, and appropriate measures to prevent and treat UTI.

Nursing diagnoses

u Altered urinary elimination u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will maintain urine specific gravity within designated limits.
- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Carefully monitor sodium bicarbonate administration because metabolic alkalosis may develop. Estimate the arterial bicarbonate level by subtracting 2 from the serum carbon dioxide level.
- u Watch for cardiac and neuromuscular problems associated with low potassium levels.
- u If irrigating agents are used, the patient needs a percutaneous nephrostomy tube and access for drainage. Stop the irrigation if intrarenal pressures increase or if fever and extreme pain occur.
- u To prevent high intrarenal pressures, check and regulate the solution flow whenever the patient changes position.
- u Keep the patient on bed rest, and apply antiembolism stockings during irrigations to reduce the risk of emboli.

Patient teaching

- u Emphasize the need for an increased, evenly spaced fluid intake, even through the night.
- u Teach the patient the signs and symptoms of renal calculi and UTI, and tell him to report them immediately.
- u Teach the patient how to check and record urine pH and when to report the results.
- u Encourage the patient to adhere to the recommended diet.
- u Explain to the patient receiving penicillamine that it may cause an allergic or serum sickness-type reaction. Describe this and other possible adverse effects, including severe proteinuria, neutropenia, tinnitus, and taste impairment.
- u Explain that periodic serum and urine evaluations are necessary to monitor for drug effectiveness.

HYDRONEPHROSIS

Hydronephrosis is an abnormal dilation of the renal pelvis and the calyces of one or both kidneys. It's caused by an obstruction of urine flow in the genitourinary tract. A partial obstruction and hydronephrosis may not produce symptoms initially, but pressure that builds up behind the area of obstruction eventually results in symptoms of renal dysfunction.

Causes

Almost any type of obstructive uropathy can lead to hydronephrosis. The most common causes are benign prostatic hyperplasia, urethral strictures, and calculi. Less common causes include strictures or stenosis of the ureter or bladder outlet; congenital abnormalities; bladder, ureteral, or pelvic tumors; blood clots; and neurogenic bladder.

If the obstruction is in the urethra or bladder, hydronephrosis is usually bilateral; if the obstruction is in a ureter, hydronephrosis is usually unilateral. Obstructions distal to the bladder cause the bladder to dilate and act as a buffer zone, delaying hydronephrosis. Total obstruction of urine flow with dilation of the collecting system ultimately causes complete cortical atrophy and cessation of glomerular filtration.

PATHOPHYSIOLOGY

Understanding postobstructive diuresis

Polyuria—urine output that exceeds 2,000 ml in 8 hours—and excessive electrolyte losses characterize postobstructive diuresis. Although usually self-limiting, this condition can cause vascular collapse, shock, and death if not treated with fluid and electrolyte replacement.

Prolonged pressure of retained urine damages renal tubules, limiting their ability to concentrate urine. Removing the obstruction relieves the pressure, but tubular function may not significantly improve for days or weeks, depending on the patient's condition.

Although diuresis typically abates in a few days, it persists if serum creatinine levels remain high. When these levels approach the normal range (0.7 to 1.4 mg/dl), diuresis usually subsides.

Complications

The most common complication of an obstructed kidney is life-threatening infection (pyelonephritis) caused by urinary stasis that exacerbates renal damage. If hydronephrosis results from acute obstructive uropathy, the patient may develop paralytic ileus. Untreated bilateral hydronephrosis can lead to renal failure, a life-threatening condition.

Assessment findings

The patient's history and chief complaints vary depending on the cause of the obstruction. For example, a patient may have no symptoms or complain of only mild pain and slightly decreased urine flow. Or he may report severe, colicky renal pain or dull flank pain that radiates to the groin and gross urinary abnormalities, such as hematuria, pyuria, dysuria, alternating oliguria and polyuria, and anuria.

A patient with hydronephrosis may report nausea, vomiting, abdominal fullness, pain on urination, dribbling, and urinary hesitancy. Pain on only one side, usually in the flank area, can signal a unilateral obstruction.

Patients at increased risk of developing hydronephrosis should be identified and monitored closely. Such populations include those with neurogenic bladder, renal calculi, and benign prostatic hyperplasia. Development of hematuria, urinary tract infection, change in voiding pattern, flank pain, and abdominal fullness can be early signs of hydronephrosis in these patients.

Diagnostic tests

Excretory urography, retrograde pyelography, renal ultrasonography, and renal function studies confirm the diagnosis. Visualization tests show concave (early stage) or convex (later stage) calyces as dilation progresses. If the disease is extensive, tests show atrophied distal and proximal tubules and obstructions.

Urine studies confirm the inability to concentrate urine, a decreased glomerular filtration rate and, possibly, pyuria if infection is present.

Treatment

The goals of treatment are to preserve renal function and prevent infection through surgical removal of the obstruction. Surgery includes dilatation for a urethral stricture or prostatectomy for benign prostatic hyperplasia.

If renal function has already been affected, therapy may include a diet low in protein, sodium, and potassium. This diet is designed to stop the progression of renal failure before surgery.

Inoperable obstructions may necessitate decompression and drainage of the kidney, using a nephrostomy tube placed temporarily or permanently in the renal pelvis. Concurrent infection requires appropriate antibiotic therapy.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered urinary elimination
- u Anxiety
- u Fluid volume deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.

- u The patient will maintain hemodynamic stability.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Administer prescribed pain medication as needed.
- u Monitor renal function studies daily, including blood urea nitrogen, serum creatinine, and serum potassium levels. Specific gravity tests can be done at the bedside.
- u Postoperatively, closely monitor intake and output, vital signs, and fluid and electrolyte status. Watch for a rising pulse rate and cold, clammy skin, which can indicate impending hemorrhage and shock.

Keep in mind that postobstructive diuresis may cause the patient to lose great volumes of dilute urine over hours or days. If this occurs, administer I.V. fluids at a constant rate, as ordered, plus an amount of I.V. fluid equal to a percentage of hourly urine to safely replace intravascular volume. (See [Understanding postobstructive diuresis.](#))

- u Consult with a dietitian to provide a diet consistent with the treatment plan that contains foods the patient will eat.
- u If a nephrostomy tube was inserted, frequently check it for bleeding and patency. Irrigate the tube only as ordered and don't clamp it. Provide meticulous skin care to the area surrounding the tube; if urine leaks, provide a protective skin barrier to decrease excoriation. Observe for signs of infection.
- u Allow the patient to express his fears and anxieties, and help him find effective coping strategies.

Patient teaching

- u Explain hydronephrosis to the patient and family members. Also explain the purpose of diagnostic tests and how they're performed.
- u If the patient is scheduled for surgery, explain the procedure and postoperative care.
- u If the patient is to be discharged with a nephrostomy tube in place, teach him how to care for it, including how to thoroughly clean the skin around the insertion site.
- u If the patient must take antibiotics after discharge, tell him to take all of the prescribed medication even if he feels better.
- u To prevent the progression of hydronephrosis to irreversible renal disease, urge an older male patient (especially a patient with a family history of benign prostatic hyperplasia or prostatitis) to have routine medical checkups. Teach him to recognize and report symptoms of hydronephrosis, such as colicky pain or hematuria, or urinary tract infection.

NEPHROTIC SYNDROME

Nephrotic syndrome isn't a disease but is characterized by marked proteinuria, hypoalbuminemia, hyperlipidemia, increased coagulation, and edema. It results from a glomerular defect that affects the vessels' permeability and indicates renal damage. The prognosis is highly variable, depending on the underlying cause, but age plays no part in progression or prognosis. Some forms of nephrotic syndrome may eventually progress to end-stage renal failure.

Causes and pathophysiology

About 75% of nephrotic syndrome cases result from primary (idiopathic) glomerulonephritis. Causes include the following:

- u *Lipid nephrosis (nil lesions)* is the main cause of nephrotic syndrome in children under age 8. The glomeruli appear normal by light microscopy. Some tubules may contain increased lipid deposits.
- u *Membranous glomerulonephritis* is the most common lesion in adult idiopathic nephrotic syndrome. It's characterized by the appearance of immune complexes, seen as dense deposits, within the glomerular basement membrane and by the uniform thickening of the basement membrane. It eventually progresses to renal failure.
- u *Focal glomerulosclerosis* can develop spontaneously at any age, occur after kidney transplantation, or result from heroin injection. About 10% of children and up to 20% of adults with nephrotic syndrome develop this condition. Lesions initially affect some of the deeper glomeruli, causing hyaline sclerosis. Involvement of the superficial glomeruli occurs later. These lesions usually cause slowly progressive deterioration in renal function, although remissions may occur in children.
- u *Membranoproliferative glomerulonephritis* causes slowly progressive lesions to develop in the subendothelial region of the basement membrane. This disorder may follow infection, particularly streptococcal infection, and occurs primarily in children and young adults.

Other causes of nephrotic syndrome include metabolic diseases such as diabetes mellitus; collagen-vascular disorders, such as systemic lupus erythematosus and periarteritis rodosa; circulatory diseases, such as heart failure, sickle cell anemia, and renal vein thrombosis; nephrotoxins, such as mercury, gold, and bismuth; infections, such as tuberculosis and enteritis; allergic reactions; pregnancy; hereditary nephritis; and certain neoplastic diseases such as multiple myeloma.

All of these diseases increase glomerular protein permeability, which leads to increased urinary excretion of protein, especially albumin, and subsequent hypoalbuminemia.

Evaluating edema

To assess pitting edema, press firmly for 5 to 10 seconds over a bony surface, such as the subcutaneous part of the tibia, fibula, sacrum, or sternum. Then remove your finger and note how long the depression remains. Document your observation on a scale from + 1 (barely detectable depression) to + 4 (persistent pit as deep as 1" [2.5 cm]).

In severe edema, tissue swells so much that fluid can't be displaced, making pitting impossible. The surface feels rock-hard, and subcutaneous tissue becomes fibrotic. Brawny edema eventually may develop.

+1 PITTING EDEMA

+4 PITTING EDEMA

BRAWNY EDEMA

Decreased serum albumin results in a decreased colloidal oncotic pressure with subsequent leakage of fluid into interstitial spaces, leading to acute and generalized edema. This loss of vascular volume leads to increased blood viscosity and coagulation disorders. It also triggers the renin-angiotensin system, causing tubular reabsorption of sodium and water and contributing to edema.

Complications

Major complications include malnutrition, infection, coagulation disorders, thromboembolic vascular occlusion (especially in the lungs and legs), and accelerated atherosclerosis. Hypochromic anemia can develop from excessive urinary excretion of transferrin. Acute renal failure may occur.

Assessment findings

The patient may complain of lethargy and depression. Your assessment may reveal two common problems: periorbital edema, which occurs primarily in the morning and is more common in children, and mild to severe dependent edema of the ankles or sacrum. (See [Evaluating edema](#).) You may note orthostatic hypotension, ascites, swollen external genitalia, signs of pleural effusion, anorexia, and pallor.

Diagnostic tests

Urinalysis reveals an increased number of hyaline, granular, and waxy, fatty casts as well as oval fat bodies. Consistent, heavy proteinuria (levels over 3.5 mg/dl for 24 hours) strongly suggests nephrotic syndrome.

Serum values that support the diagnosis include increased levels of cholesterol, phospholipids (especially low-density and very-low-density lipoproteins), and triglycerides, and decreased albumin levels.

Histologic identification of the lesion necessitates a renal biopsy.

Treatment

Effective treatment of nephrotic syndrome requires correction of the underlying cause if possible. Supportive treatment consists of a nutritious diet of 0.6 g of protein per kilogram of body weight, with restricted sodium intake, diuretics for edema, and antibiotics for infection.

Some patients respond to an 8-week course of a corticosteroid such as prednisone followed by maintenance therapy. Others respond better to a combination of prednisone and azathioprine or cyclophosphamide. Treatment for hyperlipidemia frequently is unsuccessful.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered tissue perfusion (renal) u Body image disturbance u Fluid volume excess u Risk for infection u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will identify risk factors that exacerbate decreased tissue perfusion and modify his lifestyle appropriately.
- u The patient will maintain hemodynamic stability.
- u The patient will avoid or minimize complications.
- u The patient will express positive feelings about himself.

Nursing interventions

- u Frequently check urine for protein. Urine that contains protein appears frothy.
- u Document the location and character of the patient's edema.
- u Measure blood pressure with the patient lying down and standing. Immediately report a decrease in systolic or diastolic pressure exceeding 20 mm Hg.
- u After a renal biopsy, watch for bleeding and signs of shock.

- u Monitor intake and output and weigh the patient each morning after he voids and before he eats. Make sure he's wearing the same amount of clothing each time you weigh him.
- u Ask the dietitian to plan a low-sodium diet with moderate amounts of protein.
- u Monitor plasma albumin and transferrin concentrations to evaluate overall nutritional status.
- u Provide meticulous skin care to combat the edema that usually occurs with nephrotic syndrome. Use a reduced-pressure mattress or padding to help prevent pressure ulcers.
- u To avoid thrombophlebitis, encourage activity and exercise and provide antiembolism stockings as ordered.
- u Offer the patient and family members reassurance and support, especially during the acute phase, when edema is severe and the patient's body image changes.

Patient teaching

- u If the patient is taking immunosuppressants, teach him and family members to report even mild signs of infection. If he's undergoing long-term corticosteroid therapy, teach him and family members to report muscle weakness and mental changes.
- u To prevent GI complications, suggest to the patient that he take steroids with an antacid or with cimetidine or ranitidine. Explain that the adverse effects of steroids subside when therapy stops, but warn the patient not to discontinue the drug abruptly or without a doctor's consent.
- u Stress the importance of adhering to the special diet.
- u If the doctor prescribes antiembolism stockings for home use, show the patient how to safely apply and remove them.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis is a syndrome that causes persistent dehydration, hyperchloremia, hypokalemia, metabolic acidosis, and nephrocalcinosis. Renal tubular acidosis results from the kidneys' inability to conserve bicarbonate. This disorder is classified as distal (type I, or classic renal tubular acidosis) or proximal (type II).

Distal renal tubular acidosis occurs in two forms:

- u *Primary distal renal tubular acidosis* is most prevalent in women, older children, adolescents, and young adults. The disease may result from a hereditary defect. Occasionally, it may occur for unknown reasons.
- u *Secondary distal renal tubular acidosis* has been linked to many renal or systemic conditions, such as starvation, malnutrition, and hepatic cirrhosis, and to several genetically transmitted disorders.

Proximal renal tubular acidosis results from defective reabsorption of bicarbonate in the proximal tubule. This causes bicarbonate to flood the distal tubule, which normally secretes hydrogen ions, and leads to impaired formation of titratable acids and ammonium for excretion. Metabolic acidosis ultimately results.

Proximal renal tubular acidosis also occurs in two forms:

- u In *primary proximal renal tubular acidosis*, the reabsorptive defect is idiopathic and is the only disorder present.
- u In *secondary proximal renal tubular acidosis*, the reabsorptive defect may be one of several and is due to proximal tubular cell damage from a disease such as Fanconi's syndrome.

Renal tubular acidosis affects people of all ages, including infants. The prognosis is usually good but depends on the severity of renal damage that precedes treatment.

Causes

Distal renal tubular acidosis is caused by the distal tubule's inability to secrete hydrogen ions against established gradients across the tubular membrane. This results in decreased excretion of titratable acids and ammonium, increased loss of potassium and bicarbonate in the urine, and systemic acidosis.

Type I is transmitted as an autosomal dominant trait, and type II is probably transmitted as an autosomal recessive trait but may also be autosomal dominant or X-linked.

Complications

This syndrome can result in pyelonephritis. Prolonged acidosis causes mobilization of calcium from bone and, eventually, hypercalciuria, predisposing the patient to the formation of renal calculi. Lack of calcium stunts growth in children and causes osteomalacia in adults.

Assessment findings

Parents of infants with renal tubular acidosis report that the infant is vomiting and has anorexia, constipation, occasional fever, and polyuria. Inspection reveals lethargy, weakness, tissue wasting, and growth retardation as well as signs of dehydration (poor skin turgor and dry, cracked lips), rickets (irritability, delayed closure of fontanels, and bowed legs), and nephrocalcinosis (hematuria and low abdominal or flank pain).

Older children may have urinary tract infections (UTIs), rickets, and growth problems. Adults may complain of frequent UTIs and may show signs of osteomalacia.

Diagnostic tests

Demonstration of impaired urine acidification with systemic metabolic acidosis confirms distal renal tubular acidosis. Demonstration of bicarbonate wasting due to impaired reabsorption confirms proximal renal tubular acidosis.

An ammonium chloride loading test helps determine the type of renal tubular acidosis. If the urine pH stays above 5.5 after oral administration of ammonium chloride, despite systemic acidosis, distal renal tubular acidosis is present; if the urine pH falls below 5.5, proximal renal tubular acidosis is present.

Other relevant laboratory results show:

- u decreased serum bicarbonate, potassium, and phosphorus levels
- u increased serum chloride and alkaline phosphatase levels
- u alkaline pH, with low titratable acid and ammonium content in urine, increased urine bicarbonate and potassium levels, and low specific gravity.

In later stages, X-rays may show nephrocalcinosis.

Treatment

Supportive treatment requires replacement of substances being excreted abnormally, especially bicarbonate. Treatment may include sodium bicarbonate tablets or Shohl's solution to control acidosis, oral potassium for dangerously low potassium levels, and vitamin D for bone disease. If pyelonephritis occurs, antibiotics may be prescribed as well.

Treatment for renal calculi secondary to nephrocalcinosis varies and may include supportive therapy until the calculi pass or until surgery for severe obstruction is performed.

Nursing diagnoses

u Altered growth and development u Altered nutrition: Less than body requirements u Altered parenting u Altered urinary elimination u Fluid volume deficit u Ineffective family coping: Disabling u Pain u Risk for infection

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will maintain hemodynamic stability.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Monitor laboratory test values, especially potassium levels to detect hypokalemia.
- u Administer potassium, sodium bicarbonate or Shohl's solution, vitamin D preparations, or antibiotics as ordered.
- u Consult with the dietitian to ensure an appetizing diet that is nutritionally adequate.
- u Test urine for pH, and strain it for calculi.
- u If surgery is performed to eliminate an obstruction, watch for signs of postoperative hemorrhage and shock secondary to hypovolemia.
- u If the patient is an infant or a child, encourage the parents to express their concerns and fears. Offer support as needed.

Patient teaching

- u Explain all diagnostic tests. If the patient is scheduled for surgery, explain the procedure and postoperative care.
- u If rickets develops, explain the condition and its treatment to the patient and family members.
- u Urge compliance with all medication instructions. Emphasize that the prognosis for the disorder and bone lesion healing is directly related to the adequacy of treatment.
- u Review the signs and symptoms of calculi (hematuria and low abdominal or flank pain). Tell the patient or parents to report any suspicious findings immediately.
- u Instruct the patient with low potassium levels to eat foods with a high potassium content, such as bananas, baked potatoes, orange juice, and prune juice.
- u Because renal tubular acidosis may be caused by a genetic defect, encourage family members to seek genetic counseling or screening for this disorder.

RENOVASCULAR HYPERTENSION

Renovascular hypertension occurs when systemic blood pressure increases because of stenosis of the major renal arteries or their branches, or because of intrarenal atherosclerosis. This narrowing (sclerosis) may be partial or complete, and the resulting blood pressure elevation may be benign or malignant. About 5% to 15% of patients with high blood pressure display renovascular hypertension.

Causes and pathophysiology

In about 95% of patients, renovascular hypertension results from either atherosclerosis (especially in older men) or fibromuscular diseases of the renal artery wall layers (for example, medial fibroplasia and, less commonly, intimal and subadventitial fibroplasia). Other causes include arteritis, anomalies of the renal arteries, embolism, trauma, tumor, and dissecting aneurysm.

Stenosis or a renal artery occlusion stimulates the affected kidney to release renin, an enzyme that converts angiotensinogen (a plasma protein) to angiotensin I. As angiotensin I circulates through the lungs and liver, it converts to angiotensin II, which causes peripheral vasoconstriction, increased arterial pressure and aldosterone secretion and, eventually, hypertension. (See [What happens in renovascular hypertension.](#))

Complications

Renovascular hypertension can lead to such significant complications as heart failure, myocardial infarction, cerebrovascular accident and, occasionally, renal failure.

Assessment findings

In the early stages, the patient may complain of flank pain. During your assessment, you may note reduced urine output, elevated blood pressure, and a systolic bruit over the epigastric vein in the upper abdomen on auscultation.

As the disorder progresses, the patient may report headache, nausea, anorexia, fatigue, palpitations, tachycardia, and anxiety. If renal failure occurs, you may notice alterations in the patient's level of consciousness and pitting edema. Auscultation may reveal bibasilar crackles.

Diagnostic tests

An isotopic renal blood flow scan and rapid-sequence excretory urography are needed to identify renal blood flow abnormalities and discrepancies of kidney size and shape. Renal arteriography reveals the actual arterial stenosis or obstruction.

Samples from the right and left renal veins are obtained for comparison of plasma renin levels with those in the inferior vena cava (split renal vein renins). Increased renin levels from the involved kidney that exceed levels from the uninvolved kidney by a ratio of 1.5:1.0 or greater implicate the affected kidney and determine whether surgery can reverse hypertension.

Laboratory evaluation of serum samples shows hypokalemia, hyponatremia or hypernatremia, and elevated blood volume. Elevated blood urea nitrogen (BUN) and serum creatinine levels signal the onset of renal failure.

Urine studies may reveal albuminuria and high specific gravity.

A positive captopril test can differentiate renovascular hypertension from essential hypertension before more invasive tests are done.

Treatment

Angioplasty is the treatment of choice for all patients with renovascular hypertension except those with osteal lesions or complete occlusion. Renal artery stenting is an option in some individuals to optimize vascularization. Other surgical techniques include renal artery bypass, endarterectomy, arterioplasty and, as a last resort, nephrectomy. Surgery is effective in up to 95% of cases in restoring adequate circulation and controlling severe hypertension. It can also improve severely impaired renal function.

PATHOPHYSIOLOGY

What happens in renovascular hypertension

The kidneys normally play a key role in maintaining blood pressure and volume by vasoconstriction and regulation of sodium and fluid levels. In renovascular hypertension, these regulatory mechanisms fail.

Certain conditions, such as renal artery stenosis and tumors, reduce blood flow to the kidneys. This causes juxtaglomerular cells to continuously secrete renin.

In this stage, be alert for flank pain, systolic bruit in the epigastric vein or upper abdomen, reduced urine output, and elevated renin levels.

In the liver, renin and angiotensinogen combine to form angiotensin I, which converts to angiotensin II in the lungs. This potent vasoconstrictor heightens peripheral resistance and blood pressure.

Check for headache, nausea, anorexia, elevated renin levels, and hypertension.

Angiotensin II acts directly on the kidneys, causing them to reabsorb sodium and water.

Assess for hypertension, diminished urine output, albuminuria, hypokalemia, and hypernatremia.

Angiotensin II stimulates the adrenal cortex to secrete aldosterone. This also causes the kidneys to retain sodium and water, elevating blood volume and pressure.

Expect worsening symptoms.

Intermittent pressure diuresis causes excretion of sodium and water, reduced blood volume, and decreasing cardiac output.

Check for blood pressure that increases slowly, drops (but not as low as before), and then increases again. Headache, high urine specific gravity, hyponatremia, fatigue, and heart failure also occur.

High aldosterone levels cause further sodium retention, but they can't curtail renin secretion. Excessive aldosterone and angiotensin II can damage renal tissue, leading to renal failure. Expect to find hypertension, pitting edema, anemia, decreased level of consciousness, and elevated blood urea nitrogen and serum creatinine levels.

Symptomatic measures include antihypertensives, diuretics, and a sodium-restricted diet.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered thought processes u Altered urinary elimination u Anxiety u Decreased cardiac output u Fluid volume excess u Pain u Risk for injury

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will maintain hemodynamic stability.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Prepare the patient for diagnostic tests. For example, adequately hydrate him before tests that use a contrast medium, and make sure he isn't allergic to the medium used. Watch for complications after excretory urography or arteriography.
- u Accurately monitor and record intake and output and daily weight. Weigh the patient at the same time each day (before a meal) and when he's wearing the same amount of clothing.
- u Frequently assess urine specific gravity, BUN, serum creatinine, and protein levels.
- u Check blood pressure in both arms regularly, with the patient lying down and standing. A drop of 20 mm Hg or more in either systolic or diastolic pressure on arising may necessitate a dosage adjustment in antihypertensive medications.
- u Administer drugs as ordered. Adequately medicate the patient for pain to decrease anxiety and increase comfort.
- u Maintain fluid and sodium restrictions.
- u If the patient is anorexic, offer appetizing, high-calorie meals to ensure adequate nutrition.
- u If a nephrectomy is necessary, reassure the patient that his remaining kidney is adequate for renal function.
- u Provide good postoperative care: Watch for bleeding and hypotension. If the sutures around the renal vessels slip, the patient can quickly go into shock because kidneys receive 25% of cardiac output. Report and record the number and amount of dressing reinforcements. Monitor vital signs and report hypotension, which can precipitate acute renal failure.
- u Provide a quiet, stress-free environment, if possible.
- u Encourage cardiovascular fitness, and work with the doctor and patient to develop a beneficial program.

Patient teaching

- u Help the patient and family members understand renovascular hypertension, and emphasize the importance of following the prescribed treatment regimen.
- u Describe the purpose of diagnostic tests, and explain each procedure. If the patient is scheduled for surgery, explain the procedure and postoperative care.
- u Familiarize the patient with his medications, and encourage him to take them as ordered. Suggest taking diuretics in the morning so that sleep patterns aren't disturbed.
- u Suggest regular blood pressure screenings.
- u Explain the purpose of a low-sodium diet, and stress the importance of following it. Also stress the need to restrict fluids, if appropriate.
- u Encourage the patient to perform stress-relieving exercises.

Lower urinary tract disorders

Lower urinary tract disorders include congenital anomalies of the ureter, bladder, and urethra; lower urinary tract infection; neurogenic bladder; and vesicoureteral reflux.

CONGENITAL ANOMALIES OF THE URETER, BLADDER, AND URETHRA

Congenital anomalies of the ureter, bladder, and urethra occur in about 5% of all births. They're among the most common birth defects. Some of these abnormalities are obvious at birth; others aren't recognized until they produce symptoms. Obstructions and malformations that necessitate surgery have a good prognosis.

Causes and pathophysiology

The cause of these anomalies is unknown. (For information about pathophysiology, see [Reviewing congenital urologic anomalies.](#))

Complications

Mild to severe infections, hematuria, and calculi can complicate any anomaly that prevents urine from flowing freely from the body.

Assessment findings

In *duplicated ureter*, the patient may report persistent or recurrent urinary tract infection (UTI), urinary frequency and urgency, burning on urination, diminished urine output, flank pain, fever, and chills. These signs and symptoms are associated with vesicoureteral reflux, ectopic ureters, and ureterocele.

In *retrocaval ureter (preureteral vena cava)*, the patient may complain of right flank pain, recurrent UTI, and hematuria. If renal calculi occur, the patient may complain of severe pain that travels from the costovertebral angle to the flank and then to the suprapubic area and the external genitalia. Infants may cry uncontrollably.

In *ectopic orifice of the ureter*, symptoms are rare when the ureteral orifice opens between the trigone and bladder neck. Incontinence (dribbling) occurs in about 50% of female patients; they may complain of back pain or severe abdominal pain accompanied by anuria, nausea, and vomiting if obstruction occurs. Male patients may complain of flank pain and urinary frequency and urgency.

In *stricture or stenosis of the ureter*, the patient may have back pain accompanied by anuria, nausea, and vomiting if obstruction occurs.

In *ureterocele*, the patient may report signs of obstruction and persistent or recurrent UTI.

In *exstrophy of the bladder*, which is obvious at birth, urine seeps onto the abdominal wall from abnormal ureteral orifices. Excoriation of the surrounding skin and ulceration of the exposed bladder mucosa occur. Infection and associated abnormalities are also characteristic.

In *congenital bladder diverticulum*, the patient may report fever, urinary frequency, and painful urination. UTI can occur, particularly cystitis in males.

Hypospadias usually is associated with *chordee*, making normal urination with the penis elevated impossible. The patient may exhibit an absence or deficit of the ventral prepuce and ambiguous genitalia. Vaginal discharge may occur in females.

In mild cases of *epispadias*, the orifice appears along the dorsum of the glans; in severe cases, it appears along the dorsum of the penis. In females, a bifid clitoris and a short, wide urethra are seen. Total urinary incontinence occurs when the urethral opening is proximal to the sphincter.

Diagnostic tests

In duplicated ureter, diagnostic tests may include excretory urography, cystoscopy, voiding cystourethrography, and retrograde pyelography.

In retrocaval ureter, excretory or retrograde urography demonstrates superior ureteral enlargement with spiral appearance.

In ectopic orifice of the ureter, diagnostic tests include excretory urography, urethroscopy, vaginoscopy, voiding cystourethrography, and retrograde urethrography.

In stricture or stenosis of the ureter, diagnostic tests include ultrasonography, excretory and retrograde urography, renography, and voiding cystourethrography.

In ureterocele, voiding cystourethrography, excretory urography, cystography, and cystoscopy may help to diagnose the disorder. Excretory urography and cystography may show a thin, translucent mass. Cystoscopy is used to assess the location of ureteral orifices and the changes on the submucosal tunnel.

In exstrophy of the bladder, diagnosis requires a radionuclide scan and renal ultrasonography. Buccal smears and karyotyping may be necessary.

In congenital bladder diverticulum, excretory urography shows a diverticulum obstructing the ureteral entry to the bladder. Voiding cystourethrography shows vesicoureteral reflux in the ureter, and cystoscopy confirms the diverticulum.

In hypospadias, buccal smears and karyotyping may be necessary when sexual identification is questionable.

Treatments

In duplicated ureter, surgery may be necessary for obstruction, reflux, or severe renal damage.

In retrocaval ureter, treatment involves surgical resection and anastomosis of the ureter with the renal pelvis or reimplantation into the bladder.

In ectopic orifice of the ureter, treatment consists of resection and ureteral reimplantation into the bladder for incontinence.

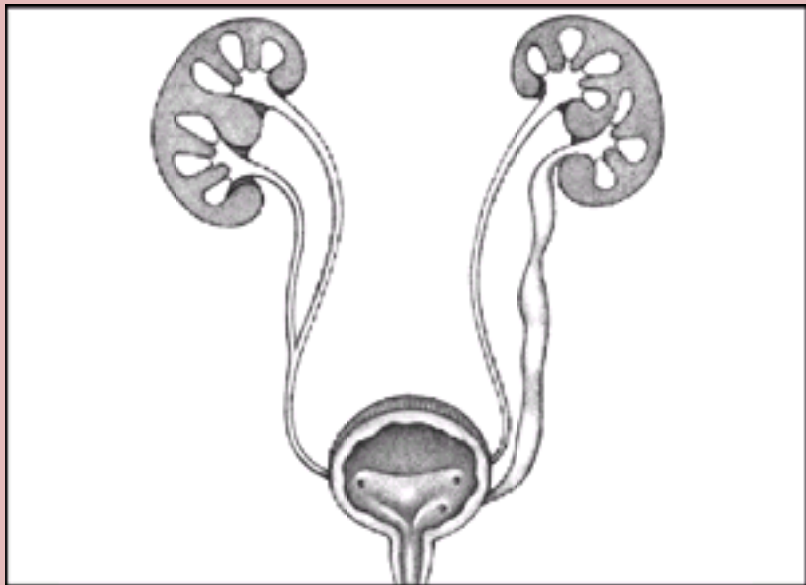

In stricture or stenosis of the ureter, treatment consists of surgical repair of the stricture. Nephrectomy may be necessary for severe renal damage, based on radionuclide studies.

PATHOPHYSIOLOGY

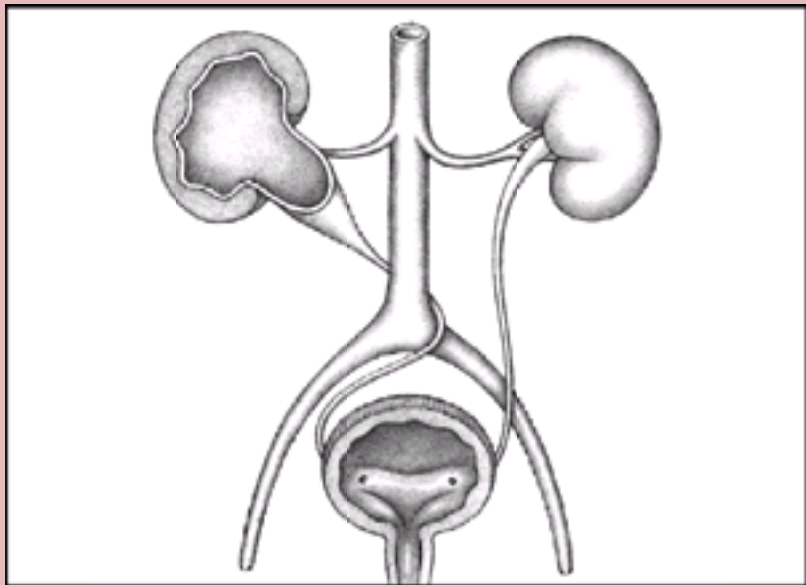

Reviewing congenital urologic anomalies

The most common malformations are duplicated ureter, retrocaval ureter, ectopic orifice of the ureter, stricture or stenosis of the ureter, ureterocele, exstrophy of the bladder, congenital bladder diverticulum, hypospadias, and epispadias.

Duplicated ureter
Referred to as either complete or incomplete, duplicated ureter is the most common ureteral anomaly. A *complete* duplicated ureter consists of a double collecting system with two separate pelvises, each with its own ureter and orifice. An *incomplete* duplicated ureter (Y type) has two separate ureters that join before entering the bladder.

Retrocaval ureter (preureteral vena cava)
In this anomaly, the right ureter passes behind the inferior vena cava before entering the bladder. Compression of the ureter between the vena cava and the spine causes dilation and elongation of the pelvis, hydroureter, hydronephrosis, and fibrosis and stenosis of the ureter in the compressed area. Although rare in either sex, retrocaval ureter has a higher incidence in males.

Ectopic orifice of the ureter

In this anomaly, the openings of single or duplicated ureters are displaced. In females, ectopic ureters usually are part of a duplicated anomaly, and the ureters open into the urethra, vestibule, or vagina beyond the external urethral sphincter. In males, ectopic ureters occur more often with a single system and commonly open into the prostatic urethra, seminal vesicles, vas deferens, or epididymis.

Stricture or stenosis of the ureter

The most common site for stricture or stenosis is the distal ureter above the ureterovesical junction; less common, the ureteropelvic junction; rare, the midureter. This anomaly is discovered during infancy in 25% of patients and before puberty in most. It's more common in males than females by a 5:2 ratio

Ureterocele

In ureterocele, the submucosal ureter bulges into the bladder. It can be unilateral, bilateral, or ectopic with resulting hydroureter and hydronephrosis.

Exstrophy of the bladder

In exstrophy of the bladder, the absence of the lower anterior abdominal wall and anterior bladder wall allows the posterior bladder wall to protrude onto the abdomen. In males, associated disorders include epispadias and undescended testes; in females, cleft clitoris, separated labia, and stenotic vagina. Skeletal and intestinal anomalies also are possible.

Congenital bladder diverticulum

A circumscribed pouch or sac (diverticulum) of the bladder wall can occur anywhere in the bladder but usually arises lateral to the ureteral orifice. A large diverticulum at the orifice can cause reflux.

Hypospadias

In this anomaly, the urethral opening is on the ventral surface of the penis or, in females (rare), within the vagina. Hypospadias occurs in 1 of 300 live male births. A genetic factor is suspected in less severe cases.

Epispadias

Epispadias is a rare disorder involving a urethral opening on the dorsal surface of the penis; in females, a fissure of the upper wall of the urethra. Epispadias occurs more commonly in males than in females and often accompanies bladder exstrophy.

In ureterocele, treatment involves surgical excision or resection of the ureterocele and reimplantation of the ureter.

In exstrophy of the bladder in infants, treatment includes surgical closure of the defect and bladder and urethral reconstruction to allow pubic bone fusion and normal continence and renal function. Additional measures may include bladder reconstruction with the use of an artificial urinary sphincter and reconstruction of a functional penis in males. Alternative treatment includes protective dressing and diapering. Urinary diversion eventually is necessary for most patients

In congenital bladder diverticulum, surgery may be necessary to correct reflux.

If hypospadias is mild, it requires no treatment. If the anomaly is severe, surgical repair usually is necessary before the child reaches school age.

In epispadias, surgical repair in several stages is always necessary.

Nursing diagnoses

u Altered family processes u Altered parenting u Altered urinary elimination u Fluid volume deficit u Impaired skin integrity u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will maintain hemodynamic stability.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u Parents will express feelings of greater control and capability in meeting their child's needs.
- u Parents will communicate feelings and anxieties about the neonate's condition and their parenting skills.

Nursing interventions

- u Because these anomalies aren't always obvious at birth, carefully evaluate the neonate's urogenital function. Document the amount and color of urine, voiding pattern, strength of stream, and any indications of infection, such as fever and urine odor.
- u In all children, watch for signs of obstruction, such as dribbling, oliguria or anuria, an abdominal mass, hypertension, fever, bacteriuria, and pyuria.
- u Monitor renal function daily; record intake and output.
- u Follow aseptic technique in handling cystostomy tubes or indwelling urinary catheters.
- u Make sure that ureteral, suprapubic, or urethral catheters remain in place and don't become contaminated. Document the type, color, and amount of drainage.
- u Apply a nonadhering film of plastic wrap over the exposed mucosa of the neonate with bladder exstrophy. Don't use heavy clamps on the umbilical cord; this causes more trauma and excoriation of the bladder surface. Don't diaper the infant. Instead, place him in an incubator and direct a stream of saline mist onto the bladder to keep it moist. Use warm water and mild soap to keep the surrounding skin clean; rinse well. Keep the area as dry as possible to prevent excoriation.
- u Provide reassurance and emotional support to the parents. Allow them to express their concerns and fears. When possible, allow them to participate in their child's care to promote normal bonding.
- u As appropriate, suggest or arrange for genetic counseling.

Patient teaching

- u Before discharge, teach the parents about the particular anomaly and its treatment. Also teach them how to care for their child at home.
- u Teach the parents how to clean around drainage tubes and how to apply sterile dressings if necessary.
- u Discuss signs of infection to watch for and report to the doctor.

LOWER URINARY TRACT INFECTION

The two forms of lower urinary tract infection (UTI) are cystitis (infection of the bladder) and urethritis (infection of the urethra). They're nearly 10 times more common in females than in males (except in elderly males) and affect 10% to 20% of all females at least once. UTI is prevalent in girls.

In adult males and in children, lower UTIs typically are associated with anatomic or physiologic abnormalities and therefore need close evaluation. Most UTIs respond readily to treatment, but recurrence and resistant bacterial flare-up during therapy are possible.

Causes

Most lower UTIs result from ascending infection by a single gram-negative, enteric bacterium, such as *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Pseudomonas*, and *Serratia*. In a patient with neurogenic bladder, an indwelling urinary catheter, or a fistula between the intestine and bladder, a lower UTI may result from simultaneous infection with multiple pathogens.

Studies suggest that infection results from a breakdown in local defense mechanisms in the bladder that allows bacteria to invade the bladder mucosa and multiply. These bacteria can't be readily eliminated by normal urination.

The pathogen's resistance to the prescribed antimicrobial therapy usually causes bacterial flare-up during treatment. Even a small number of bacteria (fewer than 10,000/ml) in a midstream urine specimen obtained during treatment casts doubt on the effectiveness of treatment.

In almost all patients, recurrent lower UTIs result from reinfection by the same organism or by some new pathogen. In the remaining patients, recurrence reflects persistent infection, usually from renal calculi, chronic bacterial prostatitis, or a structural anomaly that is a source of infection. The high incidence of lower UTI among females probably occurs because natural anatomic features facilitate infection. (See [UTI risk factors](#).)

Complications

If untreated, chronic UTI can seriously damage the urinary tract lining. Infection of adjacent organs and structures (for example, pyelonephritis) also may occur. When this happens, the prognosis is poor.

Assessment findings

The patient may complain of urinary urgency and frequency, dysuria, bladder cramps or spasms, itching, a feeling of warmth during urination, nocturia, and urethral discharge (in men). Other complaints include low back pain, malaise, nausea, vomiting, pain or tenderness over the bladder, chills, and flank pain. Inflammation of the bladder wall also causes hematuria and fever.

Diagnostic tests

Several tests are used to diagnose lower UTI. For example, microscopic urinalysis showing red blood cell and white blood cell counts greater than 10 per high-power field suggests lower UTI.

Clean-catch urinalysis revealing a bacterial count of more than 100,000/ml confirms UTI. Lower counts don't necessarily rule out infection, especially if the patient is urinating frequently, because bacteria require 30 to 45 minutes to reproduce in urine. Clean-catch collection is preferred to catheterization, which can reinfect the bladder with urethral bacteria.

Sensitivity testing is used to determine the appropriate antimicrobial drug. If the patient history and physical examination warrant, a blood test or a stained smear of urethral discharge can be used to rule out sexually transmitted disease.

UTI risk factors
<p>Certain factors increase the risk of urinary tract infection (UTI). They include natural anatomic variations, trauma or invasive procedures, urinary tract obstructions, and vesicourethral reflux.</p> <p>Natural anatomic variations</p> <p>Females are more prone to UTIs than males because the female urethra is shorter than the male urethra (about 1" to 2" [2.5 to 5 cm] compared with 7" to 8" [18 to 20 cm]). It's also closer to the anus, allowing bacterial entry into the urethra from the vagina, perineum, or rectum or from a sexual partner.</p> <p>Pregnant women are especially prone to UTIs because of hormonal changes. Also, the enlarged uterus displaces the bladder and exerts greater pressure on the ureters, increasing their length. This restricts urine flow, allowing bacteria to linger longer in the urinary tract.</p> <p>In men, release of prostatic fluid serves as an antibacterial shield. Men lose this protection around age 50 when the prostate gland begins to enlarge. This enlargement, in turn, may promote urine retention.</p> <p>Trauma or invasive procedures</p> <p>Fecal matter, sexual intercourse, and instruments, such as catheters and cystoscopes, can introduce bacteria into the urinary tract to trigger infection.</p> <p>Urinary tract obstructions</p> <p>A narrowed ureter or calculi lodged in the ureters or the bladder can obstruct urine flow. Slowed urine flow allows bacteria to remain and multiply, risking damage to the kidneys.</p> <p>Vesicourethral reflux</p> <p>Vesicourethral reflux results when pressure inside the bladder (caused by coughing or sneezing) pushes a small amount of urine from the bladder into the urethra. When the pressure returns to normal, the urine flows back into the bladder, bringing bacteria from the urethra with it.</p> <p>In vesicoureteral reflux, urine flows from the bladder back into one or both ureters. The vesicoureteral valve normally shuts off reflux. However, damage can prevent the valve from doing its job.</p> <p>Other risk factors</p> <p>Urinary stasis can promote infection, which, if undetected, can spread to the entire urinary system. And because urinary tract bacteria thrive on sugars, diabetes also is a risk factor.</p>

Voiding cystourethrography or excretory urography may disclose congenital anomalies that predispose the patient to recurrent UTI.

Treatment

Appropriate antimicrobials are the treatment of choice for most initial lower UTIs. A 7- to 10-day course of antibiotics is standard, but studies suggest that a single dose or a 3- to 5-day regimen may be sufficient to render the urine sterile. (Elderly patients may still need 7 to 10 days of antibiotics to fully benefit from treatment.) If a culture shows that urine isn't sterile after 3 days of antibiotic therapy, bacterial resistance probably has occurred, and a different antimicrobial is prescribed.

A single dose of amoxicillin or co-trimoxazole may be effective for females with acute, uncomplicated UTI. A urine culture taken 1 to 2 weeks later indicates whether the infection has been eradicated. Recurrent infections from infected renal calculi, chronic prostatitis, or structural abnormalities may necessitate surgery. Prostatitis also requires long-term antibiotic therapy. In patients without these predisposing conditions, long-term, low-dose antibiotic therapy is the treatment of choice.

Nursing diagnoses

u Altered urinary elimination u Knowledge deficit u Pain u Risk for infection u Sexual dysfunction u Sleep pattern disturbance

Key outcomes

- u The patient will report increased comfort.
- u The patient will identify risk factors that exacerbate the disease process or condition and modify his lifestyle accordingly.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.
- u The patient will reestablish sexual activity at the preillness level.

Nursing interventions

- u Watch for GI disturbances from antimicrobial therapy. If ordered, administer nitrofurantoin macrocrystals with milk or meals to prevent such distress.
- u If sitz baths don't relieve perineal discomfort, apply warm compresses sparingly to the perineum, but be careful not to burn the patient. Apply topical antiseptics on the urethral meatus as necessary.
- u Collect all urine specimens for culture and sensitivity testing carefully and promptly.

Patient teaching

- u Explain the nature and purpose of antimicrobial therapy. Emphasize the importance of completing the prescribed course of therapy or, with long-term prophylaxis, of strictly adhering to the ordered dosage.
- u Familiarize the patient with prescribed medications and their possible adverse effects. If antibiotics cause GI distress, explain that taking nitrofurantoin macrocrystals with milk or a meal can help prevent such problems. If therapy includes phenazopyridine, warn the patient that this drug turns urine red-orange and stains clothing.
- u Explain that an uncontaminated midstream urine specimen is essential for accurate diagnosis. Before collection, teach the female patient to clean the perineum properly and to keep the labia separated during urination.
- u Suggest warm sitz baths to relieve perineal discomfort.
- u To prevent recurrent lower UTIs, teach a female patient to carefully wipe the perineum from front to back and to thoroughly clean it with soap and water after bowel movements. If she's infection-prone, she should urinate immediately after sexual intercourse. Tell her never to postpone urination and to empty her bladder completely.
- u Tell the male patient that prompt treatment of predisposing conditions such as chronic prostatitis helps prevent recurrent UTIs.
- u Urge the patient to drink about 2 L (at least eight 8-oz glasses) of fluid a day during treatment. More or less than this amount may alter the antimicrobials effect. Be aware that the elderly patient may resist this suggestion because it causes him to make frequent trips, possibly up and down the stairs, to urinate.
- u Explain that fruit juices, especially cranberry juice, and oral doses of vitamin C may help acidify urine and enhance the action of some medications.

NEUROGENIC BLADDER

All types of bladder dysfunction caused by an interruption of normal bladder innervation by the nervous system are referred to as neurogenic bladder. (Other names for this disorder include neuromuscular dysfunction of the lower urinary tract, neurologic bladder dysfunction, and neuropathic bladder.) Neurogenic bladder can be hyperreflexia (hypertonic, spastic, or automatic) or flaccid (hypotonic, atonic, or autonomous).

An upper motor neuron lesion (at or above T12) causes spastic neurogenic bladder, with spontaneous contractions of detrusor muscles, increased intravesical voiding pressure, bladder wall hypertrophy with trabeculation, and urinary sphincter spasms. A lower motor neuron lesion (at or below S2 to S4) causes flaccid neurogenic bladder with decreased intravesical pressure, increased bladder capacity and residual urine retention, and poor detrusor contraction.

Causes

At one time, neurogenic bladder was thought to result primarily from spinal cord injury; now it appears to stem from a host of underlying conditions, including:

- u *cerebral disorders*, such as cerebrovascular accident, brain tumor (meningioma and glioma), Parkinson's disease, multiple sclerosis, dementia, and incontinence associated with aging
- u *spinal cord disease or trauma*, such as spinal stenosis (causing cord compression) or arachnoiditis (causing adhesions between the membranes covering the cord), cervical spondylosis, spina bifida, myelopathies from hereditary or nutritional deficiencies and, rarely, tabes dorsalis
- u *disorders of peripheral innervation*, including autonomic neuropathies resulting from endocrine disturbances, such as diabetes mellitus (most common)
- u *metabolic disturbances*, such as hypothyroidism, porphyria, or uremia (infrequent)
- u *acute infectious diseases*, such as Guillain-Barré syndrome and transverse myelitis
- u *heavy metal toxicity*
- u *chronic alcoholism*
- u *collagen diseases*, such as systemic lupus erythematosus
- u *vascular diseases*, such as atherosclerosis
- u *distant effects of certain cancers*, such as primary oat cell carcinoma of the lung
- u *herpes zoster*
- u *sacral agenesis*.

Complications

Incontinence, residual urine retention, urinary tract infection (UTI), calculus formation, and renal failure can complicate neurogenic bladder.

Assessment findings

The patient's history includes a condition or disorder that can cause neurogenic bladder. The patient has some degree of incontinence and experiences changes in initiation or interruption of micturition or an inability to completely empty the bladder. He also may have a history of frequent UTIs. Other assessment findings may be present depending on the site and extent of the spinal cord lesion. For example, with spinal cord lesions at the upper thoracic (cervical) level, hyperactive autonomic reflexes (autonomic dysreflexia) result when the bladder is distended. You may note severe hypertension, bradycardia, vasodilation (blotchy skin) above the level of the lesion, piloerection, and profuse sweating, and the patient may complain of a headache.

With *hyperreflexic neurogenic bladder*, the patient may have involuntary or frequent scanty urination, without a feeling of bladder fullness and, possibly, spontaneous spasms of the arms and legs. Anal sphincter tone may be increased. Tactile stimulation of the abdomen, thighs, or genitalia may precipitate voiding and spontaneous contractions of the arms and legs.

With *flaccid neurogenic bladder*, the patient may have overflow incontinence and diminished anal sphincter tone. Palpation and percussion reveal a greatly distended bladder. However, the patient may not experience the accompanying feeling of bladder fullness because of sensory impairment.

Diagnostic tests

Several diagnostic tests are used to assess bladder function. For example, voiding cystourethrography is used to evaluate bladder neck function, vesicoureteral reflux, and continence.

Urodynamic studies allow the evaluation of how urine is stored in the bladder, how well the bladder empties urine, and the rate of movement of urine out of the bladder during voiding. These studies consist of four components:

- Urine flow study (uroflow) shows diminished or impaired urine flow.
- Cystometry is used to evaluate bladder nerve supply, detrusor muscle tone, and intravesical pressures during bladder filling and contraction.
- Urethral pressure profile is used to determine urethral function with respect to length of the urethra and outlet pressure resistance.
- Sphincter electromyography correlates the neuromuscular function of the external sphincter with bladder muscle function during bladder filling and contraction. This indicates how well the bladder and urinary sphincter muscles work together.

Videourodynamic studies are used to correlate visual documentation of bladder function with pressure studies.

Retrograde urethrography reveals strictures and diverticula. This test isn't done routinely.

Treatment

The goals of treatment are to maintain the integrity of the upper urinary tract, control infection, and prevent urinary incontinence through evacuation of the bladder, drug therapy, surgery or, less often, nerve blocks and electrical stimulation.

Techniques for bladder evacuation include Valsalva's maneuver and intermittent self-catheterization. Tapping over the bladder can also initiate voiding but, even when performed properly, this practice isn't always successful and doesn't always eliminate the need for catheterization.

The patient can perform Valsalva's maneuver himself by sitting on the toilet and forcefully exhaling (while keeping his mouth closed). This helps the bladder release urine and promotes complete emptying.

Intermittent self-catheterization is more effective than either tapping or Valsalva's maneuver. It's a major advance in treatment because it completely empties the bladder without the risks of an indwelling catheter. A male can perform this procedure more easily, but a female can learn self-catheterization with the help of a mirror. Intermittent self-catheterization, along with a bladder retraining program, is especially useful in patients with flaccid neurogenic bladder. Anticholinergics and alpha-adrenergic stimulators can help the patient with hyperreflexic neurogenic bladder until intermittent self-catheterization is performed.

Drug therapy for neurogenic bladder may include terazosin and phenoxybenzamine to facilitate bladder emptying and propantheline, methantheline, flavoxate, dicyclomine, imipramine, and pseudoephedrine to aid urine storage.

When conservative treatment fails, surgery may be used to correct the structural impairment through transurethral resection of the bladder neck, urethral dilation, external sphincterotomy, or urinary diversion procedures. Implantation of an artificial urinary sphincter may be necessary if permanent incontinence follows surgery.

Nursing diagnoses

u Altered urinary elimination u Body image disturbance u Fluid volume deficit u Impaired skin integrity u Knowledge deficit u Risk for infection u Sensory or perceptual alterations u Sexual dysfunction

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will maintain hemodynamic stability.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.
- u The patient will maintain a positive self-concept.

Nursing interventions

- u Nursing care for patients with neurogenic bladder varies with the underlying cause and the method of treatment.
- u Use aseptic technique during insertion of an indwelling urinary catheter (a temporary measure to drain the incontinent patient's bladder). Don't interrupt the closed drainage system for any reason. Obtain urine specimens with a syringe and small-bore needle inserted through the aspirating port of the catheter itself (below the junction of the balloon instillation site). Irrigate in the same manner, if ordered.
- u Clean the catheter insertion site with soap and water at least twice per day. Don't allow the catheter to become encrusted. Keep the drainage bag below the tubing and below the level of the bladder. Clamp the tubing or empty the bag before transferring the patient to a wheelchair or stretcher to prevent accidental urine reflux if the drainage container doesn't have an antireflux valve. If urine output is considerable, empty the bag more often than once every 8 hours because bacteria can multiply in standing urine and migrate up the catheter and into the bladder.
- u When the patient is on an intermittent selfcatheterization and bladder retraining program, regulate fluid intake at 1.5 L (1.6 qt)/24 hours to maintain sufficient amounts of urine. Adjust this amount for the pediatric patient based on urodynamic study findings. For females, the goal is urine retention because no acceptable urinary incontinence devices are on the market. Males can use an external device when bladder function returns. Reevaluate the patient when urine volume returned with catheterization is 300 ml every 6 hours between independent voidings; at that point, you may need to reduce the frequency of the catheterizations. In a patient with neurogenic bladder, catheterization can be stopped when the amount of postvoiding residual urine is consistently less than 100 ml.
- u Watch for signs of infection (fever or cloudy or foul-smelling urine). Try to keep the patient as mobile as possible, or perform passive range-of-motion exercises if necessary.
- u If a urinary diversion procedure, such as catheter drainage or insertion of a suprapubic catheter, is to be performed, consult with an enterostomal therapist and coordinate plans of care.
- u Neurogenic bladder can produce emotional turmoil. Suggest a support group at a local rehabilitation center or health care facility.

Patient teaching

- u Explain all diagnostic tests clearly so that the patient understands the procedure, the time involved, and the possible results. Assure him that the lengthy diagnostic process is necessary to identify the most effective treatment plan. After the treatment plan is chosen, explain it to him in detail.
- u Encourage the patient to drink plenty of fluids every day to prevent calculus formation and infection from urinary stasis.
- u Before discharge, teach the patient and family members evacuation techniques as necessary (for example, tapping or intermittent self-catheterization). Also teach him how to care for the catheter, if appropriate.
- u Discuss sexual activities. Because the incontinent patient may feel embarrassed and worried about sexual function, provide emotional support.
- u Demonstrate good hand-washing technique, and encourage meticulous cleaning of the drainage site.
- u Teach the patient the signs of UTI, and warn him to report them immediately.

VESICoureTERAL REFLUX

In vesicoureteral reflux, urine flows from the bladder back into the ureters and eventually into the renal pelvis or the parenchyma. When the bladder empties only part

of what has been stored, urinary tract infection (UTI) may result. This disorder is most common during infancy in boys and during early childhood (ages 3 to 7) in girls. Primary vesicoureteral reflux that results from congenital anomalies is most common in females and rare in blacks. Up to 25% of asymptomatic siblings of children with diagnosed primary vesicoureteral reflux also show reflux. Secondary vesicoureteral reflux occurs in adults.

Causes

In patients with vesicoureteral reflux, incompetence of the ureterovesical junction and shortening of intravesical ureteral musculature allow backflow of urine into the ureters when the bladder contracts during voiding.

Primary vesicoureteral reflux may result from congenital anomalies of the ureters or bladder, including short or absent intravesical ureters, ureteral ectopia lateralis (greater than normal lateral placement of ureters), ureteral duplication, ureterocele, and a gaping or golf-hole ureteral orifice.

Secondary vesicoureteral reflux starts with a competent ureterovesical junction that has been damaged by bladder outlet obstruction, iatrogenic injury, trauma, or inadequate detrusor muscle buttress in the bladder. The last problem has several causes: congenital paraurethral bladder diverticulum, acquired diverticulum (from outlet obstruction), flaccid neurogenic bladder, and high intravesical pressure from outlet obstruction or an unknown cause.

Vesicoureteral reflux may also result from cystitis, with inflammation of the intravesical ureter, which causes edema and intramural ureter fixation. This usually leads to reflux in people with congenital ureteral or bladder anomalies or other predisposing conditions.

Complications

Recurrent UTIs can lead to acute or chronic pyelonephritis and renal damage due to renal scarring, hypertension, or calculi.

Assessment findings

The patient with vesicoureteral reflux typically reports symptoms and shows signs of UTI: urinary frequency and urgency, burning on urination, hematuria, foul-smelling urine and, in infants, dark, concentrated urine. With upper urinary tract involvement, the patient usually complains of high fever, chills, flank pain, painful urination, vomiting, and malaise. In children, fever, nonspecific abdominal pain, and diarrhea may be the only clinical effects.

In male infants, palpation may reveal a hard, thickened bladder (felt as a hard mass deep in the pelvis) if posterior urethral valves are causing an obstruction. Rarely, children with minimal symptoms remain undiagnosed until puberty or adulthood, when they begin to show clear signs of renal impairment, such as anemia, hypertension, and lethargy.

Diagnostic tests

The following studies are pertinent to the diagnosis of vesicoureteral reflux:

Clean-catch urinalysis shows a bacterial count over 100,000/ml, sometimes without pyuria. Microscopic examination may reveal red blood cells, white blood cells, and an increased urine pH when infection is active. Specific gravity less than 1.010 demonstrates inability to concentrate urine.

Elevated levels of serum creatinine (more than 1.2 mg/dl) and blood urea nitrogen (more than 18 mg/dl) demonstrate advanced renal dysfunction.

Voiding cystourethrography identifies the degree of reflux and shows when reflux occurs. It may also pinpoint the causative anomaly. In this procedure, contrast material is instilled into the bladder and X-rays are taken before, during, and after voiding.

Catheterization of the bladder after the patient voids is used to determine the amount of residual urine.

Excretory urography may show a dilated lower ureter, a ureter visible for its entire length, hydronephrosis, calyceal distortion, and renal scarring.

Cystoscopy, with instillation of a solution containing methylene blue or indigo carmine dye, may be used to confirm the diagnosis. After the bladder is emptied and refilled with clear sterile water, color-tinged fluid from either ureter positively confirms reflux.

Radioisotope scanning and renal ultrasonography may be used to detect reflux and screen the upper urinary tract for damage secondary to infection and other renal abnormalities.

Treatment

The goal of treatment in a patient with vesicoureteral reflux is to prevent pyelonephritis and renal dysfunction through antibiotic therapy and, when necessary, vesicoureteral reimplantation. Appropriate surgery creates a normal valve effect at the junction by reimplanting the ureter into the bladder wall at a more oblique angle.

Antibiotics usually are effective for reflux that is secondary to infection, reflux related to neurogenic bladder and, in children, reflux related to a short intravesical ureter (which disappears spontaneously with growth). Reflux related to infection usually subsides after the infection is cured, but 80% of females with vesicoureteral reflux have recurrent UTIs within a year. Recurrent infection requires long-term prophylactic antibiotic therapy and careful patient follow-up (voiding cystourethrography and excretory urography every 4 to 6 months) to track the degree of reflux.

UTI that recurs despite prophylactic antibiotic therapy necessitates vesicoureteral reimplantation. In the patient with neurogenic bladder, other treatments may be more effective in preventing reflux. These patients may benefit from transurethral sphincterotomy (to relieve the obstructed outlet) or from bladder capacity augmentation (to decrease intravesical pressure).

After surgery (as after antibiotic therapy), close medical follow-up is necessary (excretory urography every 2 to 3 years and urinalysis once per month for a year) even if symptoms haven't recurred.

Nursing diagnoses

u Altered urinary elimination u Fluid volume excess u Impaired tissue integrity u Pain u Risk for infection

Key outcomes

- u The patient will maintain fluid balance.
- u The patient will report increased comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.

Nursing interventions

- u If the patient is a child, encourage a parent to be present during diagnostic tests and procedures so that the child won't be frightened.
- u Explain postoperative care to surgical patients and their parents, as appropriate: Males receive a suprapubic catheter; females, an indwelling catheter; and both

sexes, one or two ureteral catheters or splints brought out of the bladder through a small abdominal incision. Both types of catheters keep the bladder empty and prevent pressure from stressing the surgical wound. Ureteral catheters drain urine directly from the renal pelvis and stent the anastomosis site. After complicated reimplantations, all catheters remain in place for 7 to 10 days.

- u Postoperatively, closely monitor fluid intake and output. Give analgesics and antibiotics as ordered. Make sure the catheters are patent and draining well. Maintain aseptic technique during catheter care, and watch for fever, chills, and flank pain, which suggest a blocked catheter.
- u After bladder augmentation, catheterize the patient every 2 to 3 hours at first. Gradually increase the time between catheterizations to allow the augmented bladder to expand. Irrigate for mucous sediment as needed.

Patient teaching

- u Explain all diagnostic tests and procedures to the patient and the parents, if the patient is a child.
- u Tell the surgical patient that he can move and walk with the catheters but that he must be careful not to dislodge them.
- u To ensure complete bladder emptying, teach the patient with vesicoureteral reflux to double-void (void once and then try to void again in a few minutes). Because his natural urge to void may be impaired, advise him to try to void every 2 to 3 hours even if he doesn't feel the urge.
- u Instruct the patient or the parents to watch for and report recurring signs of UTI: painful, frequent, burning urination and foul-smelling urine.
- u If the patient is taking antimicrobial drugs, make sure he understands the importance of completing the prescribed therapy or maintaining low-dose prophylaxis.
- u Before discharging the patient, stress the importance of close follow-up care and adequate daily fluid intake.

Genital disorders

Genital disorders affect the testes, prostate, and epididymis. Nonspecific genitourinary infections also affect other areas, such as the urethra, vagina, and cervix. Examples of genital disorders include benign prostatic hyperplasia, epididymitis, nonspecific genitourinary infections, prostatitis, testicular torsion, and undescended testes.

BENIGN PROSTATIC HYPERPLASIA

Although most men over age 50 have some prostatic enlargement, in benign prostatic hyperplasia (BPH) the prostate gland enlarges sufficiently to compress the urethra and cause some overt urinary obstruction. BPH begins with changes in periurethral glandular tissue. As the prostate enlarges, it may extend into the bladder and obstruct urine outflow by compressing or distorting the prostatic urethra. BPH may also cause a diverticulum musculature that retains urine when the rest of the bladder empties. Depending on the size of the enlarged prostate, the age and health of the patient, and the extent of the obstruction, BPH may be treated surgically or symptomatically.

Causes

Recent evidence suggests a link between BPH and hormonal activity. As men age, production of androgenic hormones decreases, causing an imbalance in androgen and estrogen levels and high levels of dihydrotestosterone, the main prostatic intracellular androgen. Other theoretical causes include neoplasm, arteriosclerosis, inflammation, and metabolic or nutritional disturbances.

Complications

Because BPH causes urinary obstruction, a patient may have one or more of the following complications:

- u urinary stasis, urinary tract infection (UTI), or calculi
- u bladder wall trabeculation
- u detrusor muscle hypertrophy
- u bladder diverticuli and saccules
- u urethral stenosis
- u hydronephrosis
- u paradoxical (overflow) incontinence
- u acute or chronic renal failure
- u acute postobstructive diuresis.

Assessment findings

Clinical features of BPH depend on the extent of prostatic enlargement and on the lobes affected. Characteristically, the patient complains of a group of symptoms known as prostatism: decreased urine stream caliber and force, an interrupted stream, urinary hesitancy, and difficulty starting urination, which results in straining and a feeling of incomplete voiding.

As the obstruction increases, the patient may report frequent urination with nocturia, dribbling, urine retention, incontinence and, possibly, hematuria.

Physical examination reveals a visible midline mass above the symphysis pubis, which represents an incompletely emptied bladder. Palpation discloses a distended bladder; rectal palpation reveals an enlarged prostate.

Diagnostic tests

Several tests help to confirm this diagnosis: Excretory urography may indicate urinary tract obstruction, hydronephrosis, calculi or tumors, and filling and emptying defects in the bladder.

Elevated blood urea nitrogen and serum creatinine levels suggest impaired renal function.

Urinalysis and urine culture show hematuria, pyuria, and, when the bacterial count exceeds 100,000/μl, UTI.

When symptoms are severe, cystourethroscopy is the definitive diagnostic measure and is used to help determine the best surgical procedure. It can show prostate enlargement, bladder wall changes, calculi, and a raised bladder.

A prostate-specific antigen test may be performed to rule out prostatic cancer.

Treatment

Conservative therapy includes prostatic massages, sitz baths, short-term fluid restriction (to prevent bladder distention) and, if infection develops, antimicrobials. Regular sexual intercourse may help relieve prostatic congestion. Treatment with terazosin and finasteride has also proven effective. Terazosin (Hytrin), an alpha-adrenergic blocker, releases the prostate and bladder muscles, reducing straining with urination. Finasteride (Proscar) inhibits the action of 5-alpha-reductase, thereby preventing conversion of testosterone to dihydrotestosterone. This may lead to reduced prostate size over time.

Surgery is the only effective therapy for relief of acute urine retention, hydronephrosis, severe hematuria, and recurrent UTI or for palliative relief of intolerable symptoms. A transurethral resection may be performed if the prostate weighs less than 2 oz (57 g).

In this procedure, a resectoscope removes tissue with a wire loop and an electric current. For high-risk patients, continuous drainage with an indwelling urinary

catheter alleviates urine retention. Other transurethral procedures include vaporization of the prostate or a prostate incision with a scalpel or laser.

Other procedures involve open surgical removal of the prostate. One of the following operations may be appropriate:

- u *Suprapubic (transvesical) prostatectomy* is the most common and is especially useful when prostatic enlargement remains within the bladder area.
- u *Perineal prostatectomy* usually is performed for a large gland in an older patient. The operation commonly results in impotence and incontinence.
- u *Retropubic (extravesical) prostatectomy* allows direct visualization; potency and continence usually are maintained.

Less frequently performed procedures include balloon dilatation, ultrasound needle ablation, and use of stents.

Nursing diagnoses

- u Altered urinary elimination
- u Pain
- u Risk for infection
- u Sexual dysfunction

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will minimize complications.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will express feelings about potential or actual changes in sexual activity.

Nursing interventions

- u Prepare the patient for diagnostic tests and surgery as appropriate.
- u Monitor and record the patient's vital signs, intake and output, and daily weight. Watch closely for signs of postobstructive diuresis (such as increased urine output and hypotension), which may lead to dehydration, lowered blood volume, shock, electrolyte losses, and anuria.
- u Administer antibiotics as ordered for UTI, urethral procedures that involve instruments, and cystoscopy.
- u If urine retention occurs, try to insert an indwelling urinary catheter. If the catheter can't be passed transurethally, assist with suprapubic cystostomy. Watch for rapid bladder decompression.
- u Avoid giving a patient with BPH decongestants, tranquilizers, alcohol, antidepressants, or anticholinergics because these drugs can worsen the obstruction.

After prostatic surgery:

- u Maintain the patient's comfort, and watch for and prevent postoperative complications. Observe for signs of shock and hemorrhage. Check the catheter frequently (every 15 minutes for the first 2 to 3 hours) for patency and urine color; check the dressings for bleeding.
- u Postoperatively, many urologists insert a three-way catheter and establish continuous bladder irrigation. Keep the solution flowing at a rate sufficient to maintain patency and ensure that returns are clear and light pink. Watch for fluid overload from absorption of the irrigating fluid into the systemic circulation. If a regular catheter is used, observe it closely. If drainage stops because of clots, irrigate the catheter as ordered, usually with 80 to 100 ml of normal saline solution, while maintaining aseptic technique.

ALERT Watch for septic shock, the most serious complication of prostatic surgery. Immediately report severe chills, sudden fever, tachycardia, hypotension, or other signs of shock. Start rapid infusion of I.V. antibiotics as ordered. Watch for pulmonary embolism, heart failure, and acute renal failure. Monitor vital signs, central venous pressure, and arterial pressure.

- u Administer belladonna and opium suppositories or other anticholinergics, as ordered, to relieve bladder spasms that can occur after transurethral resection.
- u Make the patient comfortable after an open procedure: Administer suppositories (except after perineal prostatectomy), and give analgesics to control incisional pain. Change dressings frequently.
- u Continue infusing I.V. fluids until the patient can drink enough on his own (2 to 3 L [2.1 to 3.2 qt]/day) to maintain adequate hydration.
- u Administer stool softeners and laxatives, as ordered, to prevent straining. Don't check for fecal impaction because a rectal examination can cause bleeding.

Patient teaching

- u After the catheter is removed, the patient may experience urinary frequency, dribbling and, occasionally, hematuria. Reassure him and family members that he'll gradually regain urinary control.
- u Reinforce prescribed limits on activity. Warn the patient against lifting, performing strenuous exercises, and taking long automobile rides for at least 1 month after surgery because these activities increase bleeding tendency. Also caution him not to have sexual intercourse for at least several weeks after discharge.
- u Teach the patient to recognize the signs of UTI. Urge him to immediately report these signs to the doctor because infection can worsen the obstruction.
- u Instruct the patient to follow the prescribed oral antibiotic regimen, and tell him the indications for using gentle laxatives.
- u Urge the patient to seek medical care immediately if he can't void at all, if he passes bloody urine, or if he develops a fever.

EPIDIDYMITIS

Epididymitis, infection of the epididymis (the cordlike excretory duct of the testis) is one of the most common infections of the male reproductive tract. It usually affects adults and is rare before puberty.

Causes

Epididymitis usually results from pyogenic organisms, such as staphylococci, *Escherichia coli*, streptococci, chlamydia, *Neisseria gonorrhoeae*, and *Treponema pallidum*. Infection usually results from established urinary tract infection (UTI) and sexually transmitted disease (STD) or prostatitis extending to the epididymis through the lumen of the vas deferens. Rarely, epididymitis is secondary to a distant infection, such as pharyngitis or tuberculosis that spreads through the lymphatic system or, less commonly, the bloodstream.

Trauma may reactivate a dormant infection or initiate a new one. In addition, epididymitis is a complication of prostatectomy and may result from chemical irritation by extravasation of urine through the vas deferens.

Complications

Bilateral epididymitis can cause sterility. (See [How epididymitis can decrease fertility](#).) Epididymitis may spread to the testis itself, causing orchitis. (See [Orchitis](#).)

Assessment findings

The patient may complain of unilateral, dull, aching pain radiating to the spermatic cord, lower abdomen, and flank and of an extremely heavy feeling in the scrotum. He may also have erythema, a high fever, and malaise and may exhibit a characteristic waddle in an attempt to protect the groin and scrotum while walking. An acute hydrocele can occur as a reaction to the inflammatory process.

Diagnostic tests

Urinalysis shows increased white blood cell (WBC) count, which indicates infection. Urine culture and sensitivity test findings may identify the causative organism.

A serum WBC count of more than 10,000/μl indicates infection. If orchitis also is present, the diagnosis must be made cautiously because symptoms mimic those of testicular torsion, a condition that requires urgent surgical intervention.

Treatment

The goal of therapy is to reduce pain and swelling and combat infection. It must begin immediately, especially in bilateral epididymitis, because sterility is always a threat.

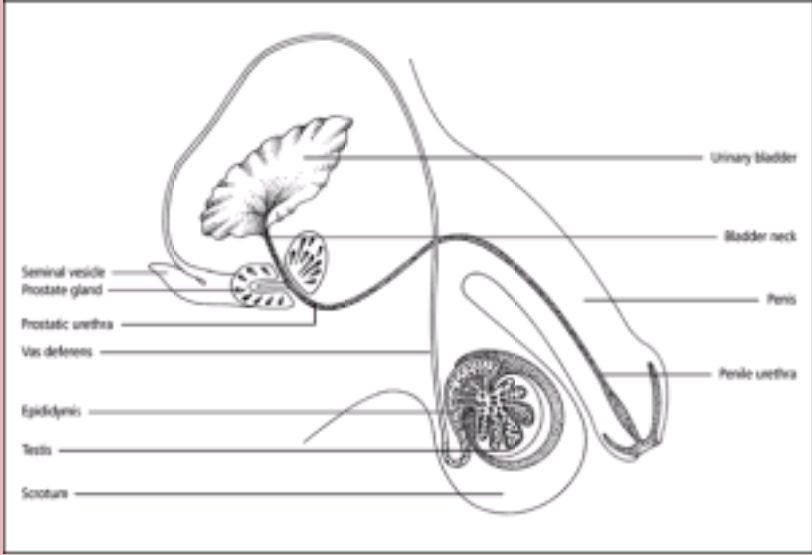

PATHOPHYSIOLOGY

How epididymitis can decrease fertility

To understand how infection occurs, review normal anatomy shown in the diagram below. Male reproductive cells, called spermatozoa (sperm), are produced in the testes—a complex system of coiled tubules. The immature sperm swim out of the testes into a long, coiled duct called the epididymis, where the maturing process continues. From here, they pass into the vas deferens, where they become fully mature. The vas deferens terminates in the prostatic urethra.

Epididymitis can inhibit the normal development of sperm, decreasing fertility: The sperm leave the body through the urethra when ejaculation occurs. In epididymitis, bacteria from other parts of the urogenital system such as the urethra travel backward through the reproductive tract to invade the epididymis. Here, these infecting organisms can interfere with sperm development, decreasing the patient's fertility.

During the acute phase, treatment consists of bed rest, scrotal elevation with towel rolls or adhesive strapping, broad-spectrum antibiotics, and analgesics. An ice bag applied to the area may reduce swelling and relieve pain (heat is contraindicated because it may damage germinal cells, which are viable only at or below normal body temperature). When pain and swelling subside and permit walking, an athletic supporter may prevent pain. Corticosteroids may be prescribed to help counteract inflammation, but their use is controversial.

When epididymitis is refractory to antibiotic therapy, epididymectomy under local anesthesia is necessary.

In an older patient undergoing prostatectomy, bilateral vasectomy may be necessary to prevent epididymitis as a postoperative complication, but antibiotics alone may prevent it.

Nursing diagnoses

- u Altered sexuality patterns
- u Altered urinary elimination
- u Knowledge deficit
- u Pain
- u Risk for infection
- u Sexual dysfunction

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will express concern about self-concept and body image.
- u The patient will express feelings about potential or actual changes in sexual activity.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will avoid or minimize complications.

Nursing interventions

- u Watch closely for signs of abscess formation (a localized, hot, red, tender area) or extension of the infection into the testes. Closely monitor temperature, and ensure adequate fluid intake.
- u Because the patient is usually uncomfortable, administer analgesics as necessary. Allow him to rest in bed, legs slightly apart, with testes elevated on a towel roll. Suggest that he wear nonconstricting, lightweight clothing until the swelling subsides. Apply ice packs as needed for comfort.
- u Administer antibiotics and antipyretics as ordered. If epididymitis is secondary to a sexually transmitted disease, treat the patient and his sexual partner with appropriate antibiotics.
- u If the patient faces the possibility of sterility, suggest supportive counseling as necessary.

Patient teaching

- u If the patient is to take antibiotics after discharge, emphasize the importance of completing the prescribed regimen even after symptoms subside.
- u Suggest that the patient wear a scrotal support while sitting, standing, or walking.
- u If epididymitis is secondary to a STD, encourage the patient to use a condom during sexual intercourse and to notify sexual partners so that they can be adequately treated for infection.

ADVANCED PRACTICE

Orchitis

Orchitis, an infection of the testes, is a serious complication of epididymitis. It also may result from mumps, which can lead to sterility, or, less often, another systemic infection.

Signs and symptoms

Typical effects of orchitis include unilateral or bilateral tenderness and redness, sudden onset of pain, and swelling of the scrotum and testes. Nausea and vomiting also occur. Sudden cessation of pain indicates testicular ischemia, which can cause permanent damage to one or both testes. Hydrocele also may be present.

Treatment

Appropriate treatment consists of immediate antibiotic therapy or, in mumps orchitis, injection of 20 ml of lidocaine near the spermatic cord of the affected testis, which may relieve swelling and pain. Although corticosteroid use is experimental, such drugs may be used to treat nonspecific granulomatous orchitis. Severe orchitis may require surgery to incise and drain the hydrocele and to improve testicular circulation. Other treatments are similar to those for epididymitis.

To prevent mumps orchitis, suggest that prepubertal males receive the mumps vaccine (or gamma globulin injection after contracting mumps).

NONSPECIFIC GENITOURINARY INFECTIONS

Nonspecific genitourinary infections, which include nongonococcal urethritis in males and mild vaginitis or cervicitis in females, have similar manifestations. Nonspecific genitourinary infections have become more prevalent since the mid 1960s and are more widespread than gonorrhea. The prognosis is good if sexual partners are treated simultaneously.

Causes

Nonspecific genitourinary infections are spread primarily through sexual intercourse. In males, nongonococcal urethritis commonly results from *Chlamydia trachomatis*. It also may result from bacteria, such as staphylococci, diphtheroids, coliform organisms, and *Gardnerella vaginalis*. Less frequently, infection may be related to preexisting strictures, neoplasms, and chemical or traumatic inflammation.

Although less is known about nonspecific genitourinary infections in females, chlamydial or corynebacterial organisms and *G. vaginalis* (which causes bacterial vaginosis) also may cause these infections.

Complications

Untreated nonspecific genitourinary infections can cause infertility. In males, nongonococcal urethritis can lead to acute epididymitis.

Assessment findings

One week to 1 month after intercourse with an infected partner, a male with nongonococcal urethritis may report a mucopurulent urethral discharge and variable dysuria. Hematuria occasionally occurs. Subclinical urethritis may be found on physical examination, especially if the patient's sex partner has a nonspecific genitourinary infection.

A female with a nonspecific genitourinary infection may report a persistent vaginal discharge or acute or recurrent cystitis for which no underlying cause can be found. She also may have cervicitis with inflammatory erosion. Both males and females with nonspecific genitourinary infections may be asymptomatic but show signs of urethral, vaginal, or cervical infection on physical examination.

Diagnostic tests

In males, smears of prostatic or urethral secretions show excessive polymorphonuclear leukocytes but few, if any, specific organisms.

In females, cervical or urethral smears show similar results.

Epithelial cells covered with bacteria confirm infection.

Treatment

Therapy for both sexes consists of 500 mg of oral metronidazole twice a day for 7 days or a single 2-g dose. For females, treatments may also include application of a vaginal cream and, occasionally, cryosurgery.

Nursing diagnoses

⌞ Altered sexuality patterns ⌞ Risk for infection ⌞ Self-esteem disturbance ⌞ Sexual dysfunction

Key outcomes

- ⌞ The patient will minimize complications.
- ⌞ The patient will voice feelings about potential or actual changes in sexual activity.
- ⌞ The patient will express concerns about self-concept, self-esteem, and body image.
- ⌞ The patient and partner will voice effective communication patterns.

Nursing interventions

No interventions other than patient teaching are needed.

Patient teaching

- ⌞ Tell the female patient to clean the pubic area before applying vaginal medication and to avoid using tampons during treatment.
- ⌞ Be sure the patient follows the dosage schedule.
- ⌞ To prevent nonspecific genitourinary infections, advise the patient to abstain from sexual intercourse with infected partners, to use condoms during sexual activity, to follow appropriate hygienic measures afterward, and to void before and after intercourse.
- ⌞ Advise the patient to inform all prior sexual partners so that they can be treated.
- ⌞ Encourage adequate fluid intake.
- ⌞ Advise the female patient not to insert foreign objects in the vagina, not to use douches and hygiene sprays routinely, and not to wear tight-fitting pants, panty hose, nylon panties, or panty liners.

PROSTATITIS

Prostatitis is an inflammation of the prostate gland. It occurs in several forms. *Acute prostatitis* most often results from gram-negative bacteria and is easily recognized and treated. *Chronic prostatitis*, which affects up to 35% of men over age 50 and is the most common cause of recurrent urinary tract infection (UTI) in men, is harder to recognize. Other classifications include *granulomatous prostatitis* (also called tuberculous prostatitis), *nonbacterial prostatitis*, and *prostatodynia* (painful prostate).

Causes

About 80% of bacterial prostatitis cases result from infection by *Escherichia coli*. The rest result from infection by *Klebsiella*, *Enterobacter*, *Proteus*, *Pseudomonas*, *Serratia*, *Streptococcus*, *Staphylococcus*, and diphtheroids, which are contaminants from the anterior urethras normal flora.

Infection probably spreads to the prostate gland by the hematogenous route or from ascending urethral infection, invasion of rectal bacteria by way of the lymphatic vessels, or reflux of infected bladder urine into prostate ducts. Less commonly, infection may result from urethral procedures performed with instruments, such as cystoscopy and catheterization, or from infrequent or excessive sexual intercourse.

Chronic prostatitis usually results from bacterial invasion from the urethra. Granulomatous prostatitis occurs secondary to a miliary spread of *Mycobacterium tuberculosis*. Nonbacterial prostatitis is probably caused by the protozoa *Mycoplasma*, *Ureaplasma*, *Chlamydia* or *Trichomonas vaginalis*, or some viruses. The cause of prostatodynia is unknown.

Complications

UTI is the most common complication of prostatitis. An untreated infection can progress to prostatic abscess, acute urine retention from prostatic edema, pyelonephritis, and epididymitis.

Assessment findings

The patient with acute prostatitis may report sudden fever, chills, low back pain, myalgia, perineal fullness, arthralgia, frequent urination, urinary urgency, dysuria, nocturia, and transient erectile dysfunction. Some degree of urinary obstruction can occur, and the urine may appear cloudy. The bladder may feel distended when palpated. When palpated rectally, the prostate is markedly tender, indurated, swollen, firm, and warm.

Clinical features of chronic bacterial prostatitis vary. Some patients are asymptomatic, but this condition usually elicits the same urinary symptoms as the acute form (but to a lesser degree). Other possible signs and symptoms include hemospermia, persistent urethral discharge, and painful ejaculation that is responsible for some sexual dysfunction. The prostate may feel soft, and crepitation may be evident if prostatic calculi are present.

Digital examination in granulomatous prostatitis may reveal a stony, hard induration of the prostate (mimicking carcinoma or a calculus). This finding may suggest prostatitis if the patient has a history of pulmonary or GI tuberculosis or has been receiving intravesical therapy for superficial bladder cancer.

With nonbacterial prostatitis, the patient usually complains of dysuria, mild perineal or low back pain, and frequent nocturia. With prostatodynia, he may complain of perineal, low back, or pelvic pain.

Diagnostic tests

A urine culture often can be used to identify the causative infectious organism.

Characteristic rectal examination findings suggest prostatitis (especially in the acute phase).

A firm diagnosis depends on comparison of bacterial growth in specimens. This test requires four specimens: one collected when the patient starts voiding (voided bladder one [VB1]); another midstream (VB2); another after the patient stops voiding and the doctor massages the prostate to produce secretions (expressed prostate secretions [EPS]); and a final voided specimen (VB3). A significant increase in colony count of the prostatic specimens (EPS and VB3) confirms prostatitis.

In granulomatous prostatitis, demonstration of M. tuberculosis in a urine or tissue biopsy from the prostate confirms the diagnosis.

In nonbacterial prostatitis, smears of prostatic secretions reveal inflammatory cells but often no causative organism. In prostatodynia, urine cultures are negative and no inflammatory cells are present in smears of prostatic secretions. Urodynamic evaluation may reveal detrusor hyperreflexia and pelvic floor myalgia from chronic spasms.

Treatment

Systemic antibiotic therapy, guided by sensitivity studies, is the treatment of choice for acute prostatitis. Aminoglycosides, in combination with penicillins or cephalosporins, may be most effective for severe cases. Co-trimoxazole is given to prevent chronic prostatitis; it's also used to combat infections with *Escherichia coli*. Other drugs used for *E. coli* infections include carbenicillin, nitrofurantoin, erythromycin, and tetracycline.

If drug therapy is unsuccessful, treatment may include transurethral resection of the prostate. Successful resection must remove all infected tissue. This procedure may lead to retrograde ejaculation and sterility and is usually not performed on young adults. Total prostatectomy is curative but may cause impotence and incontinence.

Treatment for granulomatous prostatitis consists of antitubercular drug combinations. Minocycline, doxycycline, or erythromycin is used for nonbacterial prostatitis for 4 weeks, but antibiotic therapy isn't repeated if symptoms don't subside.

Supportive therapy includes bed rest, adequate hydration, and administration of analgesics, antipyretics, and stool softeners as necessary. If symptoms are present in chronic prostatitis, treatment may consist of sitz baths and regular sexual intercourse (the patient should use condoms during the treatment phase) or ejaculation to promote drainage of prostatic secretions. Regular prostatic massage for several weeks or months is effective in some patients. Anticholinergics and analgesics may help relieve the symptoms of nonbacterial prostatitis. Alpha-adrenergic blocking agents and muscle relaxants may be used for prostatodynia.

Nursing diagnoses

u Altered sexuality patterns u Altered urinary elimination u Ineffective individual coping u Pain u Risk for infection u Self-esteem disturbance u Sexual dysfunction

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will minimize complications.
- u The patient and family members will demonstrate skill in managing the urinary elimination problem.
- u The patient will voice feelings about potential or actual changes in sexual activity.
- u The patient and partner will use available counseling, referrals, or support groups.

Nursing interventions

- u Administer analgesics for pain as ordered.
- u Ensure bed rest and adequate hydration.

- u Provide stool softeners and administer sitz baths as ordered. Avoid rectal examination because it can precipitate bleeding.
- u As necessary, prepare to assist with suprapubic needle aspiration of the bladder or a suprapubic cystostomy.
- u If transurethral resection of the prostate is performed, monitor the patient postoperatively for signs of hypovolemia (decreased blood pressure, increased pulse rate, and pale, clammy skin).
- u Check the catheter every 15 minutes for the first 2 to 3 hours after surgery for patency, urine color and consistency, and excessive urethral meatus bleeding.
- u If a three-way continuous bladder irrigation is being performed, keep the solution flow rate sufficient to maintain patency and keep the return light pink. Watch for fluid overload from absorption of the irrigating fluid into the systemic circulation. Palpate for bladder distention. If the solution stops or the patient complains of pain, irrigate the catheter with normal saline solution using a 50-ml syringe.
- u Watch for septic shock, the most serious complication of prostatic surgery. Immediately report severe chills, sudden fever, tachycardia, hypotension, or other signs of shock. Start rapid infusion of I.V. antibiotics as ordered. Watch for pulmonary embolism, heart failure, and acute renal failure. Continuously monitor vital signs and central venous pressure.
- u Administer belladonna and opium suppositories or other anticholinergics as ordered to relieve painful bladder spasms that commonly occur after transurethral resection.

Patient teaching

- u Familiarize the patient with any prescribed drugs and their possible adverse effects. Tell him to take the drugs exactly as ordered and to complete the prescribed drug regimens.
- u Tell the patient to immediately report adverse drug reactions, such as rash, nausea, vomiting, fever, chills, and GI irritation.
- u Instruct him to drink at least eight 8-oz glasses of fluid per day (about 2 L).
- u If the patient has chronic prostatitis, recommend that he stay sexually active and ejaculate regularly to promote drainage of prostatic secretions. Tell him to use a condom during sexual intercourse when he's having a bout of prostatitis.

If the patient is scheduled for transurethral resection of the prostate:

- u Tell him that after catheter removal he may have urinary frequency, dribbling, and occasional hematuria. Reassure him that he'll gradually regain urinary control. Explain this to family members so that they can offer reassurance as well.
- u Reinforce prescribed limits on activity. Warn the patient not to lift, exercise strenuously, or take long automobile rides because these increase bleeding tendency. Caution him to abstain from sexual activity for several weeks after discharge.
- u Instruct the patient to take oral antibiotics exactly as prescribed and for as long as prescribed. Also review the indications for using gentle laxatives.
- u Urge the patient to seek medical care immediately if he can't void, passes bloody urine, or develops a fever.

TESTICULAR TORSION

In testicular torsion, the spermatic cord twists with the rotation of a testis or the mesorchium (the mesentery between the testis and epididymis), strangulating the testis. It occurs unilaterally about 90% of the time. Testicular torsion is most common in males ages 12 to 18 (although it can occur at any age). With early detection and prompt treatment, the prognosis is good.

Causes and pathophysiology

The tunica vaginalis normally envelops the testis and attaches to the epididymis and spermatic cord. In intravaginal torsion (the most common type of testicular torsion in adolescents), testicular twisting may result from abnormal positioning of the testis in the tunica or from a narrowing of the mesentery support. In extravaginal torsion (most common in neonates), loose attachment of the tunica vaginalis to the scrotal lining causes spermatic cord rotation above the testis. (See [What happens in testicular torsion](#).) A sudden, forceful contraction of the cremaster muscle may precipitate this condition.

Complications

Without prompt treatment, complete testicular infarction followed by testicular atrophy can occur.

Assessment findings

The patient may report excruciating pain in the affected testis or iliac fossa. Pain increases when the scrotum is elevated. Inspection reveals tense, tender swelling in the scrotum or inguinal canal and hyperemia of the overlying skin.

Diagnostic tests

Doppler ultrasonography helps distinguish testicular torsion from strangulated hernia, undescended testes, and epididymitis.

Testicular scan using technetium tc 99m pertechnetate allows a definitive diagnosis.

Treatment

A vascular emergency, testicular torsion must be treated within 4 hours of initial pain. Treatment consists of immediate surgical repair by orchiopexy (fixation of a viable testis to the scrotum) or orchiectomy (excision of a nonviable testis). Analgesics relieve pain postoperatively.

Nursing diagnoses

- u Pain
- u Risk for infection
- u Risk for injury
- u Self-esteem disturbance

PATHOPHYSIOLOGY

What happens in testicular torsion

In extravaginal torsion, rotation of the spermatic cord above the testis causes strangulation and, eventually, infarction of the testis.

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will minimize risks for infection.
- u The patient will express positive feelings about himself.
- u The patient will minimize complications.

Nursing interventions

- u Offer reassurance, and keep the patient comfortable before and after surgery. Administer pain medication as ordered.
- u Monitor voiding, and apply a covered ice bag to the surgical site to reduce edema.
- u Protect the wound from contamination. Otherwise, allow as many normal daily activities as possible.

Patient teaching

- u Explain the surgical procedure and postoperative care. Even if the testis must be removed, reassure the patient that sexual function and fertility should be unaffected.
- u Recommend that the patient routinely wear a scrotal support when exercising.

UNDESCENDED TESTES

Undescended testes is a congenital disorder also known as cryptorchidism. One or both testes remain in the abdomen, in the inguinal canal, or at the external ring instead of descending into the scrotum. The disorder may occur bilaterally but usually affects only the right testis; it may be categorized as true or ectopic. True undescended testes remain along the path of normal descent; ectopic testes deviate from that path.

Because the testes normally descend into the scrotum in the 7th gestational month, cryptorchidism affects more premature neonates (about 30%) than full-term neonates (about 3%). In about 80% of affected neonates, the testes descend spontaneously during the first year; in the rest, they may descend later.

The prognosis for recovery is excellent because one or both testes usually descend spontaneously. If this doesn't occur, orchiopexy (fixation of a viable testis to the scrotum) can readily correct the disorder.

Causes

No one knows exactly how the testes descend into the scrotum. Some experts think that hormones play a role. Likely suspects include androgenic hormones from the placenta, the maternal or fetal adrenal glands, or the immature fetal testis. Other possible causes include maternal progesterone or gonadotropic hormones from the maternal pituitary gland.

A popular but unsubstantiated theory links undescended testes to a defective gubernaculum, the fibromuscular band that connects the testes to the scrotal floor. In the normal male fetus, testosterone stimulates the gubernaculum's formation. This band probably helps pull the testes into the scrotum by shortening as the fetus grows. Thus, cryptorchidism may result from inadequate testosterone levels or from a defect in the testes or the gubernaculum.

Complications

Undescended testes that persists into adolescence prevents spermatogenesis and results in sterility even though testosterone levels remain normal. Other complications of untreated cryptorchidism include increased testicular vulnerability to trauma and an increased risk of testicular cancer.

Assessment findings

In a patient with unilateral cryptorchidism, the scrotum on the affected side may appear underdeveloped. Occasionally, the scrotum on the unaffected side is enlarged and the testis in the scrotum on the affected side isn't palpable.

Diagnostic tests

The laboratory tests used to determine sex in questionable situations are a buccal smear, which is used to identify gender (by showing a male sex chromatin pattern), and serum gonadotropin analysis, which confirms existing testes by evaluating hormone levels in circulation.

Treatment

If the testes don't descend spontaneously by age 1, surgical correction (orchiopexy) may be needed to secure the testes to the scrotum. Commonly performed before the patient reaches age 4, orchiopexy prevents sterility, injury related to abnormal testicular position, and harmful psychological effects.

In some patients, human chorionic gonadotropin given intramuscularly may stimulate descent. This therapy is ineffective if the testes lie in the abdomen or if the patient also has an inguinal hernia.

Nursing diagnoses

- u Anxiety u Fear u Knowledge deficit u Pain u Risk for injury u Self-esteem disturbance

Key outcomes

- u The patient will express their feelings of comfort.
- u The patient will minimize complications.
- u The patient and parents will express their feelings about the situation.
- u The patient and parents will develop adequate coping mechanisms.
- u The patient will express positive feelings about himself.

Nursing interventions

- u Offer emotional support and reassurance. Encourage the parents to express their concerns about their child's condition.
- u After orchiopexy, monitor the patient's vital signs and his intake and output. Watch for urine retention. Also check his dressings. If he's old enough to understand and cooperate, encourage him to do coughing and deep-breathing exercises.
- u Keep the operative site clean. If the surgeon applied a rubber band to keep the testis in place, maintain the rubber band's tension while ensuring that the band isn't too tight.
- u If the patient is an infant or a child, encourage the parents to participate in postoperative care, such as bathing and feeding.
- u If the patient is an older child or an adult, urge him to care for himself as much as possible.

Patient teaching

- u If the patient is a neonate, review the causes of undescended testes and available treatments with the parents. Discuss the disorder's effect on reproduction if left untreated. Emphasize that testicular descent may occur spontaneously, especially in premature infants.
- u If the patient is undergoing orchiopexy, explain the surgery to the parents and the patient in terms he can understand. Tell him that a rubber band may be taped to his thigh for about 1 week after surgery to keep the testis in place. Inform him that his scrotum may swell but shouldn't be painful.
- u Tell the patient to wipe from front to back after a bowel movement. Explain that this helps to keep the operative site clean.
- u Caution the patient to avoid rough play that can cause groin injury until the doctor approves strenuous activities.
- u Suggest wearing comfortable, soft, loose-fitting clothes to prevent friction and swelling.
- u Instruct the parents to notify the doctor if the child reports or appears to have severe pain.
- u If the patient is an adult undergoing orchiopexy, explain that the procedure doesn't improve fertility or diminish his risk of developing testicular cancer. Teach him how to perform self-examination when testicular palpation is possible.

INTRODUCTION

As the site of digestion, the GI system has the critical task of supplying essential nutrients to fuel the brain, heart, lungs, and other organs and tissues. GI function also profoundly affects the quality of life by its impact on overall health. A malfunction along the GI tract or in one of the accessory GI organs can produce far-reaching metabolic effects, eventually threatening life itself.

Anatomy and physiology

The GI system has two major components: the alimentary canal and the accessory organs. The *alimentary canal*, or GI tract, consists essentially of a hollow muscular tube that begins in the mouth and ends at the anus. It includes the oral cavity, pharynx, esophagus, stomach, small intestine, and large intestine. *Accessory glands and organs* that aid GI function include the salivary glands, liver, biliary duct system (gallbladder and bile ducts), and pancreas.

Together, the GI tract and accessory organs serve two major functions: digestion, the breaking down of food and fluids into simple chemicals that can be absorbed into the bloodstream and transported throughout the body, and the elimination of waste products from the body through defecation.

Cellular anatomy

The GI tract wall consists of several layers. The *innermost layer (tunica mucosa, or mucosa)* contains epithelial and surface cells and loose connective tissue. In the small intestine, epithelial cells elaborate into millions of fingerlike projections (villi) that vastly increase their absorptive surface area. These cells also secrete gastric and protective juices and absorb nutrients. Surface cells overlie connective tissue (lamina propria), supported by a thin layer of smooth muscle (muscularis mucosa).

The *submucosa (tunica submucosa)* encircles the mucosa. It's composed of loose connective tissue, blood and lymphatic vessels, and a nerve network (the submucosal, or Meissner's, plexus). Around this layer is the tunica muscularis, composed of skeletal muscle in the mouth, pharynx, and upper esophagus, and of longitudinal and circular smooth-muscle fibers elsewhere in the GI tract. During peristalsis, longitudinal fibers shorten the lumen's length and circular fibers reduce the lumen's diameter. At points along the tract, circular fibers thicken to form sphincters. Between the two muscle layers of the tunica muscularis lies another nerve network, the myenteric, or Auerbach's, plexus. The stomach wall contains a third muscle layer.

The outer covering of the GI tract consists of connective tissue protected by epithelium. It's known as the *tunica adventitia* in the esophagus and rectum, the *tunica serosa* elsewhere. This layer (also called the visceral peritoneum) covers most of the abdominal organs and is contiguous with an identical layer (parietal peritoneum) lining the abdominal cavity. The visceral peritoneum becomes a double-layered fold around the blood vessels, nerves, and lymphatics supplying the small intestine, and attaches the jejunum and ileum to the posterior abdominal wall to prevent twisting. A similar mesenteric fold attaches the transverse colon to the posterior abdominal wall.

Digestion and elimination

Digestion starts in the oral cavity, where chewing (mastication), salivation (the beginning of starch digestion), and swallowing (deglutition) all take place.

When a person swallows a food bolus, the upper esophageal (hypopharyngeal) sphincter relaxes, allowing food to enter the esophagus. In the esophagus, peristaltic waves activated reflexively by the glossopharyngeal nerve propel food down toward the stomach. As food moves through the esophagus, glands in the esophageal mucosal layer secrete mucus, which lubricates the bolus and protects the esophageal mucosal layer from being damaged by poorly chewed foods.

In the stomach

By the time the food bolus is on its way to the stomach, the cephalic phase of digestion has already begun. In this phase, the stomach secretes digestive juices (hydrochloric acid and pepsin) in response to stimuli from the person's smelling, tasting, chewing, or thinking of food. When food enters the stomach through the cardiac sphincter, the stomach wall distends, initiating the gastric phase of digestion. In this phase, stomach wall distention stimulates the antral mucosa of the stomach to release gastrin. Gastrin, in turn, stimulates the stomach's motor functions and gastric juice secretion. These highly acidic digestive secretions (pH 0.9 to 1.5) consist mainly of pepsin, hydrochloric acid, intrinsic factor, and proteolytic enzymes.

The stomach has three major motor functions: storing food, mixing food by peristaltic contractions with gastric juices, and slowly parceling this food (now called chyme) into the small intestine for further digestion and absorption. Except for alcohol, little food absorption normally occurs in the stomach.

In the small intestine

Nearly all digestion and absorption takes place in the small intestine. The small intestine, 20' (6 m) long, lies coiled in the abdomen and consists of three major sections: the duodenum, jejunum, and ileum. The *duodenum* extends from the stomach and contains the ampulla of Vater (hepatopancreatic ampulla or Oddi's sphincter), an opening that drains bile from the common duct and pancreatic enzymes from the main pancreatic duct.

The *jejunum* follows the duodenum and leads to the *ileum*. Peristaltic contractions and various digestive secretions break down carbohydrates, proteins, and fats and enable the intestinal mucosa to absorb these nutrients, along with water and electrolytes, into the bloodstream for use by the body. The small intestine ends in the right lower abdominal quadrant at the ileocecal valve, a sphincter that empties nearly nutrient-free chyme into the large intestine.

In the large intestine

By the time chyme passes through the small intestine and enters the *ascending colon* of the large intestine, it has been reduced to mostly indigestible substances. From the ascending colon, chyme passes through the *transverse colon* and *descending colon* to the rectum, and finally into the *anal canal*, where it's expelled.

The large intestine is the site of the absorptive process. It produces no hormones or digestive enzymes. Through blood and lymph vessels in the submucosa, the proximal half of the large intestine absorbs most of the remaining water in the colon plus large amounts of sodium and chloride. The large intestine also harbors the bacteria *Escherichia coli*, *Enterobacter aerogenes*, *Clostridium welchii*, and *Lactobacillus bifidus*, which help synthesize vitamin K and break down cellulose into usable carbohydrates. Bacterial action also produces flatus, which helps propel stools toward the rectum. In addition, the mucosa produces alkaline secretions from tubular glands composed of goblet cells. This alkaline mucus lubricates the intestinal walls as food pushes through and protects the mucosa from acidic bacterial action.

In the lower part of the descending colon, long and relatively sluggish contractions cause propulsive waves known as mass movements. These movements, which normally occur several times a day, propel intestinal contents into the rectum and produce the urge to defecate.

Accessory organs of digestion

Allied to the GI tract are the liver, biliary duct system, and pancreas, which contribute hormones, enzymes, and bile vital to digestion. These organs deliver their secretions to the duodenum through the ampulla of Vater.

Liver

The liver performs complex and important functions related to digestion and nutrition. It's the body's largest gland, weighing 3 lb (1.4 kg). The highly vascular liver is enclosed in a fibrous capsule in the right upper abdominal quadrant. It plays an important role in carbohydrate metabolism, detoxifies various endogenous and exogenous toxins in plasma, and synthesizes plasma proteins, nonessential amino acids, and vitamin A. The liver also stores essential nutrients, such as iron and vitamins K, D, and B₁₂. It secretes bile and removes ammonia from body fluids, converting it to urea for excretion in urine.

Bile, a greenish liquid composed of water, cholesterol, bile salts, electrolytes, and phospholipids, is important in fat breakdown and intestinal absorption of fatty acids, cholesterol, and other lipids. When bile salts are absent from the intestinal tract, lipids are excreted and fat-soluble vitamins are absorbed poorly. Bile also aids in the liver's excretion of conjugated bilirubin (an end product of hemoglobin degradation) and thereby prevents jaundice.

The liver recycles about 80% of bile salts into bile, combining them with bile pigments (biliverdin and bilirubin—the breakdown products of red blood cells) and cholesterol. The liver metabolizes digestive end products by regulating blood glucose levels. When glucose is being absorbed through the intestine (anabolic state), the liver stores glucose as glycogen. When glucose isn't being absorbed or when blood glucose levels decrease (catabolic state), the liver mobilizes glucose to restore blood levels necessary for brain function.

The liver's functional unit, the *lobule*, consists of plates of hepatic cells (hepatocytes) that encircle a central vein and radiate outward. The plates of hepatocytes are separated from one another by *sinusoids*, which make up the liver's capillary system. Lining the sinusoids are reticuloendothelial macrophages (Kupffer's cells), which remove bacteria and toxins that enter the blood through the intestinal capillaries.

The sinusoids carry oxygenated blood from the hepatic artery and nutrient-rich blood from the portal vein. Unoxygenated blood leaves through the central vein and flows through hepatic veins to the inferior vena cava. Bile, recycled from bile salts in the blood, leaves through bile ducts (canaliculi) that merge into right and left hepatic ducts to form the common hepatic duct. This common duct joins the cystic duct from the gallbladder to form the common bile duct to the duodenum.

Gallbladder

This pear-shaped organ, 3" to 4" (8 to 10 cm) long, is joined to the liver's ventral surface by the cystic duct. It stores and concentrates bile produced by the liver. Its usual 30- to 50-ml storage capacity can increase up to 10-fold. Secretion of the hormone cholecystokinin causes gallbladder contraction and relaxation of the ampulla of Vater, releasing bile into the common bile duct for delivery to the duodenum. When the ampulla of Vater closes, bile shunts to the gallbladder for storage.

Pancreas

The pancreas is somewhat flat and is 6" to 9" (15 to 23 cm) long. It lies behind the stomach, and its head and neck extend into the curve of the duodenum. Its tail lies against the spleen.

The pancreas performs both exocrine and endocrine functions. Its exocrine function involves scattered cells that secrete more than 1,000 ml of digestive enzymes daily. Lobules and lobes (acini) of enzyme-producing cells release their secretions into ducts that merge into the pancreatic duct. This duct runs the length of the pancreas and joins the bile duct from the gallbladder before entering the duodenum. Vagal stimulation and release of the hormones secretin and cholecystokinin control the rate and amount of pancreatic secretion.

The endocrine function of the pancreas involves the islets of Langerhans, which are located between the acinar cells. More than 1 million of the islets house two cell types: beta and alpha. *Beta cells* secrete insulin to promote carbohydrate metabolism; *alpha cells* secrete glucagon, which stimulates glycogenolysis in the liver. Both hormones flow directly into the blood; their release is stimulated by blood glucose levels.

GI assessment

Your assessment of the patient with suspected GI disease must include a thorough history and physical examination.

History

Begin with a careful history that includes occupation, family history, alcohol consumption, recent exposure to infection, recent abdominal injury, and recent travel. The medical history should include previous hospital admissions; any surgery (including recent tooth extraction); any recent blood or plasma transfusions; a family history of ulcers, colitis, or cancer; and any current medications, such as aspirin, steroids, and anticoagulants.

Next, have the patient describe his chief complaint in his own words. Was the onset of symptoms abrupt or insidious? Did the symptoms follow a recent abdominal injury? Does he have abdominal pain, indigestion, heartburn, or rectal bleeding? How long has he had his symptoms? What relieves them or makes them worse?

Has the patient recently experienced nosebleeds or difficulty swallowing? Does he bruise or bleed easily? Has he had any recent weight loss or gain? Has he noticed any loss of appetite? Can he tolerate fatty foods? Is he on a special diet? Does he drink alcoholic beverages or smoke? How much and how often? Ask about bowel habits. Does he regularly use laxatives or enemas? If he experiences nausea and vomiting, what does the vomitus look like? Does changing his position relieve nausea?

Next, try to define and locate any pain. Ask the patient to describe the pain. Is it dull, sharp, burning, aching, spasmodic, or intermittent? Where is it located? How long does it last? When does it occur? Does it radiate? What relieves it? (See [Emergency signals.](#))

CULTURAL TIP Members of some cultures, such as those of Hispanic or Italian heritage, are more verbal about discomfort, whereas some individuals of Asian or Japanese descent don't verbalize discomfort. During your assessment, ask patients how they customarily deal with pain to help you accurately assess their pain.

Inspection

Observe the patient's appearance, and note the appropriateness of his behavior. Severe infection, drug toxicity, hepatic disease, or changes in fluid and electrolyte balance may cause abnormal behavior. Begin your visual inspection by observing the following:

WARNING

Emergency Signals

When assessing a patient with a GI problem, stay alert for the signs and symptoms described below, which may signal an emergency.

Abdominal pain

- Progressive, severe, or colicky pain that persists without improvement for more than 6 hours
- Acute pain associated with hypertension
- Acute pain in an elderly patient (Such a patient may have minimal tenderness, even with a ruptured abdominal organ or appendicitis.)
- Severe pain with guarding and a history of recent abdominal surgery
- Pain accompanied by evidence of free intraperitoneal air (gas) or mediastinal gas on X-ray
- Disproportionately severe pain under benign conditions (soft abdomen with normal physical findings)

Vomitus and stools

- Vomitus containing fresh blood
- Vomiting or heaving that is prolonged, with or without obstipation (intractable constipation)
- Bloody or black, tarry stools

Abdominal tenderness

- Abdominal tenderness and rigidity, even when the patient is distracted
- Rebound tenderness

Other signs

- Fever
- Tachycardia
- Hypotension
- Dehydration

If you detect any of these signs and symptoms, notify the doctor and assess the patient for deterioration such as signs of shock. Intervene as necessary by providing oxygen therapy and I.V. fluids as ordered. Place the patient on a cardiac monitor if appropriate. Provide emotional support.

- *Skin*. Look for loss of turgor, jaundice, cyanosis, pallor, diaphoresis, petechiae, spider angiomas, bruises, edema, oily or dry texture, and decreased axillary or pubic hair (may indicate hepatic disease).
- *Head*. Note the color of sclerae, sunken eyes, dentures, caries, lesions, breath odor, and tongue color, swelling, or dryness.
- *Chest*. Inspect the shape of the chest, and assess the rate, rhythm, and quality of respirations.
- *Abdomen*. Check the size and shape, noting distention, contour, visible masses, and protrusions. Note abdominal scars or fistulae, excessive skin folds (may indicate wasting), and abnormal respiratory movements (may indicate inflammation of the diaphragm).

Auscultation, palpation, and percussion

Auscultation provides helpful clues to GI abnormalities. For example, absent bowel sounds over the area to the lower right of the umbilicus may indicate peritonitis. High-pitched sounds that coincide with colicky pain may indicate small-bowel obstruction. Less intense, low-pitched rumbling noises may accompany minor irritation. A venous hum over the patient's abdomen suggests portal hypertension. A pleural friction rub may indicate a liver abscess or neoplastic disease.

Palpate the parotid glands. Enlargement can occur in alcohol-induced liver damage. Palpate the abdomen after auscultation to detect tenderness, muscle guarding, organ enlargement, and abdominal masses. Note muscle tone (boardlike rigidity points to peritonitis; transient rigidity suggests severe pain) and tenderness (rebound tenderness may indicate peritoneal inflammation; tenderness at the liver's edge may indicate hepatic disease).

Percussion helps you to detect air, fluid, and solid matter in the abdomen.

Diagnostic tests

After physical assessment, a range of tests can be used to identify GI, liver, or gallbladder malfunction.

- *Barium swallow* allows examination of the pharynx and esophagus to detect strictures, ulcers, tumors, polyps, diverticula, hiatal hernia, esophageal webs, motility disorders, and (sometimes) achalasia.
- In an *upper GI series*, swallowed barium sulfate proceeds into the esophagus, stomach, and small intestine to reveal abnormalities. The barium outlines stomach walls and delineates ulcer craters and filling defects. It can help diagnose gastritis, cancer, hiatal hernia, diverticula, strictures, and (most commonly) gastric and duodenal ulcers.
- *Small-bowel series*, an extension of the upper GI series, enables visualization of barium flowing through the small intestine to the ileocecal valve. It's used to help diagnose sprue, obstruction, motility disorders, malabsorption syndrome, Hodgkin's disease, lymphosarcoma, ischemia, bleeding, and inflammation.
- *Barium enema (lower GI X-ray)* allows visualization of the colon, permitting easier identification of lesions in this area than is possible in a small-bowel series.
- *Stool specimen* is useful in confirming suspected GI bleeding, infection, or malabsorption. Guaiac test for occult blood, microscopic stool examination for ova and parasites, and fat analysis necessitates several specimens.
- *Inesophagogastroduodenoscopy*, insertion of a fiber-optic scope allows direct visual inspection of the esophagus, stomach and, sometimes, duodenum; *proctosigmoidoscopy* permits inspection of the rectum and distal sigmoid colon; *colonoscopy* enables inspection of the descending, transverse, and ascending colon.
- *Gastric analysis* includes the examination of gastric secretions and analysis of acid content.
- *Esophageal acidity test* is used to assess lower sphincter competence by measuring intraesophageal pH with an electrode attached to a manometric catheter. This sensitive test is used for patients who complain of persistent heartburn and helps to discriminate GI problems from problems in other systems.
- In an *acid perfusion test*, normal saline and acidic solutions are perfused separately into the esophagus through a nasogastric tube to distinguish pain caused by the backflow of acidic juices into the esophagus from pain caused by angina pectoris or other disorders.
- *Duodenal drainage* is used to diagnose cholelithiasis, choledocholithiasis, biliary obstruction, hepatic cirrhosis, and pancreatic disease and to differentiate types of jaundice. It permits measurement of bile flow and the collection of specimens, which are examined for mucus, blood, cholesterol crystals, pancreatic enzymes, cancer cells, bacteria, and calcium bilirubinate.
- *Peritoneal fluid analysis* includes examination of peritoneal fluid for gross appearance, erythrocyte and leukocyte counts, cytologic studies, microbiological studies for bacteria and fungi, and determinations of protein, glucose, amylase, ammonia, and alkaline phosphatase levels.
- *Portal and hepatic vein manometry* is used to locate obstructions in the extrahepatic portion of the portal vein and in the portal inflow system and to detect pressure in the presinusoidal vessels.
- *Percutaneous or transvenous liver biopsy* can be used to determine the cause of unexplained hepatomegaly, hepatosplenomegaly, cholestasis, or persistently abnormal liver function tests. This test is also useful in confirming suspected systemic infiltrative disease (sarcoidosis, for example) and suspected primary or metastatic hepatic tumors.
- *In gallbladder ultrasonography*, sound waves are used to visualize the gallbladder and locate obstructions, calculi, and tumors.
- *Abdominal X-ray*, also called flatplate of the abdomen or kidney-ureter-bladder radiography, is used to detect and evaluate tumors, renal calculi, abnormal gas collection, and other abdominal disorders.
- *Liver function studies* are used to measure serum enzyme levels and other substances.
- *Oral cholecystography* is used to confirm gallbladder disease through radiographic examination of the gallbladder after administration of a contrast medium.
- *Endoscopic retrograde cholangiopancreatography* enables direct visualization of the proximal duodenum. This test is used to help determine the cause of jaundice; evaluate tumors and inflammation of the pancreas, gallbladder, and liver; and locate obstructions in the pancreatic duct and hepatobiliary tree.

- ⌞ *I.V. cholangiography*, also called T tube cholangiography or postoperative cholangiography, is used to visualize the intrahepatic and extrahepatic bile ducts and locate obstructing lesions in the major ducts.
- ⌞ *Percutaneous transhepatic cholangiography* is used to differentiate obstructive from intrahepatic types of jaundice and to detect hepatic dysfunction and calculi.
- ⌞ *Angiography* demonstrates hepatic arterial circulation (deranged in cirrhosis) and is used to help diagnose primary or secondary hepatic tumors.
- ⌞ *Radioisotope liver scan* can detect such abnormalities as tumors, cysts, and abscesses.
- ⌞ *Computed tomography scanning* produces three-dimensional images of the biliary tract, liver, and pancreas and is used to help distinguish between obstructive and nonobstructive jaundice; to identify abscesses, cysts, pseudocysts, hematomas, and tumors; and to diagnose and evaluate pancreatitis.

Intubation

Certain GI disorders require intubation to empty the stomach and intestine, to aid diagnosis and treatment, to decompress obstructed areas, to detect and treat GI bleeding, and to administer medications or feedings. Tubes generally inserted through the nose are short nasogastric tubes (Levin, Salem Sump, and specialized Sengstaken-Blakemore tubes) and long intestinal tubes (Cantor and Miller-Abbott tubes). The larger Ewald tube is usually inserted orally.

Mouth and esophageal disorders

Any GI disorder can cause serious signs and symptoms. Disorders of the mouth and esophagus often lead to dysphagia, predisposing the patient to nutritional deficiencies and respiratory and cardiovascular complications.

CORROSIVE ESOPHAGITIS AND STRICTURE

Accidental or intentional ingestion of a caustic chemical produces corrosive esophagitis. This injury is similar to a burn and is characterized by esophageal inflammation and damage. It may be temporary or may lead to permanent stricture (narrowing or stenosis) of the esophagus, which is correctable only through surgery. In children, household chemical ingestion is accidental; in adults, it's usually a suicide attempt or gesture.

The severity and location of the damage depend on the type and amount of chemical ingested. The corrosive agent may damage only the mucosa or submucosa or it may injure all esophageal layers. Tissue damage occurs in three phases: an acute phase, marked by edema and inflammation; a latent phase, characterized by ulceration, exudation, and tissue sloughing; and a chronic phase of diffuse scarring.

Causes

Ingestion of lye or other strong alkalis is the most common cause of corrosive esophagitis. Less often, strong acids, such as toilet bowl cleaners and hydrochloric acid, are ingested.

Complications

Severe injury can quickly lead to esophageal perforation, mediastinitis, and death from infection, shock, or massive hemorrhage (if the aorta is perforated). In less severe cases, secondary infection occurs 3 to 4 days after ingestion. Stricture of the esophagus may occur within weeks of the ingestion or, less commonly, several years later.

Assessment findings

In corrosive esophagitis and stricture, assessment findings depend on the cause and severity of the injury. Usually, the patient's history reveals recent chemical ingestion. He may report gagging at the time of ingestion and intense pain in his mouth and anterior chest. Other common complaints include a marked increase in salivation and an inability to swallow. If he's unable to speak, suspect laryngeal damage.

On inspection, you may notice tachypnea and drooling. The patient's mouth may show obvious mucosal burns of the lips and oropharynx, with whitened membranes and edema of the soft palate and uvula. If the patient vomits, inspect the vomitus for blood and pieces of esophageal tissue. These findings signal severe damage. As part of the inspection, smell the patient; an identifiable odor will be apparent if ammonia or formaldehyde was ingested.

Palpation may reveal crepitation, an indication of esophageal perforation and mediastinitis and, possibly, destruction of the entire esophagus.

In severe cases, auscultation may disclose marked hypotension.

Diagnostic tests

Endoscopy and barium swallow may be ordered to assess the severity of esophageal damage.

Endoscopy may be used to determine the extent of the injury in patients with a history of chemical ingestion and an oropharynx that appears abnormal. However, endoscopy use is controversial because of the risk of perforating the damaged esophagus.

Barium swallow is usually performed 1 week after chemical ingestion and every 3 weeks thereafter as ordered. This test is useful for identifying segmental spasm or fistula but may not reveal mucosal injury. The test is contraindicated if esophageal perforation is suspected.

Treatment

An immediate priority is to identify the type and amount of chemical ingested. Sometimes, this can be done by examining the empty containers of the ingested material or by calling the local poison control center.

Conservative treatment includes monitoring the patient's condition and administering medications as ordered. Drug therapy may include narcotics for pain relief; corticosteroids, such as prednisone and hydrocortisone, to reduce inflammation and inhibit fibrosis; and a broad-spectrum antibiotic, such as ampicillin, to protect the patient taking a corticosteroid against infection by his own mouth flora. If the patient has burns of the oral mucosa, topically applied agents, such as lidocaine viscous and dyclonine, can provide temporary pain relief and coat the burned area. This protects the area from further injury.

If an esophageal stricture develops, bougienage is performed. In this procedure, a slender, flexible, cylindrical instrument called a bougie is passed into the esophagus to dilate it. If stricture is untreatable with bougienage, surgery is required. Immediate surgery is necessary if the patient develops esophageal perforation. Some patients require corrective surgery, which may involve transplanting a piece of the colon to repair the damaged esophagus. Even after surgery, stricture may recur at the site of the anastomosis.

Supportive treatment includes I.V. therapy (to replace fluids) or total parenteral nutrition if the patient can't swallow. As the patient's condition improves, nutrition can gradually progress to clear liquids, then to a soft diet.

Nursing diagnoses

- ⌞ Altered nutrition: Less than body requirements
- ⌞ Altered oral mucous membrane
- ⌞ Anxiety
- ⌞ Pain
- ⌞ Risk for infection

Key outcomes

- u The patient will show no evidence of weight loss.
- u The patient will avoid or minimize complications.
- u The patient will express feelings of comfort.
- u The patient will voice his feelings about his condition.

Nursing interventions

- u Support the patient and the family emotionally. Stay with them during periods of severe crisis.
- u Don't induce vomiting or lavage because this will expose the esophagus and oropharynx to injury a second time. Avoid performing gastric lavage because the caustic chemical may cause further damage to the mucous membrane of the GI lining.
- u Depending on the severity of the injury, provide vigorous support of vital functions, such as oxygen, mechanical ventilation, I.V. fluid administration, and treatment for shock as needed.
- u Carefully observe and record intake and output.
- u Administer analgesics, corticosteroids, and antibiotics as ordered.
- u Monitor the patient for complications. Watch for the development of fever, which may signal a secondary infection. Observe him for a return of dysphagia, which may indicate esophageal stricture and can occur within weeks of chemical ingestion.
- u Provide parenteral nutrition as ordered until the patient can tolerate oral foods.
- u Stay with the patient when he first tries eating. If his esophagus wasn't destroyed, he can usually attempt to eat 3 to 4 days after the acute phase subsides.
- u If surgery is scheduled, provide appropriate preoperative and postoperative care.
- u Because the adult who has ingested a corrosive agent has usually done so with suicidal intent, encourage the patient and family members to seek psychological counseling. Make appropriate referrals.
- u When the patient is a child, look for signs of abuse or neglect. Notify the authorities if you see such signs.

Patient teaching

- u Teach the patient and family members about the damage to the esophagus and necessary treatments to relieve symptoms and repair the injury. Make sure they understand potential complications, such as esophageal perforation and infection.
- u Warn the patient not to swallow topical medications, especially if he's allowed nothing by mouth.
- u Teach parents whose child ingested a chemical to take safety precautions, such as locking accessible cabinets and keeping all corrosive agents out of a child's reach.
- u Discuss and encourage long-term follow-up because these patients have an increased risk of squamous cell carcinoma of the esophagus.

GASTROESOPHAGEAL REFLUX DISEASE

Commonly known as heartburn, gastroesophageal reflux disease (GERD) is the backflow of gastric or duodenal contents, or both, into the esophagus and past the lower esophageal sphincter (LES), without associated belching or vomiting. Reflux may cause symptoms or pathologic changes. Persistent reflux can cause reflux esophagitis, an inflammation of the esophageal mucosa. The prognosis varies with the underlying cause.

Causes

Normally, gastric contents don't back up into the esophagus because the LES creates enough pressure around the lower end of the esophagus to close it. Reflux occurs when LES pressure is deficient or pressure in the stomach exceeds LES pressure. When this happens, the LES relaxes, allowing gastric contents to regurgitate into the esophagus. Any of the following predisposing factors can lead to reflux:

- u pyloric surgery (alteration or removal of the pylorus), which allows reflux of bile or pancreatic juice
- u nasogastric intubation for more than 4 days
- u any agent that lowers LES pressure: food, alcohol, cigarettes, anticholinergics (atropine, belladonna, propantheline), and other drugs (morphine, diazepam, calcium channel blockers, meperidine)
- u hiatal hernia with incompetent sphincter
- u any condition or position that increases intraabdominal pressure.

Complications

Reflux esophagitis, the primary complication of GERD, can lead to other sequelae, including esophageal stricture, esophageal ulcer, and replacement of the normal squamous epithelium with columnar epithelium (Barrett's epithelium). A patient with severe reflux esophagitis may also develop anemia from chronic low-grade bleeding of inflamed mucosa.

Pulmonary complications may develop if the patient experiences reflux of gastric contents into the throat and subsequent aspiration. Reflux aspiration can lead to chronic pulmonary disease.

Assessment findings

The patient complains of heartburn that typically occurs 1 to 2 hours after eating. It often worsens with vigorous exercise, bending, or lying down. He may report relief by using antacids or sitting upright. If asked, he may recall regurgitating without associated nausea or belching. This symptom is often described as a feeling of warm fluid traveling up the throat, followed by a sour or bitter taste in the mouth if the fluid reaches the pharynx.

Heartburn is the most common feature of reflux, but the patient may report any of the following signs and symptoms:

- u a feeling of fluid accumulation in the throat without a sour or bitter taste. This is caused by hypersecretion of saliva.
- u odynophagia, possibly followed by a dull substernal ache. This symptom may indicate severe, long-term reflux dysphagia from esophageal spasm, stricture, or esophagitis.
- u bright red or dark brown blood in vomitus.
- u chronic pain that may mimic angina pectoris, radiating to the neck, jaw, and arm. (This pain may be associated with esophageal spasm and may result from reflux esophagitis.)
- u nocturnal hypersalivation, a rare symptom that the patient says awakens him with coughing, choking, and a mouth full of saliva.

In children, assessment findings may identify failure to thrive and forceful vomiting caused by esophageal irritation. Keep in mind that vomiting can lead to aspiration pneumonia.

Diagnostic tests

A careful history and physical examination are essential to the diagnosis. Several tests help to confirm it:

- u The esophageal acidity test, a standard test for acid reflux, is the most sensitive and accurate measure of gastroesophageal reflux. Gastroesophageal scintillation testing may also detect reflux.
- u Esophageal manometry is used to evaluate the resting pressure of the LES and determine sphincter competence.
- u An acid perfusion test confirms esophagitis.
- u Esophagoscopy and biopsy allow visualization and tissue sampling of the esophagus. These tests are used to evaluate the extent of the disease and confirm pathologic changes in the mucosa.

⌵ Barium swallow with fluoroscopy reveals normal findings except in patients with advanced disease. In children, barium esophagography under fluoroscopic control may show reflux.

Treatment

Effective management relieves symptoms by reducing reflux through gravity, strengthening the LES with drug therapy, neutralizing gastric contents, and reducing intra-abdominal pressure. Treatment should also include reviewing how the patient's lifestyle or dietary habits may affect his LES pressure and reflux symptoms. (See [Factors affecting LES pressure.](#))

In mild cases, diet therapy may reduce symptoms sufficiently so that no other treatment is required. Positional therapy, which relieves symptoms by reducing intra-abdominal pressure, is especially useful in infants and children with uncomplicated cases.

For intermittent reflux, antacids given 1 hour before and 3 hours after meals and at bedtime may be effective. Drug therapy may also include cholinergic drugs, such as bethanechol, to increase LES pressure, and histamine-2 receptor antagonists, such as famotidine and ranitidine, to reduce gastric acidity. A 4-week course of lansoprazole is useful in acute cases. Metoclopramide and sucralfate have also been used with beneficial results.

Surgery is usually reserved for patients with refractory symptoms or serious complications. Indications for surgery include pulmonary aspiration, hemorrhage, esophageal obstruction or perforation, intractable pain, incompetent LES, or associated hiatal hernia. Surgical procedures reduce reflux by creating an artificial closure at the gastroesophageal junction. Several surgical approaches involve wrapping the gastric fundus around the esophagus. Other surgical procedures include a vagotomy or pyloroplasty (which may be combined with an antireflux regimen) to modify gastric contents.

Nursing diagnoses

⌵ Altered nutrition: Less than body requirements ⌵ Anxiety ⌵ Knowledge deficit ⌵ Pain ⌵ Risk for aspiration

Key outcomes

- ⌵ The patient will express an understanding of the disorder and treatment regimen.
- ⌵ The patient will express feelings of comfort.
- ⌵ The patient won't show signs of aspiration.
- ⌵ The patient will avoid or minimize complications.

Nursing interventions

- ⌵ Offer emotional and psychological support to help the patient cope with pain and discomfort.
- ⌵ In consultation with a dietitian, develop a diet that takes the patient's food preferences into account but, at the same time, helps to minimize his reflux symptoms. If the patient is obese, place him on a weight reduction diet as ordered.
- ⌵ To reduce intra-abdominal pressure, have the patient sleep in a reverse Trendelenburg position (with the head of the bed elevated 6" to 12" [15 to 30 cm]). He should avoid lying down immediately after meals and eating late-night snacks.
- ⌵ After surgery, provide care as you would for any patient who has undergone a laparotomy. Pay particular attention to the patient's respiratory status because the surgical procedure is performed close to the diaphragm. Administer prescribed analgesics, oxygen, and I.V. fluids. Monitor his intake and output and check his vital signs. If surgery was performed using a thoracic approach, watch and record chest tube drainage. If needed, provide chest physiotherapy.

Factors affecting LES pressure
Various dietary and lifestyle elements can increase or decrease lower esophageal sphincter (LES) pressure. Take these into account as you plan the patient's treatment program.
What increases LES pressure
<ul style="list-style-type: none">⌵ Protein⌵ Carbohydrates⌵ Nonfat milk⌵ Low-dose ethanol
What decreases LES pressure
<ul style="list-style-type: none">⌵ Fat⌵ Whole milk⌵ Orange juice⌵ Tomatoes⌵ Antiflatulent (simethicone)⌵ Chocolate⌵ High-dose ethanol⌵ Cigarette smoking⌵ Lying on right or left side⌵ Sitting

Patient teaching

- ⌵ Teach the patient about the causes of GERD, and review his antireflux regimen of medication, diet, and positional therapy.
- ⌵ Discuss recommended dietary changes. Advise the patient to sit upright after meals and snacks, and to eat small, frequent meals. Explain that he should eat meals at least 2 to 3 hours before lying down. Tell him to avoid highly seasoned food, acidic juices, alcoholic drinks, bedtime snacks, and foods high in fat because these reduce LES pressure.
- ⌵ Instruct the patient to avoid situations or activities that increase intra-abdominal pressure, such as bending, coughing, vigorous exercise, obesity, constipation, and wearing tight clothing. Caution him to refrain from using any substance that reduces sphincter control, including cigarettes, alcohol, fatty foods, and certain drugs.
- ⌵ Encourage compliance with the drug regimen. Review the desired drug actions and potential adverse effects.

HIATAL HERNIA

Hiatal hernia (also called hiatus hernia) is a defect in the diaphragm that permits a portion of the stomach to pass through the diaphragmatic opening into the chest. It commonly produces no symptoms. Three types of hiatal hernia can occur: a sliding hernia, a paraesophageal (rolling) hernia, or a mixed hernia. A mixed hernia includes features of the sliding and rolling hernias. (See [Types of hiatal hernia.](#))

The incidence of this disorder increases with age. By age 60, about 60% of people have hiatal hernias. However, most have no symptoms; the hernia is an incidental finding during a barium swallow, or it may be detected by tests that follow the discovery of occult blood. The prevalence (especially of the paraesophageal type) is

higher in women than in men.

Causes

In a sliding hernia, the muscular collar around the esophageal and diaphragmatic junction loosens, permitting the lower portion of the esophagus and the upper portion of the stomach to rise into the chest when intra-abdominal pressure increases. This muscle weakening may be associated with normal aging, or it may be secondary to esophageal carcinoma, kyphoscoliosis, trauma, or surgery. A sliding hernia may also result from certain diaphragmatic malformations that can cause congenital weakness.

The exact cause of a paraesophageal hiatal hernia isn't fully understood. One theory holds that the stomach isn't properly anchored below the diaphragm, permitting the upper portion of the stomach to slide through the esophageal hiatus when intra-abdominal pressure increases.

Increased intra-abdominal pressure can be caused by such conditions as ascites, pregnancy, obesity, constrictive clothing, bending, straining, coughing, Valsalva's maneuver, and extreme physical exertion.

Complications

If the hiatal hernia is associated with gastroesophageal reflux, the esophageal mucosa may become irritated, leading to esophagitis, esophageal ulceration, hemorrhage, peritonitis, and mediastinitis. Aspiration of refluxed fluids may lead to respiratory distress, aspiration pneumonia, or cardiac dysfunction from pressure on the heart and lungs.

Other complications include esophageal stricture and incarceration, in which a large portion of the stomach is caught above the diaphragm. Incarceration may lead to perforation, gastric ulcer, and strangulation and gangrene of the herniated stomach portion.

Assessment findings

When a sliding hernia causes symptoms, the patient typically complains of heartburn, indicating an incompetent lower esophageal sphincter (LES) and gastroesophageal reflux. The patient history usually reveals that heartburn occurs 1 to 4 hours after eating and is aggravated by reclining, belching, or conditions that increase intra-abdominal pressure. Heartburn may be accompanied by regurgitation or vomiting. The patient may complain of retrosternal or substernal chest pain (typically after meals or at bedtime), reflecting reflux of gastric contents, distention of the stomach, and spasm.

Keep in mind that the patient with a paraesophageal hernia is usually asymptomatic. Because this type of hernia doesn't disturb the closing mechanism of the LES, it doesn't usually cause gastric reflux and reflux esophagitis. Symptoms, when present, usually stem from incarceration of a stomach portion above the diaphragmatic opening. The symptomatic patient may report a feeling of fullness after eating or, if the hernia interferes with breathing, a feeling of breathlessness or suffocation. She may also complain of chest pain resembling angina pectoris.

ALERT During the history, watch for the following signs and symptoms of possible complications:

- u dysphagia, especially after ingestion of very hot or cold foods, alcoholic beverages, or a large amount of food (may indicate esophagitis, esophageal ulceration, or stricture)
- u bleeding, which may be mild or massive, frank or occult (may indicate esophagitis or erosion of the gastric pouch)
- u severe pain and shock (signs of incarceration) in which a large portion of the stomach is caught above the diaphragm (usually in paraesophageal hernia). (Incarceration requires immediate surgery because it can lead to perforation or strangulation and gangrene of the herniated stomach portion.)

PATHOPHYSIOLOGY

Types of hiatal hernia

These figures depict the normal stomach and the primary forms of hiatal hernia.

In a sliding hernia, both the stomach and the gastroesophageal junction slip up into the chest, so the gastroesophageal junction is above the diaphragmatic hiatus. This type of hernia causes symptoms if the lower esophageal sphincter (LES) is incompetent, which permits gastric reflux and heartburn.

In a paraesophageal, or rolling, hernia, a part of the greater curvature of the stomach rolls through the diaphragmatic defect. This type of hernia usually doesn't cause gastric reflux and heartburn because the closing mechanism of the LES is unaffected. However, it can cause displacement or stretching of the stomach or lead to strangulation of the herniated portion.

NORMAL STOMACH

SLIDING HERNIA

PARAESOPHAGEAL OR ROLLING HERNIA

Diagnostic tests

Chest X-ray occasionally shows an air shadow behind the heart in a large hernia; infiltrates appear in the lower lung lobes if the patient aspirated the refluxed fluids.

Barium swallow with fluoroscopy is the most specific test for detecting a hiatal hernia. The hernia may appear as an outpouching containing barium at the lower end of the esophagus. (Small hernias are difficult to recognize.) This study also shows diaphragmatic abnormalities.

HOME CARE

Living with hiatal hernia

Follow these guidelines to help your patient live with hiatal hernia:

- u Explain that the patient will need medications indefinitely, even after surgery.
- u Teach her about dietary changes to reduce reflux. For example, instruct her to eat small, frequent, bland meals.
- u Tell her to avoid alcohol, spices, and other beverages and foods that worsen her symptoms.
- u Suggest that she recline in a semi-Fowler's position after eating and that she elevate the head of the bed on 6" (15-cm) blocks.
- u Instruct her to avoid activities that increase intra-abdominal pressure, such as coughing, wearing restrictive clothing, and straining.

Serum hemoglobin and hematocrit levels may be decreased in patients with paraesophageal hernia.

Endoscopy and biopsy are used to differentiate between hiatal hernia, varices, and other small gastroesophageal lesions. These tests are also used to identify the mucosal junction and the edge of the diaphragm indenting the esophagus and can be used to rule out cancer that might otherwise remain undetected.

Esophageal motility studies reveal esophageal motor or lower esophageal pressure abnormalities before surgical repair of the hernia.

pH studies are used to assess for reflux of gastric contents.

Acid perfusion test indicates that heartburn results from esophageal reflux when hydrochloric acid perfusion through a nasogastric tube provokes this symptom.

Treatment

The goal of therapy is to relieve symptoms by minimizing or correcting the incompetent LES (if present) and to manage and prevent complications. Drugs, activity modifications, and diet changes reduce gastroesophageal reflux.

Antacids neutralize refluxed fluids; using antacids is probably the best treatment for intermittent reflux. Intensive antacid therapy may call for hourly dosing; however, the choice of antacids should take into account the patient's bowel function. Histamine-2 receptor antagonists also modify the acidity of fluid refluxed into the esophagus.

Drug therapy to strengthen LES tone may consist of a cholinergic agent such as bethanechol. Metoclopramide has also been used to stimulate smooth-muscle contraction, increase LES tone, and decrease reflux after eating.

Other measures to reduce intermittent reflux include restricting any activity that increases intra-abdominal pressure and discouraging smoking because it stimulates gastric acid production. Modifying the diet to include smaller, more frequent meals and eliminating spicy or irritating foods may also reduce reflux.

Rarely, surgery is required when symptoms persist despite medical treatment or if complications develop. Indications for surgery include esophageal stricture, significant bleeding, pulmonary aspiration, or incarceration or strangulation of the herniated stomach portion. Techniques vary, but most forms of surgery create an artificial closing mechanism at the gastroesophageal junction to strengthen the barrier function of the LES. The surgeon may use an abdominal or a thoracic approach.

Rare postsurgical complications include mucosal erosion, ulcers, and bleeding of the gastric pouch; pressure on the left lung due to the size and placement of the pouch; and formation of a volvulus.

A sliding hernia without an incompetent sphincter rarely produces reflux or symptoms and thus requires no treatment. A large rolling hernia should be surgically repaired (even if it produces no symptoms) because of the high risk of complications, especially strangulation.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Impaired swallowing
- u Knowledge deficit
- u Pain
- u Risk for aspiration

Key outcomes

- u The patient will avoid or minimize complications.
- u The patient won't show evidence of aspiration.
- u The patient will maintain a patent airway.
- u The patient will express feelings of comfort.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Prepare the patient for diagnostic tests. After endoscopy, watch for signs of perforation (decreasing blood pressure, rapid pulse, shock, sudden pain) caused by the endoscope.
- u Administer prescribed antacids and other medications, and monitor patient response.
- u To reduce intra-abdominal pressure and prevent aspiration, have the patient sleep in a reverse Trendelenburg position (with the head of the bed elevated 6" to 12" [15 to 30 cm]).
- u If surgery is necessary, prepare the patient and provide appropriate preoperative and postoperative care.

Patient teaching

- u Teach the patient about hiatal hernia. (See [Living with hiatal hernia](#).)
- u Explain significant symptoms, diagnostic tests, and prescribed treatments. Teach the patient about her prescribed medications.

MALLORY-WEISS SYNDROME

Mallory-Weiss syndrome is characterized by mild to massive and usually painless bleeding. It results from a tear in the mucosa or submucosa of the cardia or lower esophagus. Such a tear, usually singular and longitudinal, results from prolonged or forceful vomiting.

About 60% of these tears involve the cardia; 15%, the terminal esophagus; and 25%, the region across the esophagogastric junction. Mallory-Weiss syndrome is most common in men over age 40, especially alcoholics.

Causes

Forceful or prolonged vomiting is the direct cause of Mallory-Weiss syndrome. The tear in the gastric mucosa probably occurs when the upper esophageal sphincter fails to relax during vomiting. This lack of sphincter coordination seems more common after excessive intake of alcohol. Other factors or conditions that can increase intra-abdominal pressure and predispose a person to esophageal tearing include coughing, straining during bowel movements, trauma, seizures, childbirth, hiatal hernia, esophagitis, gastritis, and atrophic gastric mucosa.

Complications

Hypovolemia may develop if bleeding is excessive. Rarely, massive bleeding, usually from a tear on the gastric side near the cardia, quickly leads to fatal shock.

Assessment findings

Typically, the history reveals a recent bout of forceful vomiting, followed by vomiting of bright red blood. The patient may describe this bleeding as mild to massive and may complain of accompanying epigastric or back pain. He also may report passing large amounts of blood rectally a few hours to several days after normal vomiting. Be alert for a history of hiatal hernia or alcoholism.

Diagnostic tests

Fiber-optic endoscopy of esophageal tears confirms Mallory-Weiss syndrome. In most patients, lesions appear as recently produced, erythematous, longitudinal cracks in the mucosa. In older tears, lesions appear as raised, white streaks surrounded by erythema.

Angiography (selective celiac arteriography) can be used to determine the bleeding site but not the cause. This procedure may be used when endoscopy isn't available.

Serum hematocrit (HCT) helps to quantify blood loss.

Treatment

Because GI bleeding usually stops spontaneously, treatment often consists of supportive measures and careful observation. Treatment must be geared to the severity of bleeding. In some patients, blood transfusion is necessary. If severe bleeding continues, other treatments may include:

- u angiography, with infusion of a vasoconstrictor (vasopressin) into the superior mesenteric artery or direct infusion into a vessel that leads to the bleeding artery.
- u endoscopy with electrocoagulation or heater probe for hemostasis.
- u transcatheter embolization or thrombus formation with an autologous blood clot or other hemostatic material (insertion of artificial material, such as shredded absorbable gelatin sponge or, less often, the patient's own clotted blood through a catheter into the bleeding vessel to aid thrombus formation).
- u surgery to suture each laceration (for massive recurrent or uncontrollable bleeding).

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (GI)
- u Anxiety
- u Fear
- u Pain
- u Risk for fluid volume deficit
- u Risk for infection

Key outcomes

- u The patient will maintain adequate fluid volume.
- u The patient will express feelings of comfort.
- u The patient will express his feelings and anxieties.
- u The patient will avoid or minimize complications.
- u The patient's laboratory values will return to normal.
- u The patient's vital signs will remain stable.

Nursing interventions

- u Provide support for the patient, particularly if bleeding has frightened him.
- u Keep the patient warm and monitor vital signs, urine output, and overall clinical status.
- u Limit activity to prevent further bleeding.
- u Monitor the patient's hemoglobin level and HCT and his red blood cell count.
- u Insert a large-bore (14G to 18G) I.V. line, and start a temporary infusion of normal saline solution, as ordered, in case a transfusion is necessary.
- u Draw blood for coagulation studies (prothrombin time, partial thromboplastin time, and platelet count), and typing and crossmatching. As ordered, keep units of matched blood on hand. Transfuse blood if ordered.
- u Avoid giving the patient medications that may cause nausea or vomiting.
- u If surgery is necessary, prepare the patient for the scheduled surgery.

Patient teaching

- u Explain Mallory-Weiss syndrome and its treatment.
- u Advise the patient to avoid alcohol, aspirin, and other substances irritating to the GI tract.
- u Encourage an alcoholic patient to join a support group, such as Alcoholics Anonymous, or refer him for counseling.

STOMATITIS AND OTHER ORAL INFECTIONS

Stomatitis is a common infection that can occur in children or adults, alone or as part of a systemic disease. This inflammation of the oral mucosa may also extend to the buccal mucosa, lips, and palate. The two main types are acute herpetic stomatitis and aphthous stomatitis.

Acute herpetic stomatitis is usually self-limiting; however, it may be severe and, in neonates, generalized and potentially fatal. This type of stomatitis is common in children between ages 1 and 3.

Aphthous stomatitis is common in girls and female adolescents and usually heals spontaneously, without a scar, in 10 to 14 days. Other oral infections include gingivitis, periodontitis, and Vincent's angina. (See [Understanding oral infections.](#))

Causes

Acute herpetic stomatitis is caused by the herpes simplex virus. The cause of aphthous stomatitis is unknown, but autoimmune and psychosomatic causes are under investigation. Predisposing factors associated with aphthous stomatitis include stress, fatigue, anxiety, febrile states, trauma, and overexposure to the sun.

Complications

Stomatitis may be complicated by nutritional deficiencies if painful oral lesions cause dysphagia or make chewing difficult. In an immunocompromised patient, it can lead to esophagitis and sepsis.

Assessment findings

A patient with acute herpetic stomatitis usually reports symptoms of sudden onset, including mouth pain, malaise, lethargy, anorexia, irritability, and a fever that may last 1 to 2 weeks. He may also complain of bleeding gums and extreme tenderness of the oral mucosa.

On inspection, the gums typically appear swollen with papulovesicular ulcers evident in the mouth and throat. Eventually, these ulcers become punched-out lesions with reddened areolae. The pain usually disappears 2 to 4 days before healing of the ulcers is complete. Palpation commonly reveals submaxillary lymphadenitis. If the patient is a child, be sure to inspect his hands; thumb sucking can spread the viral infection to the hands.

In aphthous stomatitis, typical complaints are burning and tingling of the oral mucosa and painful ulcers. Mouth inspection reveals a slight swelling of the mucous membrane and single or multiple shallow ulcers with whitish centers and red borders, measuring about 2 to 5 mm in diameter. These ulcers appear and heal at one site, then reappear at another.

Understanding oral infections		
DISEASES AND CAUSES	ASSESSMENT FINDINGS	TREATMENT
Gingivitis		
<ul style="list-style-type: none">Early sign of hypovitaminosis, diabetes, blood dyscrasiasOccasionally related to the use of oral contraceptives	<ul style="list-style-type: none">Inflammation with painless swelling, redness, change of normal contours, bleeding, and peritoneal pocket (gum detachment from the teeth)	<ul style="list-style-type: none">Removal of irritating factors (calculus, faulty dentures)Good oral hygiene, regular dental checkups, vigorous chewingOral or topical corticosteroids

<ul style="list-style-type: none">Streptococcal infectionIrritation or injury, jagged teeth, ill-fitting dentures, biting during seizures, spicy foods, smoking, sensitivity to toothpaste or mouthwashVitamin B deficiency, anemiaSkin conditions: lichen planus, erythema multiforme, pemphigus vulgaris	<ul style="list-style-type: none">Reddened, ulcerated, or swollen tongue (may obstruct airway)Painful chewing and swallowingSpeech difficultyPainful tongue without inflammation	<ul style="list-style-type: none">Treatment of underlying causeTopical anesthetic mouthwash or systemic analgesics (aspirin or acetaminophen) for painful lesionsGood oral hygiene, regular dental checkups, vigorous chewingAvoidance of hot, cold, or spicy foods and alcohol
Candidiasis		
<ul style="list-style-type: none">Also called thrush<i>Candida albicans</i>Predisposing factors: denture use, diabetes mellitus, immunosuppressant therapy	<ul style="list-style-type: none">Cream-colored or bluish white pseudomembranous patches on the tongue, mouth, or pharynxPain, fever, lymphadenopathy	<ul style="list-style-type: none">Hydrogen peroxide and normal saline mouthwashesClotrimazole tablets dissolved in the mouth five times/dayNystatin troches (100,000 U) dissolved in the mouth four times/dayFluconazole orally or I.V. daily

Diagnostic tests

Diagnosis depends on the physical examination. The following tests may help to identify the type of infection : A smear of ulcer exudate allows identification of the causative organism in Vincent's angina, and viral cultures may be performed on fluid and herpetic vesicles in acute herpetic stomatitis.

Treatment

For both acute herpetic and aphthous stomatitis, treatment is conservative, focusing on symptom relief until the infection resolves.

For acute herpetic stomatitis, symptom management includes nonantiseptic warm-water mouth rinses and topical medications to relieve pain and reduce inflammation.

Topical anesthetic solutions that may be used include lidocaine viscous or dyclonine. Topical corticosteroids may also be prescribed. Acyclovir may be ordered to manage herpetic stomatitis. Supplementary treatments to ease symptoms until the infection subsides include a soft, pureed, or liquid diet and, in severe cases of

stomatitis, I.V. fluids and bed rest.

For aphthous stomatitis, a topical anesthetic coating agent, such as kaolin and milk of magnesia, is the primary treatment. The coating helps to relieve severe oral pain while preventing further irritation.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered oral mucous membrane
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient's lesions or wounds will show improvement or heal.
- u The patient will avoid complications.
- u The patient will express feelings of comfort.
- u The patient or family members will describe routine oral care.
- u The patient or family members will demonstrate good oral hygiene practices.

Nursing interventions

- u If the patient's mouth hurts, show him how to clean his teeth with sponges instead of a toothbrush. Suggest that he rinse with hydrogen peroxide or normal saline mouthwash to soothe irritated mucosa, debride oral structures, and prevent superinfection.
- u Administer prescribed analgesics to relieve painful stomatitis. If ordered, apply a topical coating or swishing agent to relieve pain.
- u If the patient has difficulty chewing or swallowing, contact the dietitian and develop a meal plan based on soft, liquid, or pureed foods. A change in food consistency often eases discomfort while maintaining adequate nutrition. Icy cold drinks may be well tolerated. In severe cases, supplement oral foods with I.V. fluid or nasogastric feedings.

Patient teaching

- u Teach the patient and family members about the infection and its expected course. For the patient with herpetic stomatitis, emphasize the importance of good oral hygiene to prevent the spread of infection.
- u Show the patient or his parents how to apply ordered topical medications. Discuss recommended dietary changes and adverse effects of prescribed medications.
- u Caution the patient to avoid antiseptic and glycerine-containing mouthwashes while he has stomatitis because these irritate mouth ulcers.
- u Advise the patient with aphthous stomatitis to avoid such precipitating factors as stress and fatigue.

TRACHEOESOPHAGEAL FISTULA AND ESOPHAGEAL ATRESIA

Tracheoesophageal fistula and esophageal atresia are among the most serious congenital anomalies in neonates. They may develop separately but usually occur together. In tracheoesophageal fistula, an abnormal connection develops between the trachea and the esophagus. In esophageal atresia, the esophagus is closed off at some point.

Both disorders are surgical emergencies, requiring immediate diagnosis and correction. Sometimes they coexist with other serious anomalies, such as congenital heart disease, imperforate anus, genitourinary abnormalities, and intestinal atresia.

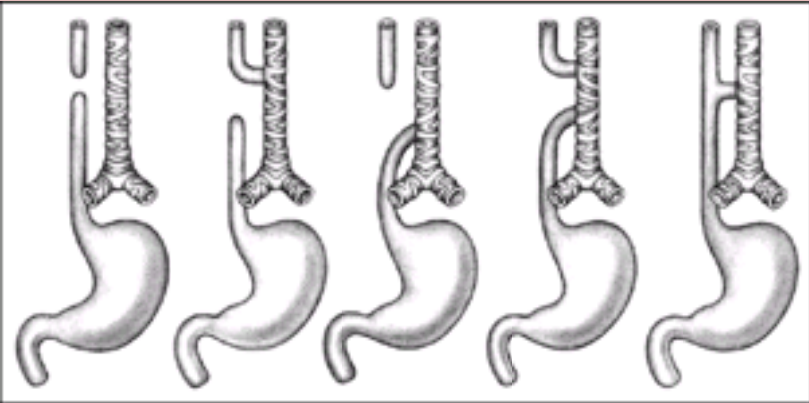

Congenital malformations of the esophagus occur in about 1 in 4,000 live births. These malformations have many anatomic variations. (See [Types of tracheoesophageal anomalies](#).) They're classified in the following ways:

- u In type C tracheoesophageal fistula with esophageal atresia—by far the most common esophageal malformation—the upper section of the esophagus terminates in a blind pouch (which has no fistula). The lower section ascends from the stomach and connects with the trachea by a short fistulous tract.

Types of tracheoesophageal anomalies

The American Academy of Pediatrics classifies tracheoesophageal anomalies as shown below:

Type A (7.7%) Esophageal atresia without fistula	Type B (0.8%) Esophageal atresia with tracheoesophageal fistula to the proximal segment	Type C (86.5%) Esophageal atresia with fistula to the distal segment only	Type D (0.7%) Esophageal atresia with fistula to both segments	Type E or H (4.2%) Tracheoesophageal fistula without atresia
--	---	---	---	---

- u In type A atresia, both esophageal segments are blind pouches, and neither has a fistulous connection to the airway.
- u In type E (also known as type H or tracheoesophageal fistula without atresia), the fistula may occur anywhere between the level of the cricoid cartilage and the mid-esophagus. The fistula, which may be as small as a pinpoint, is usually higher in the trachea than in the esophagus.
- u In types B and D, the upper portion of the esophagus opens into the trachea. (In type D, an additional fistula connects the trachea and the esophagus at a lower level.) Infants with either anomaly may experience life-threatening aspiration of saliva or food.

Causes

Tracheoesophageal fistula and esophageal atresia result from failure of the embryonic esophagus and trachea to develop and separate correctly.

Complications

These anomalies must be treated or the infant will die. Immediate complications include aspiration of secretions into the lungs leading to respiratory distress, cessation of breathing, or pneumonia.

Assessment findings

Both the maternal history and patient history should be included in the assessment. In most patients, the maternal history reveals hydramnios. About one-third of these infants are born prematurely.

On inspection, the neonate with type C tracheoesophageal fistula with esophageal atresia usually appears to swallow normally. Soon after swallowing, however, he begins to cough, struggle, and become cyanotic. Unless suctioned, he will aspirate fluids returning from the blind pouch of the esophagus and stop breathing. Inspection may disclose drooling from the mouth with possible bubbling through the nostrils. Stomach distention may be apparent on inspection and palpation.

An infant with type A esophageal atresia appears normal at birth. However, inspection reveals excessive drooling, even though he appears to swallow normally. As secretions fill the esophageal sac and overflow into the oropharynx, the infant develops mucus in the oropharynx, causing increased drooling. If the infant is inspected during feeding, he typically regurgitates and aspirates, causing respiratory distress and cessation of breathing unless he's suctioned.

With type E tracheoesophageal fistula, the patient history may reveal frequent episodes of pneumonitis, pulmonary infection, and abdominal distention. On inspection, the child may not drool excessively because the esophagus doesn't end in a blind pouch. However, if he's inspected while drinking, he's likely to cough, choke, and become cyanotic as excessive mucus builds up in his oropharynx. Inspection and palpation may also disclose abdominal distention, particularly when the infant cries. Crying may force air from the trachea through the fistula into the esophagus, causing some air to settle in the stomach. If the fistula is small, a congenital malformation may not be suspected initially, delaying diagnosis for as long as a year.

In both type B (proximal fistula) and type D (fistula to both segments), inspection initially reveals a normal-appearing neonate who begins to aspirate saliva into the airway. Aspiration may lead to bacterial pneumonitis.

Diagnostic tests

Tests used to help confirm and classify tracheoesophageal fistula and esophageal atresia include a radiopaque #8 or #10 French catheter passed through the nose, which confirms the presence of a blind pouch in the proximal esophagus if it meets an obstruction between 4" and 5" (10 and 13 cm) distal to the nostrils.

Chest X-ray demonstrates the catheter position in the esophagus and can also show a dilated, air-filled upper esophageal pouch; pneumonia in the right upper lobe of the lung; or bilateral pneumonitis. Both pneumonia and pneumonitis suggest aspiration.

Abdominal X-ray shows gas in the bowel in a distal fistula (type C) but none in a proximal fistula (type B) or in atresia without fistula (type A).

Cinefluorography allows visualization on a fluoroscopic screen. After a #10 or #12 French catheter is passed through the patient's nostril into the esophagus, a small amount of contrast medium is instilled to define the tip of the upper pouch. Findings help differentiate between overflow aspiration from a blind end (atresia) and aspiration due to passage of liquids through a tracheoesophageal fistula.

Bronchoscopy with telescopic endoscopy also can confirm the diagnosis in most patients.

Treatment

Tracheoesophageal fistula and esophageal atresia require surgical correction and are usually emergencies. The type of surgery and when it's performed depend on several factors: the nature of the anomaly, the patient's general condition, and the presence of coexisting congenital defects.

Depending on what type of anomaly the child has, a sump tube may be placed in the esophageal pouch until surgery is performed. This procedure is done to remove accumulated secretions, decreasing the possibility of aspiration. A gastrostomy tube may be placed to decompress the stomach. The child's respiratory status must be closely monitored.

Both before and after surgery, positioning varies according to the doctor's preferences and the child's anatomy: The child may be placed in a supine position, with his head low to aid drainage or elevated to prevent aspiration.

To correct gastroesophageal reflux and esophageal atresia, a thoracotomy is performed and the fistula is ligated, after which the upper and lower segments of the esophagus are anastomosed. In patients who are poor surgical risks, such as those born prematurely or those with other congenital defects, correction of combined tracheoesophageal fistula and esophageal atresia is done in two stages. The first stage consists of gastrostomy (for gastric decompression, prevention of reflux, and feeding) and closure of the fistula. One to 2 months later, the esophagus is anastomosed.

Correction of esophageal atresia alone requires anastomosis of the proximal and distal esophageal segments in one or two stages. End-to-end anastomosis often produces postoperative stricture; end-to-side anastomosis is less likely to do so. If the esophageal ends are widely separated, treatment may include a colonic interposition (grafting a piece of the colon) or elongation of the proximal segment of the esophagus by bougienage. About 10 days after surgery, and again 1 month and 3 months later, X-rays are required to evaluate the effectiveness of surgical repair.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Anxiety u Ineffective airway clearance u Pain u Risk for aspiration u Risk for infection

Key outcomes

- u The patient will maintain a patent airway.
- u The patient won't show signs of aspiration.
- u The patient will avoid or minimize complications.
- u The patient will maintain adequate weight.
- u Family members will express their feelings regarding the patient's disorder.

Nursing interventions

- u Provide emotional and psychological support to the parents. Stay with them during periods of extreme stress. Encourage them to participate in the infant's care and to hold and touch him as much as possible to facilitate bonding.
- u Monitor the infant's respiratory status continuously. Administer oxygen and perform chest physiotherapy and suctioning as needed. Provide a humid environment. Observe the infant closely for signs of airway obstruction, such as an anxious facial expression and an increased respiratory rate.
- u To prevent aspiration, make sure the infant is given nothing by mouth. Perform suction of the naso-pharynx until a sump tube can be placed in the esophageal pouch. Irrigate the sump tube as necessary to ensure patency.
- u Position the infant as ordered to prevent aspiration.
- u Comfort the infant by stroking his back gently and by handling him carefully. Administer pain medications as ordered. When the sump tube is in place, a pacifier can be given to help satisfy the infant's sucking needs.
- u Administer antibiotics and parenteral fluids as ordered. Keep accurate intake and output records.
- u Maintain gastrostomy tube feedings as ordered. Such feedings initially consist of dextrose and water (not more than a 5% solution); later, add a proprietary formula (first diluted and then full strength). If the infant develops gastric atony, use an iso-osmolar formula.

After corrective surgery:

- u Monitor the patient's respiratory status. He may be on mechanical ventilation for the first few days after surgery. If so, maintain the setting as ordered.
- u Keep the infant in the position ordered, and carefully administer I.V. fluids to maintain electrolyte and fluid balance.
- u Administer prescribed medications, such as analgesics for pain and antibiotics for pneumonia.
- u Provide care for the gastrostomy to prevent reflux, and provide feedings. Maintain adequate nutrition through gastrostomy feedings or, if the infant's condition allows, oral feedings. Oral feedings can usually resume 8 to 10 days postoperatively. If gastrostomy or oral feedings are impossible because of intolerance or decreased intestinal motility, provide total parenteral nutrition as ordered.
- u When the sump pump is removed after surgery, suction the infant as necessary. Be gentle and perform the procedure quickly to prevent removal of oxygen from the area and to prevent trauma.
- u If the patient has chest tubes postoperatively, check them frequently for patency. Maintain proper suction, measure and mark drainage periodically, and milk the tubing as necessary.

ALERT Observe the patient carefully for signs of postoperative complications, such as abnormal esophageal motility, recurrent fistulas, pneumothorax, esophageal stricture, reflux esophagitis, recurrent bronchitis, hiatal hernia, and failure to thrive. Esophageal motility dysfunction or hiatal hernia may develop after surgical correction of esophageal atresia.

Patient teaching

- u Teach the parents about the disorder. Reinforce the doctor's explanation as necessary. Explain the diagnostic tests and the type of corrective surgery required.
- u Teach the parents how to care for their infant at home. Be sure they understand how to position, hold, and feed the child. Refer them to the social service department and local home health care agencies as necessary.

Stomach, intestinal, and pancreatic disorders

Acute or chronic inflammation is commonly associated with disorders of the stomach, intestines, and pancreas. In addition, ulceration, herniation, or the development of diverticula may damage the GI mucosa lining the stomach and intestines.

APPENDICITIS

Appendicitis, the most common major surgical disease, is an inflammation of the vermiform appendix, a small, fingerlike projection attached to the cecum just below the ileocecal valve. Although the appendix has no known function, it does regularly fill and empty itself of food. Appendicitis occurs when the appendix becomes inflamed from ulceration of the mucosa or obstruction of the lumen.

Appendicitis can occur at any age, and it affects both sexes equally; however, between puberty and age 25, it's more prevalent in men. Since the advent of antibiotics, the incidence and mortality of appendicitis have declined. If untreated, this disease is fatal.

Causes

Appendicitis probably results from an obstruction of the appendiceal lumen, caused by a fecal mass, stricture, barium ingestion, or viral infection. This obstruction sets off an inflammatory process that can lead to infection, thrombosis, necrosis, and perforation.

Complications

The most common and perilous complication of appendicitis occurs when the appendix ruptures or perforates. When this happens, the infected contents spill into the abdominal cavity, causing peritonitis. Other complications include appendiceal abscess and pyelophlebitis.

Assessment findings

During the initial phase of appendicitis, the patient typically complains of abdominal pain. Pain may be generalized, but within a few hours it becomes localized in the right lower abdomen (McBurney's point). The patient may also report anorexia, nausea, one or two episodes of vomiting, and a low-grade fever. Later signs and symptoms include malaise, constipation and, rarely, diarrhea.

Inspection typically shows a patient who walks bent over to reduce right lower quadrant pain. When sleeping or lying in a supine position, he may keep his right knee bent up to decrease pain.

Auscultation usually reveals normal bowel sounds. Initially, palpation and percussion disclose no localized abdominal findings except diffuse tenderness in the midepigastriac area and around the umbilicus. Later, palpation may disclose tenderness in the right lower abdominal quadrant that worsens when the patient is asked to cough or on gentle percussion. Rebound tenderness and spasm of the abdominal muscles are also usually present. There may be pain in the right lower quadrant resulting from palpating the lower left quadrant (Rovsing's sign).

If the appendix is positioned retroceally or in the pelvis, abdominal tenderness may be completely absent; instead, rectal or pelvic examination reveals tenderness in the flank.

Keep in mind that abdominal rigidity and tenderness worsen as the condition progresses. Sudden cessation of abdominal pain signals perforation or infarction.

Diagnostic tests

Moderately elevated white blood cell count, with increased numbers of immature cells, supports the diagnosis.

Imaging studies aren't necessary in patients with a typical presentation of appendicitis.

ASSESSMENT TIP Because other disorders can mimic appendicitis in presentation, diagnosis must rule out illnesses with similar symptoms: bladder infection, gastroenteritis, ileitis, colitis, acute salpingitis, tubo-ovarian abscess, diverticulitis, gastritis, ovarian cyst, pancreatitis, renal colic, and uterine disease.

Treatment

Appendectomy is the only effective treatment. If peritonitis develops, treatment involves GI intubation, parenteral replacement of fluids and electrolytes, and administration of antibiotics.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered tissue perfusion (GI) u Impaired skin integrity u Knowledge deficit u Pain u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will avoid or minimize complications.

- u The patient's skin integrity will remain intact.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain adequate caloric intake.
- u The patient's fluid volume will remain within normal parameters.

Nursing interventions

- u Make sure the patient with suspected or known appendicitis receives nothing by mouth until surgery is performed.
- u Administer I.V. fluids to prevent dehydration. Never administer cathartics or enemas because they may rupture the appendix.
- u Don't administer analgesics until the diagnosis is confirmed because they mask symptoms. When the diagnosis is confirmed, analgesics may be given.
- u Place the patient in Fowler's position to reduce pain. (This is also helpful postoperatively.)

ALERT Never apply heat to the right lower abdomen; this can cause the appendix to rupture.

- u When the diagnosis is confirmed, provide preoperative care, including giving prescribed medications.

After appendectomy:

- u Monitor vital signs and intake and output.
- u Give analgesics as ordered.
- u Administer I.V. fluids as necessary to maintain fluid and electrolyte balance.
- u Document bowel sounds, passing of flatus, or bowel movements—all signs of peristalsis. These signs in a patient whose nausea and boardlike abdominal rigidity have subsided indicate readiness to resume oral fluids.
- u Watch closely for possible surgical complications, such as an abscess or wound dehiscence.
- u If peritonitis occurs, nasogastric drainage may be necessary to decompress the stomach and reduce nausea and vomiting. If so, record drainage. Provide good mouth and nose care.

Patient teaching

- u Explain what happens in appendicitis.
- u Help the patient understand the required surgery and its possible complications. If time allows, provide preoperative teaching.
- u Teach the patient how to care for the incision. If he has a surgical dressing, demonstrate how to change it properly. Instruct him to observe the incision daily and to report any swelling, redness, bleeding, drainage, or warmth at the site.
- u Review the proper use of all prescribed medications. Be sure the patient knows how to administer each drug and understands the desired effects and possible adverse reactions.
- u Discuss postoperative activity limitations with the patient. Tell him to follow the doctor's orders for driving, returning to work, and resuming physical activity.

CELIAC DISEASE

Celiac disease (also called idiopathic steatorrhea, nontropical sprue, gluten enteropathy, celiac sprue) is relatively uncommon. It's characterized by poor food absorption and intolerance of gluten, a protein in wheat and wheat products. With treatment (eliminating gluten from the patient's diet), the prognosis is good, but residual bowel changes may persist in adults.

Celiac disease affects twice as many females as males and is more common among relatives, especially siblings. The incidence in the general population is about 1 in 3,000. This disease primarily affects whites of northwestern European ancestry; it's rare among Blacks, Jews, Asians, and people of Mediterranean ancestry. It may occur in adults but usually affects children, most commonly between ages 9 and 18 months.

Causes

Several theories exist to explain the causes of celiac disease, but a genetic predisposition is undoubtedly important. Celiac disease may also result from an intramucosal enzyme defect that produces an inability to digest gluten. Resulting tissue toxicity produces rapid cell turnover, increases epithelial lymphocytes, and damages surface epithelium of the small bowel. Another theory holds that the disease involves an abnormal immune response. According to research findings, the presence of human leukocyte antigen B8 may be the primary determinant of celiac disease.

The primary dysfunction, malabsorption of gluten, results from atrophy of the villi in the small bowel and a decrease in the activity and amount of enzymes in the surface epithelium. Atrophy of intestinal villi leads to malabsorption of fat, carbohydrates, and protein. It also causes loss of calories, fat-soluble vitamins, and essential minerals and electrolytes.

Complications

Celiac disease can be fatal if not detected and properly treated because patients become malnourished and debilitated, making them vulnerable to infection and secondary adrenal insufficiency.

In severe cases, complications include anemia from malabsorption of iron, vitamin B₆, or vitamin B₁₂, which, if untreated, can lead to syncope, heart failure, and angina.

Bleeding disorders can result from vitamin K deficiency. Rarely, ulceration of the jejunum or ileum occurs. Patients also have a higher-than-usual incidence of intestinal lymphoma.

Assessment findings

Both the patient and family history should be investigated. If the patient is a child, the history may reveal that symptoms emerged during the first year of life, shortly after gluten-containing cereal was introduced into the diet. The family history may disclose that siblings, parents, or other relatives have had obscure digestive complaints such as intermittent diarrhea or, in children, failure to thrive and gain weight.

Symptoms are varied but typically include recurrent attacks of diarrhea, steatorrhea, abdominal distention from flatulence, stomach cramps, weakness, anorexia and, occasionally, increased appetite without weight gain. The patient or her parents may report bulky, foul-smelling stools. The patient may experience mood changes and irritability. Women may report amenorrhea.

On inspection, the patient may have a distended abdomen or appear malnourished. In children, you may notice a potbelly and obvious muscle wasting. Skin inspection may show dryness or rashes, such as eczema, psoriasis, dermatitis herpetiformis, and acne rosacea. Other findings on inspection include generalized fine, sparse, prematurely gray hair; brittle nails; and localized hyperpigmentation on the face, lips, or mucosa.

Sometimes the patient denies diarrhea or steatorrhea but complains of bone pain, especially in the lower back, rib cage, and pelvis. This symptom may indicate compression fractures in adults or rickets in children caused by calcium loss and vitamin D deficiency. The patient may also have a history of seizures or paresthesia.

Diagnostic tests

Because celiac disease produces clinical effects in many body systems, a variety of tests may be ordered.

Small-bowel biopsy showing histologic changes confirms the diagnosis. Histologic changes reveal a mosaic pattern of alternating flat and bumpy areas on the bowel surface (reflecting an almost total absence of villi) and an irregular, blunt, and disorganized network of blood vessels. These changes appear most prominently in the jejunum.

Upper GI series, followed by a small-bowel series, demonstrates protracted barium passage. The barium shows up in a segmented, coarse, scattered, and clumped pattern; the jejunum shows generalized dilation.

Glucose tolerance test shows poor glucose absorption.

Xylose tolerance test discloses low urine and blood levels of xylose (less than 3 g over 5 hours); however, renal disease may cause a false-positive result.

Serum carotene levels are low, indicating malabsorption. (Because the body neither stores nor manufactures carotene, the patient must ingest carotene for several days before the test.)

Stool specimen analysis, after a 72-hour stool collection, shows excess fat.

Hemoglobin (Hb) level and hematocrit (HCT), as well as white blood cell and platelet counts, may be decreased.

Albumin, sodium, potassium, cholesterol, and phospholipid levels are reduced; prothrombin time is commonly decreased.

Treatment

Elimination of gluten from the patient's diet is the required—and lifelong—treatment. About 80% of patients improve after this exclusion, but full return to normal absorption and bowel histology may not occur for months or may never occur. The gluten-free diet is high in protein but low in carbohydrates and fat. Depending on individual tolerance, the diet initially consists of proteins and is gradually expanded to include other nutrients.

Supportive treatment may include supplemental iron, vitamin B₁₂, and folic acid; reversal of electrolyte imbalance (by I.V. infusion if necessary); I.V. fluid replacement for dehydration; corticosteroids (prednisone, hydrocortisone) to treat accompanying adrenal insufficiency; vitamin K for hypoprothrombinemia; and, when necessary, parenteral nutrition.

Nursing diagnoses

⌞ Altered nutrition: Less than body requirements ⌞ Altered tissue perfusion (GI) ⌞ Diarrhea ⌞ Fluid volume deficit ⌞ Ineffective individual coping ⌞ Knowledge deficit ⌞ Pain

Key outcomes

- ⌞ The patient will express feelings of comfort.
- ⌞ The patient will maintain adequate caloric intake.
- ⌞ The patient will develop a normal bowel pattern.
- ⌞ The patient and family members will express an understanding of the disorder and treatment regimen.
- ⌞ The patient's fluid volume will remain within normal parameters.

Nursing interventions

- ⌞ Observe the patient's nutritional status and progress by daily calorie counts and weight checks. Evaluate his tolerance to new foods. In the early stages, offer small, frequent meals to counteract anorexia.
- ⌞ Assess the patient's fluid status: Record intake, urine output, and number of stools (may exceed 10 per day). Watch for signs of dehydration, such as dry skin and mucous membranes and poor skin turgor.
- ⌞ Check serum electrolyte levels. Watch for signs of hypokalemia (weakness, lethargy, rapid pulse, nausea, and diarrhea) and low calcium levels (impaired blood clotting, muscle twitching, and tetany).
- ⌞ Monitor prothrombin time and Hb level and HCT. Protect the patient from bleeding and bruising. Administer vitamin K, iron, folic acid, and vitamin B₁₂ as ordered. Early in the treatments, give hematinic supplements as ordered. Use the Z-track method to give iron I.M. If the patient can tolerate oral iron, give it between meals, when absorption is best. Dilute oral iron preparations, and give them through a straw to prevent staining the teeth.
- ⌞ Insert a nasogastric tube to relieve abdominal distention, if ordered, and attach the tube to intermittent suction. Monitor drainage, noting color, consistency, and amount.
- ⌞ Protect the patient with osteomalacia from injury by keeping the side rails up and assisting with ambulation as necessary.
- ⌞ Give steroids as ordered. Monitor the patient for desired effects and assess regularly for cushingoid adverse reactions, such as hirsutism and muscle weakness.
- ⌞ Provide a gluten-free diet for the patient.
- ⌞ Assess the patient's acceptance and understanding of the disease, and encourage regular reevaluation.

Patient teaching

- ⌞ Explain celiac disease to the patient or, if the patient is a young child, to the parents. Review the signs and symptoms as well as required diagnostic tests and treatments.
- ⌞ Emphasize the importance of a gluten-free diet. Reassure the family that the patient usually begins to improve dramatically within a few days of beginning the diet. If the patient is a child, tell the parents that her weight should return to within the normal range for her age within 6 months to 1 year after starting the diet.
- ⌞ Reinforce specific dietary guidelines. Advise eliminating of gluten-containing foods, such as wheat, barley, rye, and oats, as well as foods made from these grains, such as breads and baked goods. Suggest substituting of corn, rice, or soybean flour. Refer the patient to a dietitian, who can develop a meal plan and suggest ways to obtain gluten-free food. Point out that health food stores are usually a good source for these foods.
- ⌞ Urge the patient or her parents to carefully read food labels to avoid products with hidden gluten content. For example, grains are typically used as fillers. In particular, caution them to avoid foods containing “vegetable protein.”

CROHN'S DISEASE

Crohn's disease, a type of inflammatory bowel disease, may affect any part of the GI tract but usually involves the terminal ileum. The disease extends through all layers of the intestinal wall and may involve regional lymph nodes and the mesentery.

Crohn's disease occurs equally among both sexes and is more common in Jewish individuals. Onset of the disease is usually before age 30.

Crohn's disease has a varied nomenclature. When it affects only the small bowel, it's also known as regional enteritis. If the disorder also involves the colon or only affects the colon, it's known as Crohn's disease of the colon. (Crohn's disease of the colon also has been termed granulomatous colitis, an inaccurate term because not all patients develop granulomas.)

Causes and pathophysiology

Although researchers are still probing the etiology of Crohn's disease, possible causes include lymphatic obstruction, infection, allergies, and other immune disorders, such as altered immunoglobulin A production and increased suppressor T-cell activity. Genetic factors may also play a role: Crohn's disease sometimes occurs in monozygotic twins, and 10% to 20% of patients with the disease have one or more affected relatives. However, no simple pattern of inheritance has been identified.

Inflammation spreads slowly and progressively, beginning with lymphadenia and obstructive lymphedema in the submucosa, where Peyer's patches develop in the intestinal mucosa. Lymphatic obstruction causes edema, with mucosal ulceration and development of fissures, abscesses and, sometimes, granulomas. The mucosa may acquire a characteristic “cobblestone” look.

As the disease progresses, fibrosis occurs, thickening the bowel wall and narrowing the lumen. Serositis (serosal inflammation) also develops, causing inflamed bowel loops to adhere to other diseased or normal loops. This may result in bowel shortening. Because inflammation usually occurs segmentally, the bowel may become a patchwork of healthy and diseased segments. Eventually, the diseased parts of the bowel become thicker, narrower, and shorter.

Complications

Anal fistula, resulting from severe diarrhea and enzymatic corrosion of the perineal area, is the most common complication. A perineal abscess may also develop during the active inflammatory state. Fistulas may develop to the bladder or vagina or even to the skin in an old scar area. Other complications include intestinal obstruction, nutritional deficiencies (caused by malabsorption and maldigestion) and, rarely, peritonitis.

Assessment findings

Generally, the patient reports gradual onset of signs and symptoms, marked by periods of remission and exacerbation. Because signs and symptoms may be intermittent, the patient may postpone seeking medical attention for some time.

The patient typically complains of fatigue, fever, abdominal pain, diarrhea (usually without obvious bleeding) and, occasionally, weight loss. Questioning may reveal that diarrhea worsens after emotional upset or ingestion of poorly tolerated foods, such as milk, fatty foods, and spices.

The patient with regional enteritis, often a young adult, may report similar signs and symptoms as well as anorexia, nausea, and vomiting. Typically, this patient describes his abdominal pain as steady, colicky, or cramping. It usually occurs in the right lower abdominal quadrant.

On inspection, the patient's stool may appear soft or semiliquid, without gross blood (a distinguishing clinical feature from the bloody diarrhea seen in ulcerative colitis). Palpation may reveal tenderness in the right lower abdominal quadrant; it may also disclose an abdominal mass, indicating adherent loops of bowel.

Diagnostic tests

Laboratory analysis to detect occult blood in stools is usually positive.

Small-bowel X-rays may show irregular mucosa, ulceration, and stiffening.

Barium enema that reveals the string sign (segments of stricture separated by normal bowel) supports the diagnosis. This test may also show fissures and narrowing of the lumen.

Sigmoidoscopy and colonoscopy may show patchy areas of inflammation, thus helping to rule out ulcerative colitis. These studies may also reveal the characteristic coarse irregularity (cobblestone appearance) of the mucosal surface. When the colon is involved, discrete ulcerations may be evident.

Biopsy, performed during sigmoidoscopy or colonoscopy, reveals granulomas in up to half of all specimens.

Laboratory test findings indicate increased white blood cell count and erythrocyte sedimentation rate. Other findings include hypokalemia, hypocalcemia, hypomagnesemia, and decreased hemoglobin (Hb) level.

Treatment

Effective management of Crohn's disease requires drug therapy and significant lifestyle changes, including physical rest and dietary restrictions. In debilitated patients, treatment includes total parenteral nutrition to maintain nutrition while resting the bowel.

Drug therapy, designed to combat inflammation and relieve symptoms, may include:

- u corticosteroids, such as prednisone, to reduce signs and symptoms of diarrhea, pain, and bleeding by decreasing inflammation
- u immunosuppressant agents such as azathioprine to suppress the body's response to antigens
- u sulfasalazine or mesalamine (alone or together) to reduce inflammation
- u metronidazole to treat perianal complications
- u antidiarrheals, such as diphenoxylate and atropine, to combat diarrhea (contraindicated in patients with significant bowel obstruction)
- u narcotics to control pain and diarrhea.

Lifestyle changes, such as stress reduction and reduced physical activity, help to rest the bowel, giving it time to heal. Dietary changes that decrease bowel activity while still providing adequate calories and nutrition are also essential. Dietary modifications include elimination of high-fiber foods (no fruits or vegetables) and foods that irritate the mucosa (such as dairy products, and spicy and fatty foods). Foods that stimulate excessive intestinal activity (such as carbonated or caffeine-containing beverages) should also be avoided. Vitamins may be prescribed to compensate for the bowel's inability to absorb nutrients.

If complications develop, surgery may be required. Indications for surgery include bowel perforation, massive hemorrhage, fistulas, or acute intestinal obstruction. Colectomy with ileostomy is often necessary in patients with extensive disease of the large intestine and rectum.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (GI)
- u Body image disturbance
- u Diarrhea
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for fluid volume deficit
- u Risk for impaired skin integrity

Key outcomes

- u The patient will maintain adequate caloric intake.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's bowel movements will return to a normal pattern and consistency.
- u The patient will avoid complications.
- u The patient will express feelings of comfort.
- u The patient will express an understanding of the disease process and treatment regimen.
- u The patient will exhibit adequate coping mechanisms and seek appropriate sources of support.

Nursing interventions

- u Provide emotional support to the patient and his family. Listen to the patient's concerns, and help him cope with body image disturbance.
- u Record fluid intake and output (including the number of stools), and weigh the patient daily. Watch for dehydration, and maintain fluid and electrolyte balance. Be alert for signs of intestinal bleeding (bloody stools); check stools for occult blood.
- u Schedule patient care to include rest periods throughout the day.
- u Provide the patient with a diet that is high in protein, calories, and vitamins. Provide small, frequent meals throughout the day rather than three large meals.
- u Carefully monitor the patient on total parenteral nutrition, and provide meticulous site care.
- u If the patient is receiving steroids, watch for adverse reactions such as GI bleeding. Remember that steroids can mask signs of infection.
- u Monitor Hb level and hematocrit. Give iron supplements and blood transfusions as ordered.
- u Administer medications as ordered. Monitor the patient to ensure that medications are producing desired effects without adverse reactions.
- u Provide good patient hygiene and meticulous oral care if the patient is restricted to nothing by mouth. After each bowel movement, provide careful skin care. Always keep a clean, covered bedpan within the patient's reach. Ventilate the room to eliminate odors.
- u Monitor the patient for complications. Watch for fever and pain on urination, which may signal bladder fistula. Abdominal pain, fever, and a hard, distended abdomen may indicate intestinal obstruction.
- u If the patient is scheduled for surgery, provide appropriate preoperative care. Before ileostomy, arrange for a visit by an enterostomal therapist.
- u After surgery, frequently check the patient's I.V. line and nasogastric tube for proper functioning. Monitor vital signs and fluid intake and output. Maintain acid-base balance. Watch for wound infection, and provide meticulous stoma care.

Patient teaching

- u Teach the patient about Crohn's disease, its symptoms, and its complications. Explain ordered diagnostic tests; make sure he's aware of all pretest dietary restrictions or other pretest guidelines. Answer his questions.
- u Emphasize the importance of adequate rest. Explain that it helps to reduce intestinal motility and promote healing.
- u Encourage the patient to identify and reduce sources of stress in his life. If stress clearly aggravates his disease, teach him stress-management techniques or refer him for counseling.
- u Make sure the patient understands prescribed dietary changes. Emphasize the need for a restricted diet, which may be trying, especially for a young patient. Refer him to a dietitian for further instruction if necessary.
- u Give the patient a list of foods to avoid, including milk products, spicy or fried high-residue foods, raw vegetables and fruits, and whole-grain cereals. Advise him to avoid carbonated, caffeine-containing, or alcoholic beverages (because they increase intestinal activity) and extremely hot or cold foods or fluids (because they increase flatus). Remind him to take supplemental vitamins, if prescribed.
- u Teach the patient about prescribed medications, including their desired effects and possible adverse reactions. Urge him to call his doctor if adverse reactions occur.
- u If the patient smokes, encourage him to quit, and assist him in joining a smoking-cessation program. Point out that smoking can aggravate his disease by altering bowel motility.
- u Instruct the patient to notify his doctor if he experiences signs and symptoms of complications, such as fever, fatigue, weakness, a rapid heart rate, abdominal cramping or pain, vomiting, and acute diarrhea.
- u If the patient is scheduled for surgery, provide preoperative teaching. Reinforce the doctor's explanation of the surgery, and mention possible complications.
- u Postoperatively, teach stomal care to the patient and his family. Realize that ileostomy changes the patient's body image, so provide reassurance and emotional support. Refer the patient and family members to the local chapter of the National Foundation for Ileitis and Colitis for further support. If the patient has an ostomy, put him in touch with the United Ostomy Association.

DIVERTICULAR DISEASE

Diverticular disease is a disorder in which bulging pouches (diverticula) in the GI wall push the mucosal lining through the surrounding muscle. The most common site for diverticula is in the sigmoid colon, but they may develop anywhere, from the proximal end of the pharynx to the anus. (See [Esophageal diverticula](#).) Other typical sites are the duodenum, near the pancreatic border or the ampulla of Vater, and the jejunum. Diverticular disease of the stomach is rare and may be a precursor of peptic or neoplastic disease. Diverticular disease of the ileum (Meckel's diverticulum) is the most common congenital anomaly of the GI tract. (See [Meckel's diverticulum](#).)

Diverticular disease has two clinical forms. In diverticulosis, diverticula are present but don't cause symptoms. In diverticulitis, a far more serious disorder, diverticula become inflamed and can cause complications, such as obstruction, infection, and hemorrhage.

Diverticular disease is most common in adults age 45 and older. It affects 30% of adults over age 60.

Causes and pathophysiology

A diverticulum develops when pressure in the intestinal lumen is exerted on weak areas, such as points where blood vessels enter the intestine, causing a break in the muscular continuity of the GI wall. The pressure in the lumen forces the intestine out, creating a pouch (diverticulum).

Diverticulitis occurs when retained undigested food mixed with bacteria accumulates in the diverticulum, forming a hard mass (fecalith). This substance cuts off the blood supply to the diverticulum's thin walls, increasing its susceptibility to attack by colonic bacteria. Inflammation follows bacterial infection.

Diet, especially highly refined foods, may be a contributing factor. Lack of fiber reduces fecal residue, narrows the bowel lumen, and leads to higher intra-abdominal pressure during defecation.

CULTURAL TIP Diverticulosis is less common in nations where the diet contains abundant natural bulk and fiber.

Complications

Most complications of diverticular disease are caused by diverticulitis. In severe diverticulitis, the diverticula can rupture, producing abscesses or peritonitis. Diverticular rupture occurs in up to 20% of patients.

Diverticulitis may also lead to intestinal obstruction, resulting from edema or spasm related to inflammation or, in chronic diverticulitis, from fibrosis and adhesions that narrow and seal the bowel's lumen.

Other complications include rectal hemorrhage or portal pyemia (generalized septicemia with abscess formation) from artery or vein erosion. Occasionally, the inflamed colon segment may produce a fistula by adhering to the bladder or other organs.

In elderly patients, a rare complication of diverticulosis (without diverticulitis) is hemorrhage from colonic diverticula, usually in the ascending colon. Such hemorrhage is usually mild to moderate and easily controlled. Occasionally, bleeding is life-threatening.

Assessment findings

Usually, the patient with diverticulosis is symptom-free. Occasionally, the history reveals intermittent pain in the left lower abdominal quadrant, which may be relieved by defecation or the passage of flatus. The patient may report alternating bouts of constipation and diarrhea. The assessment usually reveals no clinical findings. Rarely, palpation discloses abdominal tenderness in the left lower quadrant.

The patient with diverticulitis may have a history of diverticulosis, diagnosed incidentally on radiography of the GI tract. Investigation of his dietary history commonly reveals low fiber consumption. He may report recent consumption of foods containing seeds or kernels, such as tomatoes, nuts, popcorn, and strawberries, or indigestible roughage, such as celery and corn. Seeds and undigested roughage can block the neck of a diverticulum, causing diverticulitis.

The patient with diverticulitis typically complains of moderate pain in the left lower abdominal quadrant, which he may describe as dull or steady. Straining, lifting, or coughing may aggravate his pain. Other signs and symptoms include mild nausea, flatus, and intermittent bouts of constipation, sometimes accompanied by rectal bleeding. Some patients report diarrhea.

On inspection, the patient with diverticulitis may appear distressed. Palpation may confirm his reports of left lower quadrant abdominal pain. He may have a low-grade fever.

In acute diverticulitis, the patient may report muscle spasms and show signs of peritoneal irritation. Palpation may reveal guarding and rebound tenderness. Rectal examination may disclose a tender mass if the inflamed area is close to the rectum.

Diagnostic tests

Various tests may be used to establish the diagnosis, determine complications, and rule out other disorders such as cancer.

Results of barium studies confirm the diagnosis. An upper GI series confirms or rules out diverticulosis of the esophagus and upper bowel; a barium enema confirms or rules out diverticulosis of the lower bowel. Barium-filled diverticula can be single, multiple, or clustered like grapes and may have a wide or narrow mouth. Barium outlines, but doesn't fill, diverticula blocked by impacted stools. In patients with acute diverticulitis, a barium enema could rupture the bowel, so this procedure isn't done before the acute phase resolves.

Esophageal diverticula

Esophageal diverticula are circumscribed sacs or pouches that can involve one or more layers of the mucosa. They generally occur later in life but can also affect infants and children. The disorder is three times more common in men than in women.

Diverticula result from either muscular abnormalities or inflammatory processes adjacent to the esophagus. Signs and symptoms can include weight loss, dysphagia, heartburn, gurgling sounds when swallowing, nocturnal coughing, bad taste in the mouth, halitosis and, rarely, bleeding. Regurgitation of saliva or food particles can lead to aspiration, causing pulmonary complications, such as bronchitis, bronchiectasis, and lung abscess. The disorder may also lead to esophageal perforation.

Barium swallow usually confirms the diagnosis by showing a characteristic outpouching. Esophagoscopy helps rule out another lesion as the cause.

Depending on the degree of involvement, treatment can range from bland diets and antacids to surgical removal. An esophagomyotomy may be needed to prevent recurrence. Distal myotomy is usually performed if the diverticulum is associated with esophageal motor abnormalities.

Radiography may reveal colonic spasm if irritable bowel syndrome accompanies diverticular disease.

Biopsy may be used to rule out cancer. Colonoscopic biopsy isn't recommended during acute diverticular disease because of the strenuous bowel preparation it requires.

Blood studies may show leukocytosis and an elevated erythrocyte sedimentation rate in diverticulitis, especially if the diverticula are infected.

Stool test results show occult blood in 20% of patients with diverticulitis.

Treatment

Patient management depends on the type of diverticular disease and the severity of symptoms. Asymptomatic diverticulosis generally requires no treatment. Intestinal diverticulosis that causes pain, mild GI distress, constipation, or difficult defecation may respond to a liquid or low-residue diet, stool softeners, and occasional doses of mineral oil. These measures relieve symptoms, minimize irritation, and lessen the risk of progression to diverticulitis. After pain subsides, patients also benefit from increased water consumption (eight glasses per day), a high-residue diet, and bulk medication such as psyllium.

ADVANCED PRACTICE

Meckel's diverticulum

Meckel's diverticulum is a congenital abnormality that occurs when a blind tube like the appendix opens into the distal ileum near the ileocecal valve. This disorder results when the intra-abdominal portion of the yolk sac fails to close completely during fetal development. It occurs in about 2% of the population, mostly in males.

Complications

Uncomplicated Meckel's diverticulum produces no symptoms, but complications cause melena and abdominal pain, especially around the umbilicus. The lining of the diverticulum may be either gastric mucosa or pancreatic tissue. This disorder can lead to peptic ulceration, perforation, and peritonitis and may resemble acute appendicitis.

Meckel's diverticulum can also cause bowel obstruction when a fibrous band that connects the diverticulum to the abdominal wall, the mesentery, or other structures snares a loop of the intestine. This can cause intussusception into the diverticulum or volvulus near the diverticular attachment to the back of the umbilicus or another intra-abdominal structure.

Meckel's diverticulum should be considered in patients with GI obstruction or hemorrhage, especially when routine GI X-rays are negative.

Treatment

Treatment involves surgical resection of the inflamed bowel and antibiotic therapy, if infection occurs.

Treatment for patients with mild diverticulitis without signs of perforation is intended to prevent constipation and combat infection. Therapy may include bed rest, a liquid diet, stool softeners, a broad-spectrum antibiotic, meperidine to control pain and relax smooth muscle, and an antispasmodic, such as propantheline, to control muscle spasms.

For patients with more severe diverticulitis, treatment consists of the above measures and I.V. therapy. A nasogastric (NG) tube to relieve intra-abdominal pressure is usually required, and the patient is allowed nothing by mouth.

Patients who hemorrhage need blood replacement and careful monitoring of fluid and electrolyte balance. Such bleeding usually stops spontaneously. If it continues,

angiography for catheter placement and infusion of vasopressin into the bleeding vessel is effective. Rarely, surgery may be required.

A colon resection to remove a diseased segment of intestine may be required to treat patients with diverticulitis that is unresponsive to medical treatment or causes severe recurrent attacks in the same area.

Nursing diagnoses

u Altered tissue perfusion (GI) u Anxiety u Constipation u Diarrhea u Fluid volume deficit u Knowledge deficit u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's bowel movements will return to normal.
- u The patient's vital signs will remain stable.
- u The patient will express an understanding of the disease process and treatment regimen.

Nursing interventions

- u Keep in mind that diverticulitis, which produces more serious symptoms and complications, usually requires more interventions than diverticulosis.
- u If the patient is anxious, provide psychological support. Listen to his concerns and offer reassurance when appropriate.
- u Administer medications (antibiotics, stool softeners, antispasmodics) as ordered. Monitor the patient for the desired effects, and observe for possible adverse reactions. If pain is severe, administer analgesics such as meperidine as ordered.
- u Inspect all stools carefully for color and consistency. Note the frequency of bowel movements.
- u Maintain bed rest for the patient with acute diverticulitis. Don't permit him to perform any actions that increase intra-abdominal pressure, such as lifting, straining, bending, and coughing.
- u Maintain the diet as ordered. The patient experiencing an acute attack is usually maintained on a liquid diet. If the patient's symptoms are severe, or if he experiences nausea and vomiting or abdominal distention, insert an NG tube and attach it to intermittent suction as ordered. Make sure this patient receives nothing by mouth, and administer ordered I.V. fluids. As symptoms subside, gradually advance the diet. In addition, foods that could lodge in the diverticulum (such as seeds, nuts, and fruit peels) should be avoided.
- u Monitor the patient for signs and symptoms of complications. Watch for temperature elevation, increasing abdominal pain, blood in stools, and leukocytosis.

ALERT If diverticular bleeding occurs, the patient may require angiography and catheter placement for vasopressin infusion. If so, inspect the insertion site frequently for bleeding, check pedal pulses often, and keep the patient from flexing his legs at the groin. Also watch for vasopressin-induced fluid retention (apprehension, abdominal cramps, seizures, oliguria, or anuria) and severe hyponatremia (hypotension; rapid, thready pulse; cold, clammy skin; and cyanosis).

- u If surgery is scheduled, provide routine preoperative care. Also perform any special required procedures, such as administering antibiotics and providing a specific diet for several days preoperatively.

After colon resection:

- u Watch for signs of infection. Provide meticulous wound care because perforation may have already infected the area. Check drainage sites frequently for signs of infection (pus on dressing, foul odor) or fecal drainage. Change dressings as necessary.
- u Encourage coughing and deep breathing to prevent atelectasis.
- u Watch for signs of postoperative bleeding, such as hypotension and decreased hemoglobin and hematocrit level.
- u Record intake and output accurately. Administer I.V. fluids and medications as ordered.
- u Keep the NG tube patent. If it dislodges, notify the surgeon at once; don't attempt to reposition it. After the NG tube is removed, advance the patient's diet as ordered, and note how he tolerates diet changes.
- u If the patient has a colostomy, provide care and give the patient an opportunity to express his feelings.

Patient teaching

- u In uncomplicated diverticulosis, patient teaching focuses on bowel and dietary habits.
- u Explain what diverticula are and how they form. Teach the patient about necessary diagnostic tests and prescribed treatments.
- u Be sure the patient understands the desired actions and possible adverse effects of his prescribed medications.
- u Review recommended dietary changes. Encourage the patient to drink 2 to 3 L of fluid per day. Emphasize the importance of dietary roughage and the harmful effects of constipation and straining during a bowel movement. Advise increasing the intake of foods high in undigestible fiber, such as fresh fruits and vegetables, whole grain breads, and wheat or bran cereals. Warn that a high-fiber diet may temporarily cause flatulence.
- u Advise the patient to relieve constipation with stool softeners or bulk-forming cathartics.

ALERT Instruct the patient to take bulk-forming cathartics with plenty of water; if swallowed dry, they may absorb enough moisture in the mouth and throat to swell and obstruct the esophagus or trachea.

- u Tell the patient to notify the doctor if he has a temperature over 101° F (38.3° C); abdominal pain that is severe or that lasts for more than 3 days; or blood in his stools. Emphasize that these symptoms indicate complications.
- u Provide preoperative teaching to the patient needing surgery. Reinforce the doctor's explanation of the surgery, and discuss possible complications.
- u Postoperatively, teach the patient to care for his colostomy as needed. Arrange for a visit by an enterostomal therapist.

GASTRITIS

Gastritis is an inflammation of the gastric mucosa; it may be acute or chronic. Acute gastritis, the most common stomach disorder, produces mucosal reddening, edema, and superficial surface erosion. Chronic gastritis is common among elderly people and people with pernicious anemia. It's often present as chronic atrophic gastritis, in which all stomach mucosal layers are inflamed, with a reduced number of chief and parietal cells. Acute or chronic gastritis can occur at any age.

Causes

Acute gastritis has many causes, including:

- u chronic ingestion of irritating foods, such as hot peppers (or an allergic reaction to them) or alcohol
- u such drugs as aspirin and other nonsteroidal anti-inflammatory agents (in large doses), cytotoxic agents, caffeine, corticosteroids, antimetabolites, phenylbutazone, and indomethacin
- u ingested poisons, especially dichlorodiphenyltrichloroethane (DDT), ammonia, mercury, carbon tetrachloride, or corrosive substances
- u endotoxins released from infecting bacteria, such as staphylococci, *Escherichia col*, and salmonella.

Acute gastritis also may develop in acute illnesses, especially when the patient has major trauma, burns, severe infection, or hepatic, renal, or respiratory failure.

Chronic gastritis may be associated with peptic ulcer disease or gastrostomy because these conditions cause chronic reflux of pancreatic secretions, bile, and bile acids from the duodenum into the stomach. Recurring exposure to irritating substances, such as drugs, alcohol, cigarette smoke, and environmental agents, may also lead to chronic gastritis. Chronic gastritis may occur with pernicious anemia, renal disease, or diabetes mellitus.

Bacterial infection with *Helicobacter pylori* can cause acute or chronic gastritis.

Complications

Gastritis usually resolves when the causative agent is removed. Persistent or untreated disease can lead to hemorrhage, shock, obstruction, perforation, peritonitis, and gastric cancer.

Assessment findings

The patient history may reveal one or more causative agents. After exposure to the offending substance, the patient with acute gastritis typically reports rapid onset of such symptoms as epigastric discomfort, indigestion, cramping, anorexia, nausea, hematemesis, and vomiting. The patient's symptoms may last a few hours to a few days.

The patient with chronic gastritis may describe similar symptoms, experience only mild epigastric discomfort, or have only vague complaints. For example, the patient may report intolerance of spicy or fatty foods or have mild epigastric pain that is relieved by eating. Patients with chronic atrophic gastritis are often asymptomatic.

On inspection, the patient may appear normal or show such signs of distress as fatigue, grimacing, and restlessness, depending on the severity of symptoms. If gastric bleeding has occurred, he may appear pale and his vital signs may reveal tachycardia and hypotension. Inspection and palpation may disclose abdominal distention, tenderness, and guarding. Auscultation may reveal increased bowel sounds.

Diagnostic tests

Upper GI endoscopy (commonly with biopsy) confirms gastritis when it's performed within 24 hours of bleeding. Biopsy reveals the inflammatory process. If the procedure fails to stimulate acid production, it confirms achlorhydria. In patients with pernicious anemia, gastroscopy fails to reveal the intrinsic factor. This procedure is contraindicated after ingestion of a corrosive agent.

Laboratory analyses can be used to detect occult blood in vomitus or stools (or both) if the patient has gastric bleeding.

Hemoglobin level and hematocrit are decreased if the patient has developed anemia from bleeding.

Treatment

An immediate therapeutic priority is to eliminate the cause of gastritis. For example, bacterial gastritis is treated with antibiotics and ingested poisons are neutralized with the appropriate antidote. When the associated disease is treated or the offending agent is eradicated or neutralized, the gastric mucosa usually begins to heal.

Treatment for a patient with acute gastritis is symptomatic and supportive. Healing usually occurs within a few hours to a few days after the cause is eliminated. Histamine antagonists, such as cimetidine, ranitidine, or famotidine, may be ordered to block gastric secretion. Antacids, such as aluminum hydroxide and magnesium hydroxide, may be used as buffering agents. Some patients also require analgesics.

When gastritis causes massive bleeding, treatment includes blood replacement; iced saline lavage, possibly with norepinephrine; angiography with vasopressin infused in normal saline solution; and, sometimes, surgery.

Surgery is a last resort, performed only if more conservative treatments fail. Vagotomy and pyloroplasty have been used with limited success. Rarely, partial or total gastrectomy may be required.

Because patients with chronic gastritis may be asymptomatic or have only vague complaints, no specific treatment, except for avoiding aspirin and spicy foods, may be necessary. If symptoms develop or persist, antacids may be taken. If pernicious anemia is the underlying cause, vitamin B₁₂ is administered parenterally.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Ineffective individual coping u Knowledge deficit u Pain u Risk for fluid volume deficit

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will maintain normal fluid volume.
- u The patient will maintain weight.
- u The patient will express concerns about his current condition.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Provide physical and emotional support to the patient to help him manage his symptoms.
- u If the patient is vomiting, give antiemetics and replace I.V. fluids as ordered. Monitor fluid intake and output and electrolyte levels.
- u Monitor the patient for returning symptoms as food is reintroduced after he has received nothing by mouth. At this time, provide a bland diet that takes into account his food preferences.
- u Offer small, frequent meals to reduce the amount of irritating gastric secretions. Help the patient identify specific foods that cause gastric upset and eliminate them from his diet.
- u Administer prescribed medications as ordered, and monitor the patient's response.
- u If pain or nausea interferes with the patient's appetite, administer pain medications or antiemetics about 1 hour before meals.
- u If surgery is necessary, prepare the patient preoperatively and provide appropriate postoperative care.

Patient teaching

- u Teach the patient about gastritis. Explain the relationship between his symptoms and the causative agents so that he'll understand the need to modify his diet or lifestyle. Be attentive to his questions, and inform him about diagnostic tests and treatments.
- u If the patient is scheduled for surgery, reinforce the doctor's explanation of the procedure and provide preoperative teaching.
- u Give the patient a list of irritating foods to avoid, such as spicy or highly seasoned foods, alcohol, and caffeine. Be sure he understands that these changes are lifelong measures to prevent recurrence of gastritis. If necessary, refer him to dietitian for further instruction.
- u If the patient smokes, encourage him to quit by pointing out that this habit can cause or aggravate symptoms by irritating the gastric mucosa. Refer him to a smoking-cessation program.
- u If appropriate, help the patient identify the need for stress reduction. Teach him stress-reduction techniques, such as meditation, deep breathing, progressive relaxation, and guided imagery.
- u Urge the patient to seek immediate attention for recurring symptoms, such as hematemesis, nausea, and vomiting.
- u To prevent recurrence, stress the importance of taking prophylactic medications as ordered. To reduce gastric irritation, advise the patient to take steroids with milk, food, or antacids. Instruct him to take antacids between meals and at bedtime and to avoid aspirin-containing compounds.
- u Teach family members the importance of supporting the patient as he makes the necessary dietary and lifestyle changes.

GASTROENTERITIS

Gastroenteritis (also called intestinal flu, traveler's diarrhea, viral enteritis, and food poisoning) is an inflammation of the stomach and small intestine that is self-limiting. The bowel reacts to any of the varied causes of gastroenteritis with hypermotility, producing severe diarrhea and secondary depletion of intracellular fluid.

Gastroenteritis occurs in people of all ages. It's a major cause of morbidity and mortality in underdeveloped nations. In the United States, this disorder ranks second to the common cold as a cause of lost work time and fifth as the cause of death among young children. It can be life-threatening in elderly and debilitated people.

Causes

Gastroenteritis has many possible causes, including:

- u bacteria, such as *Staphylococcus aureus*, *Salmonella*, *Shigella*, *Clostridium botulinum*, *C. perfringens*, and *Escherichia coli*
- u amoebae, especially *Entamoeba histolytica*
- u parasites, such as *Ascaris*, *Enterobius*, and *Trichinella spiralis*
- u viruses, such as adenoviruses, echoviruses, and coxsackieviruses
- u ingestion of toxins, such as poisonous plants and toadstools

PREVENTION

Preventing traveler's diarrhea

It the patient travels, especially to developing nations, discuss precautions that he can take to reduce his chances of getting traveler's diarrhea.

Explain that traveler's diarrhea is caused by inadequate sanitation and occurs after bacteria-contaminated food or water is ingested. These organisms attach to the lining of the small intestine, where they release a toxin that causes diarrhea and cramps. To minimize this risk, advise him to:

- u drink water (or brush his teeth with water) only if it's chlorinated. Chlorination protects the water supply from bacterial contaminants such as *Escherichia col*.
- u avoid beverages in glasses that may have been washed in contaminated water.
- u refuse ice cubes that may have been made from contaminated water.
- u drink only beverages made with boiled water, such as coffee and tea, or those in bottles or cans.
- u sanitize impure water by adding 2% tincture of iodine (5 drops/L of clear water; 10 drops/L of cloudy water) or by adding liquid laundry bleach (about 2 drops/L of clear water; 4 drops/L of cloudy water).
- u avoid uncooked vegetables, unpeeled fresh fruits, salads, unpasteurized milk, and other dairy products.
- u beware of foods offered by street vendors.

If traveler's diarrhea occurs despite precautions, bismuth subsalicylate, diphenoxylate with atropine, or loperamide can be used to relieve the symptoms.

- u drug reactions from antibiotics
- u food allergens.

Complications

In most patients, the disorder resolves with no sequelae. However, persistent or untreated gastroenteritis can cause severe dehydration and loss of crucial electrolytes, which can lead to shock, vascular collapse, renal failure and, rarely, death. Typically, infants, elderly people, and debilitated patients are at greatest risk because of their immature or impaired immune systems.

Assessment findings

Patient history commonly reveals the acute onset of diarrhea accompanied by abdominal pain and discomfort. The patient may complain of cramping, nausea, and vomiting. He may also report malaise, fatigue, anorexia, fever, abdominal distention, and rumbling in the lower abdomen. If diarrhea is severe, he may experience rectal burning, tenesmus, and bloody mucoid stools.

Investigate the patient's history to try to determine the cause of the signs and symptoms. Ask about ingestion of contaminated food or water. The cause may be apparent if the patient reports that others who ingested the same food or water have similar signs and symptoms. Also ask about the health of other family members and about recent travels. (See [Preventing traveler's diarrhea.](#))

Inspection may reveal slight abdominal distention. On palpation, the patient's skin turgor may be poor, a sign of dehydration. Auscultation may disclose hyperactive bowel sounds and, if the patient is dehydrated, orthostatic hypotension or generalized hypotension. Temperature may be either normal or elevated.

Diagnostic tests

Laboratory studies are used to identify the causative bacteria, parasites, or amoebae. These studies include Gram stain, stool culture (by direct rectal swab), or blood culture.

Treatment

Medical management is usually supportive, consisting of bed rest, nutritional support, increased fluid intake and, occasionally, antidiarrheal therapy. If gastroenteritis is severe or affects a young child or an elderly or debilitated person, hospitalization may be required. Treatment may include I.V. fluid and electrolyte replacement and administration of antidiarrheals, antiemetics, and antimicrobials.

Antidiarrheals, such as bismuth subsalicylate, are typically used as the first line of defense against diarrhea. If necessary, other antidiarrheals, such as camphorated opium tincture (paregoric), diphenoxylate with atropine, and loperamide, may be ordered.

Antiemetics (oral, I.V., or rectal suppository), such as prochlorperazine and trimethobenzamide, may be prescribed for severe vomiting. Antiemetics should be avoided in patients with viral or bacterial gastroenteritis.

Specific antibiotic administration is restricted to patients who have bacterial gastroenteritis, as identified by diagnostic testing.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Diarrhea
- u Pain
- u Risk for fluid volume deficit

Key outcomes

- u The patient will maintain weight without further loss.
- u The patient will express feelings of comfort.
- u The patient will maintain adequate fluid volume.
- u The patient's vital signs will remain stable.

Nursing interventions

- u Plan your care to allow uninterrupted rest periods for the patient. Rest usually helps to relieve the patient's symptoms, increase his resistance, and conserve his strength.
- u If the patient is nauseated, advise him to avoid quick movements, which can increase the severity of nausea.
- u If the patient can tolerate oral fluid intake, replace lost fluids and electrolytes with broth, ginger ale, and lemonade, as tolerated. Vary his diet to make eating more enjoyable, and allow some choice of foods. Warn him to avoid milk and milk products, which may provoke recurrence.
- u Monitor fluid status carefully. Take vital signs at least every 4 hours, weigh the patient daily, monitor for fluid and electrolyte balance, and record intake and output.
- u Watch for signs of dehydration, such as dry skin and mucous membranes, fever, and sunken eyes.
- u If dehydration occurs, administer oral and I.V. fluids as ordered. If necessary, a potassium supplement may be added to the I.V. solution. If the patient is receiving a potassium supplement, be especially alert for the development of hyperkalemia.
- u Administer medications as ordered. Correlate dosages and routes with the patient's meals and activities. (For example, give antiemetics 30 to 60 minutes before meals.)
- u Wash your hands thoroughly after giving care to avoid spreading infection, and use standard precautions whenever handling vomitus or stools.
- u To ease anal irritation caused by diarrhea, clean the area carefully and apply a repellent cream such as petroleum jelly. Warm sitz baths and application of witch hazel compresses can also soothe irritation.
- u If food poisoning is probable, contact public health authorities so they can interview patients and food handlers and take samples of the suspected contaminated food.

Patient teaching

- u Teach the patient about gastroenteritis, describing its symptoms and varied causes. Explain why a stool specimen may be necessary for diagnosis. Discuss the purpose of prescribed treatments.
- u Instruct the patient to wait until his diarrhea subsides and then to start drinking unsweetened fruit juice, tea, bouillon, or other clear broths and eating bland, soft foods, such as cooked cereal, rice, and applesauce. Tell him to avoid foods that are spicy, greasy, or high in roughage, such as whole-grain products and raw fruits or vegetables. Explain that eating these foods can precipitate recurrent diarrhea.
- u Carefully review the proper use of all prescribed medications with the patient, making sure that he fully understands the desired effects of the drugs and their possible adverse effects.
- u Teach preventive measures. If the patient expects to travel, advise him to pay close attention to what he eats and drinks, especially in developing nations. Review proper hygiene measures to prevent recurrence. Instruct the patient to thoroughly cook foods, especially pork; refrigerate perishable foods, such as milk, mayonnaise, potato salad, and cream-filled pastry; always wash his hands with warm water and soap before handling food, especially after using the bathroom; clean utensils thoroughly; and eliminate flies and roaches in the home.

HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease (also called congenital megacolon, aganglionic megacolon) is a congenital disorder of the large intestine characterized by the absence or marked reduction of parasympathetic ganglion cells in the colorectal wall. This disorder impairs intestinal motility and causes severe, intractable constipation.

Without prompt treatment, an infant with colonic obstruction may die within 24 hours from enterocolitis that leads to severe diarrhea and hypovolemic shock. With prompt treatment, the prognosis is good.

Hirschsprung's disease occurs in 1 in 5,000 to 1 in 2,000 live births. It's up to seven times more common in males than in females (although the aganglionic intestinal segment is usually shorter in males than in females) and is more prevalent in whites. Total aganglionosis of the large intestine affects both sexes equally. Clinical effects usually appear shortly after birth, but mild symptoms may not be recognized until adolescence or early adulthood.

Causes

Hirschsprung's disease is believed to be caused by a congenital, usually familial defect. The disease may coexist with other congenital anomalies, particularly trisomy 21 and anomalies of the urinary tract such as megaloureter. Women with Hirschsprung's disease are at higher risk for having affected children.

Symptoms result when the aganglionic bowel segment contracts without the reciprocal relaxation needed to propel the stools forward. In 90% of patients, this aganglionic segment is in the rectosigmoid area, but it occasionally extends to the entire colon and parts of the small intestine.

Complications

Disease progression causes most complications, such as nutritional deficiencies, severe diarrhea, enterocolitis, and hypovolemic shock. In infants, the main cause of death is enterocolitis, caused by fecal stagnation that leads to bacterial overgrowth, production of bacterial toxins, intestinal irritation, profuse diarrhea, hypovolemic shock, and perforation.

Assessment findings

In a neonate with Hirschsprung's disease, the history commonly reveals failure to pass meconium within the first 24 to 48 hours after birth and vomiting of bile-stained or fecal contents. The family history may disclose that siblings, parents, or other relatives have had difficulty passing stools.

On inspection, the infant may have abdominal distention, causing him to breathe rapidly and, possibly, grunt. A stool mass may be felt on palpation. Rectal examination reveals a rectum without stools; then, when the examining finger is withdrawn, an explosive gush of malodorous gas and liquid stools occurs.

In more advanced disease, the patient may have a history of anorexia, nausea, and lethargy. Inspection may show evidence of dehydration, such as pallor, loss of skin turgor, dry mucous membranes, and sunken eyes. In patients with severe disease, failure to grow is characterized by wasted extremities and loss of subcutaneous tissue, with a large protuberant abdomen.

The older infant, child, or adult usually complains of intractable constipation (usually requiring laxatives and enemas). In adolescents and adults, the examination also reveals poor physical condition as well as the symptoms described above.

Adult megacolon, although rare, usually affects men. The patient with this disorder may report a history of chronic, intermittent constipation, with possible rectal bleeding. On inspection, this patient appears in poor physical condition and has a distended abdomen.

Diagnostic tests

Rectal biopsy showing absence of ganglion cells allows a definitive diagnosis. Suction aspiration, using a small tube inserted into the rectum, may be performed initially.

Full-thickness surgical biopsy (under general anesthesia) may be performed if findings from suction aspiration are inconclusive.

Barium enema in older infants, children, and adults shows a narrow segment of distal colon with a sawtooth appearance and a funnel-shaped segment above it to help confirm the diagnosis and identify the extent of intestinal involvement. Significantly, infants with Hirschsprung's disease retain barium longer than the usual 12 to 24 hours, so delayed films are often helpful when other characteristic signs are absent.

Rectal manometry reveals failure of the internal anal sphincter to relax and contract.

Upright plain films of the abdomen show marked colonic distention.

Treatment

Surgery to restore normal defecation is the treatment of choice. The most effective surgical procedure involves pulling the normal ganglionic segment through to the anus. Before surgery, preliminary bowel preparation with an antibiotic, such as neomycin and nystatin, is necessary.

Corrective surgery in an infant is usually delayed until the child is at least 10 months old. Management of an infant until the time of surgery consists of daily colonic lavage to empty the bowel. If total obstruction is present in the neonate, a temporary colostomy or ileostomy is necessary to decompress the colon.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Constipation u Fluid volume deficit u Knowledge deficit u Risk for altered parenting u Risk for impaired skin integrity u Risk for infection

Key outcomes

- u The patient will maintain adequate caloric intake.
- u The patient will avoid complications.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's bowel function will return to normal.
- u The patient's skin integrity will remain intact.

Nursing interventions

- u Provide psychological support to the patient and his family. Because an infant with Hirschsprung's disease needs surgery and hospitalization so early in life, parents may have difficulty establishing an emotional bond with their child. To promote bonding, encourage them to participate in their child's care as much as possible.
- u Monitor vital signs and intake and output, and maintain fluid and electrolyte balance.
- u Keep the patient in an upright position. The infant can be placed in an infant seat.

ALERT Observe the patient for signs of complications, such as fever, bloody diarrhea, and vomiting; notify the doctor immediately if any of these occur.

- u Initiate and maintain I.V. therapy as ordered. Administer antibiotics and monitor the patient for desired effects and possible adverse reactions.
- u If ordered, insert a nasogastric (NG) tube connected to low-pressure, intermittent suction. Note the color, consistency, and amount of drainage.
- u Provide adequate nutrition.
- u If shock occurs, provide transfusions as ordered.

After colostomy or ileostomy:

- u Place the infant in a heated incubator, with the temperature set at 98° to 99° F (36.7° to 37.2° C), or in a radiant warmer. Monitor vital signs, watching for sepsis and enterocolitis (increased respiratory rate with abdominal distention).
- u Carefully monitor and record fluid intake and output (including drainage from an ileostomy or a colostomy) as well as electrolyte levels. An ileostomy is especially likely to cause excessive electrolyte losses. Measure and record NG tube drainage, and replace fluids and electrolytes as ordered. Check the stools carefully for excess water, which is a sign of fluid loss.
- u Provide total parenteral nutrition if ordered.
- u Check the urine for specific gravity, glucose (total parenteral nutrition may lead to osmotic diuresis), and blood.
- u To prevent aspiration pneumonia and skin breakdown, turn and reposition the patient often. Also, suction the nasopharynx frequently.
- u Keep the area around the stoma clean and dry, and cover it with dressings or a colostomy or ileostomy appliance to absorb drainage. To prevent infection, use aseptic technique until the wound heals. Watch for prolapse, discoloration, or excessive bleeding (slight bleeding is common). To prevent excoriation, use a powder, such as karaya gum, or a protective stoma disk.
- u Begin oral feedings, as ordered, when bowel sounds resume. An infant may best tolerate predigested formulas.

Before final corrective surgery:

- u If a colostomy or an ileostomy isn't performed, perform colonic lavage at least once per day with normal saline solution to evacuate the colon. Keep in mind that ordinary enemas and laxatives don't clean the colon adequately. Keep accurate records of how much lavage solution is instilled. Repeat lavage until the return solution is completely free of fecal particles.
- u Administer antibiotics for bowel preparation as ordered.

After final corrective surgery:

- u Keep the wound clean and dry, and check for significant inflammation (some inflammation is normal). Don't use a rectal thermometer or suppository until the wound has healed. After 3 or 4 days, the infant will have a first bowel movement—a liquid stool—that will probably create discomfort. Record the number of stools.
- u Check the urine for blood, especially in a boy; extensive surgical manipulation can cause bladder trauma.
- u Watch for signs of possible anastomotic leaks (sudden development of abdominal distention unrelieved by gastric aspiration, temperature spike, extreme irritability), which could lead to pelvic abscess.
- u Begin oral feedings when active bowel sounds resume and NG tube drainage decreases. As an additional check, clamp the NG tube for brief, intermittent periods as ordered. If abdominal distention develops, the patient isn't ready to begin oral feedings. Begin oral feedings with clear fluids, increasing bulk as tolerated.

Patient teaching

- u Explain Hirschsprung's disease to the patient and the parents. Be sure they understand necessary diagnostic tests and treatments.
- u Before surgery, provide appropriate preoperative teaching to the patient or the parents. Reinforce the doctor's explanation of the procedure and its possible complications as necessary.
- u Instruct the patient or the parents, as appropriate, to recognize signs of fluid loss and dehydration (decreased urine output, sunken eyes, poor skin turgor) and of enterocolitis (sudden, marked abdominal distention, vomiting, diarrhea, fever, lethargy).
- u Before discharge, if possible, make sure the parents or the adult patient consults an enterostomal therapist for valuable tips on colostomy or ileostomy care.
- u If the patient is a child, instruct the parents to watch for foods that increase the number of stools and to avoid offering these foods. Reassure them that their child will, in time, probably gain sphincter control and eat a normal diet. Warn them that complete continence can take years to develop, and constipation may recur.

When part of an internal organ protrudes through an abnormal opening in the containing wall of its cavity, a hernia results. In an inguinal hernia—the most common type—the large or small intestine, omentum, or bladder protrudes into the inguinal canal.

Hernias can be reducible (if the hernia can be manipulated back into place with relative ease); incarcerated (if the hernia can't be reduced because adhesions have formed in the hernial sac); or strangulated (if part of the herniated intestine becomes twisted or edematous, causing serious complications).

Inguinal hernias can be direct (herniation through an area of muscle weakness in the inguinal canal) or indirect (herniation through the inguinal ring). Indirect hernias, the more common form, can develop at any age but are especially prevalent in infants under age 1. This form is three times more common in males.

Causes

Inguinal hernias result from abdominal muscles weakened by congenital malformation, traumatic injury, or aging; or from increased intra-abdominal pressure (due to heavy lifting, exertion, pregnancy, obesity, excessive coughing, or straining with defecation).

Inguinal hernia is a common congenital malformation that may occur in males during the 7th month of gestation. Normally, at this time, the testicle descends into the scrotum, preceded by the peritoneal sac. If the sac closes improperly, it leaves an opening through which the intestine can slip, causing a hernia.

Complications

Inguinal hernia may lead to incarceration or strangulation. Strangulation can interfere with normal blood flow and peristalsis, possibly leading to intestinal obstruction and necrosis.

Assessment findings

The patient history may reveal precipitating factors, such as weight lifting, recent pregnancy, and excessive coughing. Usually, the patient reports the appearance of a lump in the inguinal area when he stands or strains. He may also complain of sharp, steady groin pain, which tends to worsen when tension is placed on the hernia and improve when the hernia is reduced.

If the patient has a large hernia, inspection may reveal an obvious swelling in the inguinal area. If he has a small hernia, the affected area may simply appear full. As part of your inspection, have the patient lie down. If the hernia disappears, it's reducible. Also ask him to perform Valsalva's maneuver; while he does so, inspect the inguinal area for characteristic bulging.

Auscultation should reveal bowel sounds. The absence of bowel sounds may indicate incarceration or strangulation. Palpation helps to determine the size of an obvious hernia. It also can disclose the presence of a hernia in a male patient. (See [Detecting inguinal hernia.](#))

Diagnostic tests

Although assessment findings are the cornerstone of diagnosis, suspected bowel obstruction requires X-rays and a white blood cell count, which may be elevated.

Treatment

The choice of therapy depends on the type of hernia. For a reducible hernia, temporary relief may result from moving the protruding organ back into place. Afterward, a truss may be applied to keep the abdominal contents from protruding through the hernial sac. (A truss is a firm pad with a belt attached that is placed over the hernia to keep it reduced.) Although a truss doesn't cure a hernia, the device is especially helpful for an elderly or a debilitated patient, for whom any surgery is potentially hazardous.

Herniorrhaphy is the preferred surgical treatment for infants, adults, and otherwise-healthy elderly patients. This procedure replaces hernial sac contents into the abdominal cavity and seals the opening. Another effective procedure is hernioplasty, which involves reinforcing the weakened area with steel mesh, fascia, or wire.

A strangulated or necrotic hernia requires bowel resection. Rarely, an extensive resection may require a temporary colostomy.

Nursing diagnoses

- u Activity intolerance
- u Altered tissue perfusion (GI)
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will avoid complications.
- u The patient's bowel function will return to normal.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient's vital signs will remain stable.

Nursing interventions

- u Apply a truss only after a hernia has been reduced. For best results, apply it in the morning before the patient gets out of bed. Assess the skin daily and apply powder for protection because the truss may be irritating.
- u Watch for and immediately report signs of incarceration and strangulation. Don't try to reduce an incarcerated hernia; doing so may perforate the bowel. If severe intestinal obstruction arises because of hernial strangulation, tell the doctor immediately. A nasogastric tube may be inserted promptly to empty the stomach and relieve pressure on the hernial sac.
- u When surgery is scheduled, closely monitor vital signs and provide routine preoperative preparation. If necessary, administer I.V. fluids and analgesics for pain as ordered. Control fever with acetaminophen or tepid sponge baths as ordered. Place the patient in Trendelenburg's position to reduce pressure on the hernia site.
- u After surgery, provide routine postoperative care. Don't allow the patient to cough, but do encourage deep breathing and frequent turning. Apply ice bags to the scrotum to reduce swelling and relieve pain; elevating the scrotum on rolled towels also reduces swelling. Administer analgesics as necessary. In males, a jock strap or suspensory bandage may be used to provide support.

Patient teaching

- u Explain what an inguinal hernia is and how it's usually treated. Point out that elective surgery is the treatment of choice and is safer than waiting until hernial complications develop, necessitating emergency surgery. Warn the patient that a strangulated hernia can require extensive bowel resection, involving a protracted hospital stay and, possibly, a colostomy.

ADVANCED PRACTICE

Detecting inguinal hernia

To detect a hernia in a male patient, ask him to stand, keeping the leg on the side to be examined slightly flexed and resting his weight on the other leg.

Insert an index finger into the lower part of the scrotum and invaginate the scrotal skin so that the finger advances through the external inguinal ring (about 1½" to 2" [4 to 5 cm]). Tell the patient to cough.

If you feel pressure against your fingertip, an indirect hernia exists; if you feel pressure against the side of your finger, a direct hernia exists.

- u Teach the patient who won't undergo surgery to watch for signs of incarceration or strangulation. Tell him that severe pain, nausea, vomiting, and diarrhea may indicate complications. Warn him and family members that shock, high fever, and bloody stools are signs of complete obstruction and must be reported at once. Tell them that immediate surgery is needed if complications occur.
- u If the patient uses a truss, instruct him to bathe daily and apply liberal amounts of cornstarch or baby powder to prevent skin irritation. Warn against applying the truss over clothing, which reduces its effectiveness and may cause slippage. Point out that wearing a truss doesn't cure a hernia and may be uncomfortable.
- u If surgery is scheduled, provide preoperative teaching. Reinforce the doctor's explanation of the surgery and its possible complications. Reassure the patient that he'll have no tubes or drains after surgery unless his hernia is complicated by strangulation or incarceration.
- u Tell the postoperative patient that he'll probably be able to return to work or school and resume all normal activities within 2 to 4 weeks. Remind him to obtain his doctor's permission before returning to work or completely resuming his normal activities.
- u Before discharge, warn the patient against lifting or straining. Instruct him to watch for signs of infection (oozing, tenderness, warmth, redness) at the incision site. Tell him to keep the incision clean and covered until the sutures are removed.

ADVANCED PRACTICE

Paralytic ileus

Paralytic (adynamic) ileus is a physiologic form of intestinal obstruction that may develop in the small bowel after abdominal surgery. It causes decreased or absent intestinal motility that usually disappears spontaneously after 2 to 3 days.

Causes

This condition can develop as a response to trauma, toxemia, or peritonitis or as a result of electrolyte deficiency (especially hypokalemia) and the use of certain drugs, such as pain medications, ganglionic blocking agents, and anticholinergics. It can also result from vascular causes, such as thrombosis and embolism.

Signs and symptoms

Clinical effects of paralytic ileus include severe, continuous abdominal discomfort with nausea and vomiting. Abdominal distention is also present. Bowel sounds are diminished or absent. The patient may be severely constipated or pass flatus and small, liquid stools.

Treatment

Paralytic ileus that lasts longer than 48 hours necessitates intubation for decompression and nasogastric suctioning to restore intravascular volume and correct electrolyte disorders.

When paralytic ileus results from surgical manipulation of the bowel, treatment may also include administration of prokinetic agents, such as metoclopramide, erythromycin, and cisapride.

Special considerations

When caring for patients with paralytic ileus, warn those receiving cholinergic agents to expect certain paradoxical adverse effects, such as intestinal cramps and diarrhea. Check frequently for returning bowel sounds.

- u Inform the postoperative patient that the risk of recurrence depends on the success of the surgery, his general health, and his lifestyle.

INTESTINAL OBSTRUCTION

Intestinal obstruction is the partial or complete blockage of the lumen of the small or large bowel. It's commonly a medical emergency. Complete obstruction in any part of the bowel, if untreated, can cause death within hours from shock and vascular collapse. Intestinal obstruction is most likely after abdominal surgery or in people with congenital bowel deformities.

Causes and pathophysiology

Intestinal obstruction results from mechanical or nonmechanical (neurogenic) blockage of the lumen. Causes of mechanical obstruction include adhesions and strangulated hernias (usually associated with small-bowel obstruction); carcinomas (usually associated with large-bowel obstruction); foreign bodies, such as fruit pits, gallstones, and worms; compression of the bowel wall from stenosis; intussusception; volvulus of the sigmoid or cecum; tumors; and atresia.

Nonmechanical obstruction usually results from paralytic ileus, the most common of all intestinal obstructions. Paralytic ileus is a physiological form of intestinal obstruction that usually develops in the small bowel after abdominal surgery. (See [Paralytic ileus.](#))

Other nonmechanical causes of obstruction include electrolyte imbalances; toxicity, such as that associated with uremia or generalized infection; neurogenic abnormalities such as spinal cord lesions; and thrombosis or embolism of mesenteric vessels.

Although intestinal obstruction may occur in several forms, the underlying pathophysiology is similar. (See [Effects of intestinal obstruction.](#))

Complications

Intestinal obstruction can lead to perforation, peritonitis, septicemia, secondary infection, metabolic alkalosis or acidosis, hypovolemic or septic shock and, if untreated, death.

Assessment findings

Investigation of the patient's history often reveals predisposing factors, such as surgery (especially abdominal surgery), radiation therapy, and gallstones. The history may also disclose certain illnesses that can lead to obstruction, such as Crohn's disease, diverticular disease, and ulcerative colitis. Family history may reveal colorectal cancer in one or more relatives.

ALERT If the patient reports a recent change in bowel habits or blood in his stools, colon cancer may be the cause of obstruction.

Hiccups are a common complaint in all types of bowel obstruction. Other specific assessment findings depend on the cause of obstruction—mechanical or nonmechanical—and its location in the bowel.

Mechanical obstruction of the small bowel

The patient may complain of colicky pain, nausea, vomiting, and constipation. If obstruction is complete, he may report vomiting of fecal contents. This results from vigorous peristaltic waves that propel bowel contents toward the mouth instead of the rectum.

Inspection may reveal a distended abdomen, the hallmark of all types of mechanical obstruction. Auscultation may reveal bowel sounds, borborygmi, and rushes (occasionally loud enough to be heard without a stethoscope). Palpation may disclose abdominal tenderness. Rebound tenderness may be noted in patients with obstruction that results from strangulation with ischemia.

Mechanical obstruction of the large bowel

In a patient with a mechanical obstruction of the large bowel, a history of constipation is common, with a more gradual onset of signs and symptoms than in small-bowel obstruction. Several days after constipation begins, the patient may report the sudden onset of colicky abdominal pain, producing spasms that last less than 1 minute and recur every few minutes.

The patient's history may reveal constant hypogastric pain, nausea and, in the later stages, vomiting. He may describe his vomitus as orange-brown and foul smelling, which is characteristic of large-bowel obstruction. On inspection, the abdomen may appear dramatically distended, with visible loops of large bowel. Auscultation may reveal loud, high-pitched borborygmi.

Partial obstruction usually causes similar signs and symptoms, in a milder form. Leakage of liquid stools around the partial obstruction is common.

Nonmechanical obstruction

The patient with a nonmechanical obstruction, such as paralytic ileus, usually describes diffuse abdominal discomfort instead of colicky pain. Typically, he also reports frequent vomiting, which may consist of gastric and bile contents but, rarely, fecal contents. He may also complain of constipation and hiccups.

If obstruction results from vascular insufficiency or infarction, the patient may complain of severe abdominal pain. On inspection, the abdomen is distended. Early in the disease, auscultation discloses decreased bowel sounds; this sign disappears as the disorder progresses.

PATHOPHYSIOLOGY

Effects of intestinal obstruction

Intestinal obstruction develops in three forms:

- Simple. Blockage prevents intestinal contents from passing, with no other complications.
- Strangulated. Blood supply to part or all of the obstructed section is cut off, in addition to blockage of the lumen.
- Close-looped. Both ends of a bowel section are occluded, isolating it from the rest of the intestine.

In all three forms, the physiologic effects are similar: When intestinal obstruction occurs, fluid, air, and gas collect near the site. Peristalsis increases temporarily as the bowel tries to force its contents through the obstruction, injuring intestinal mucosa and causing distention at and above the site of the obstruction.

Because distention blocks venous blood flow, normal absorptive processes cease. As a result, the bowel begins to secrete water, sodium, and potassium into the fluid pooled in the lumen. Obstruction in the upper intestine results in metabolic alkalosis from dehydration and loss of gastric hydrochloric acid. Obstruction in the lower intestine causes slower dehydration and loss of intestinal alkaline fluids, resulting in metabolic acidosis.

Ultimately, intestinal obstruction may lead to ischemia, necrosis, and death.

Diagnostic tests

Various tests help to establish the diagnosis and pinpoint complications. For example, abdominal X-rays confirm intestinal obstruction and reveal the presence and location of intestinal gas or fluid. In small-bowel obstruction, a typical “stepladder” pattern emerges, with alternating fluid and gas levels apparent in 3 to 4 hours. In large-bowel obstruction, barium enema reveals a distended, air-filled colon or a closed loop of sigmoid with extreme distention (in sigmoid volvulus).

Serum sodium, chloride, and potassium levels may decrease because of vomiting.

White blood cell counts may be normal or slightly elevated if necrosis, peritonitis, or strangulation occurs.

Serum amylase level may increase, possibly from irritation of the pancreas by a bowel loop.

Hemoglobin concentration and hematocrit may increase, indicating dehydration.

Sigmoidoscopy, colonoscopy, or a barium enema may be used to help determine the cause of obstruction; however, these tests are contraindicated if perforation is suspected.

Treatment

Surgery is usually the treatment of choice. One important exception is paralytic ileus in which nonoperative therapy is usually attempted first. The type of surgery depends on the cause of blockage. For example, if a tumor is obstructing the intestine, a colon resection with anastomosis is performed; if adhesions are obstructing the lumen, these are lysed.

Surgical preparation is often lengthy, taking as long as 6 to 8 hours. It includes correction of fluid and electrolyte imbalances; decompression of the bowel to relieve vomiting and distention; treatment of shock and peritonitis; and administration of broad-spectrum antibiotics. Often, decompression is begun preoperatively with passage of a nasogastric (NG) tube attached to continuous suction. This tube relieves vomiting, reduces abdominal distention, and prevents aspiration. In strangulating obstruction, preoperative therapy also usually requires blood replacement and I.V. fluids.

Postoperative care involves careful patient monitoring and interventions geared to the type of surgery. Total parenteral nutrition may be ordered if the patient has a protein deficit from chronic obstruction, postoperative or paralytic ileus, or infection.

Nonsurgical treatment may be attempted in some patients with partial obstruction, particularly those who suffer recurrent partial obstruction or who developed it after surgery or a recent episode of diffuse peritonitis.

Nonsurgical treatment usually includes decompression with an NG tube attached to low-pressure, continuous suction; correction of fluid and electrolyte deficits, administration of broad-spectrum antibiotics; and, occasionally, total parenteral nutrition. Rarely, a long nasointestinal tube is used for decompression.

Throughout nonsurgical treatment, the patient's condition must be closely monitored. If the condition fails to improve or deteriorates, surgery is required.

Another indication for nonsurgical treatment is nonmechanical obstruction from adynamic ileus (paralytic ileus). Most of these cases occur postoperatively and disappear spontaneously in 2 or 3 days. However, if the disorder doesn't resolve in 48 hours, treatment consists of decompression with an NG tube attached to low-pressure, continuous suction. Oral intake is restricted until bowel function resumes; then, the diet is gradually advanced.

In the patient with paralytic ileus, decompression occasionally responds to colonoscopy or rectal tube insertion. When paralytic ileus develops secondary to another illness, such as severe infection or electrolyte imbalance, the primary problem must also be treated. If conservative treatment fails, surgery is required.

In both surgical and nonsurgical treatment, drug therapy includes antibiotics and analgesics or sedatives, such as meperidine or phenobarbital (but not opiates because they inhibit GI motility).

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered tissue perfusion (GI) u Fluid volume deficit u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's bowel function will return to normal.
- u The patient will maintain adequate caloric intake.
- u The patient's vital signs will remain stable.

Nursing interventions

- u Because intestinal obstruction may be fatal and often causes overwhelming pain and distress, patients require skillful supportive care and keen observation.
- u Allow the patient nothing by mouth, as ordered, but make sure to provide frequent mouth care to help keep mucous membranes moist. Look for signs of dehydration (thick, swollen tongue; dry, cracked lips; dry oral mucous membranes). If surgery won't be performed, the patient may be allowed a few ice chips. Avoid using lemon-glycerin swabs, which can increase mouth dryness.
- u Insert an NG tube to decompress the bowel as ordered. Attach the tube to low-pressure, intermittent suction. Monitor drainage for color, consistency, and amount. Irrigate the tube, if necessary, with normal saline solution to maintain patency.
- u If ordered, assist with insertion of a weighted nasointestinal tube such as a Miller-Abbott, Cantor, or Harris tube. If a weighted tube was inserted, check periodically to make sure it's advancing. Help the patient turn from side to side (or walk around, if he can) to facilitate passage of the tube.
- u Begin and maintain I.V. therapy as ordered. Monitor intake and output. Maintain fluid and electrolyte balance by monitoring electrolyte, blood urea nitrogen, and creatinine levels. Provide I.V. fluids to keep levels within normal ranges.

ALERT Monitor vital signs frequently. A drop in blood pressure may be a sign of reduced circulating blood volume due to blood loss from a strangulated hernia. As much as 10 L of fluid can collect in the small bowel, drastically reducing plasma volume. Observe closely for signs of shock (pallor, rapid pulse, and hypotension). Provide blood replacement therapy as necessary.

- u Administer analgesics, broad-spectrum antibiotics, and other medications as ordered. Monitor the patient for the desired effects and for adverse reactions.
- u To ease discomfort, help the patient change positions frequently. Continually assess his pain. Remember, colicky pain that suddenly becomes constant could signal perforation.
- u Watch for signs of metabolic alkalosis (changes in sensorium; slow, shallow respirations; hypertonic muscles; tetany) or acidosis (shortness of breath on exertion; disorientation; and later, deep, rapid breathing, weakness, and malaise). Watch for signs and symptoms of secondary infection, such as fever and chills.
- u Monitor urine output carefully to assess renal function, circulating blood volume, and possible urine retention due to bladder compression by the distended intestine. If you suspect bladder compression, catheterize the patient for residual urine immediately after he has voided. Also measure abdominal girth frequently to detect progressive distention.
- u Keep the patient in semi-Fowler's or Fowler's position as much as possible. These positions help to promote pulmonary ventilation and ease respiratory distress from abdominal distention. Listen for bowel sounds, and watch for other signs of resuming peristalsis (passage of flatus and mucus through the rectum).
- u If surgery is scheduled, prepare the patient as required.
- u After surgery, provide all necessary postoperative care. Care for the surgical site, maintain fluid and electrolyte balance, relieve pain and discomfort, maintain respiratory status, and monitor intake and output.

Patient teaching

- u Teach the patient about his disorder, focusing on his type of intestinal obstruction, its cause, and signs and symptoms. Listen to his questions and take time to answer them.
- u Explain necessary diagnostic tests and treatments. Make sure the patient understands that these procedures are necessary to relieve the obstruction and reduce pain. Review in pretest guidelines; for example, advise him to lie on his left side for about 30 minutes before X-rays are taken.
- u Prepare the patient and family members for the possibility of surgery. Provide preoperative teaching, and reinforce the doctor's explanation of the surgery. Demonstrate techniques for coughing and deep breathing, and teach the patient how to use incentive spirometry.
- u Tell the patient what to expect postoperatively. After surgery, if he has a colostomy or ileostomy, teach him how to care for it, and arrange for an enterostomal therapist to visit him. Also review incisional care. Provide emotional support and positive reinforcement before and after surgery.
- u Discuss postoperative activity limitations and point out why these restrictions are necessary.
- u Review the proper use of prescribed medications, focusing on their correct administration, desired effects, and possible adverse reactions.
- u Emphasize the importance of following a structured bowel regimen, particularly if the patient had a mechanical obstruction from fecal impaction. Encourage him to eat a high-fiber diet and to exercise daily.
- u Reassure the patient who had an obstruction from paralytic ileus that recurrence is unlikely. However, remind him to report any recurrence of abdominal pain, abdominal distention, nausea, or vomiting.

INTUSSUSCEPTION

Intussusception—a pediatric emergency—occurs when a portion of the bowel telescopes or invaginates into an adjacent bowel portion. (See [Understanding intussusception](#).) Because this disorder leads to bowel obstruction and other serious complications, it can be fatal, especially if treatment is delayed for more than 24 hours.

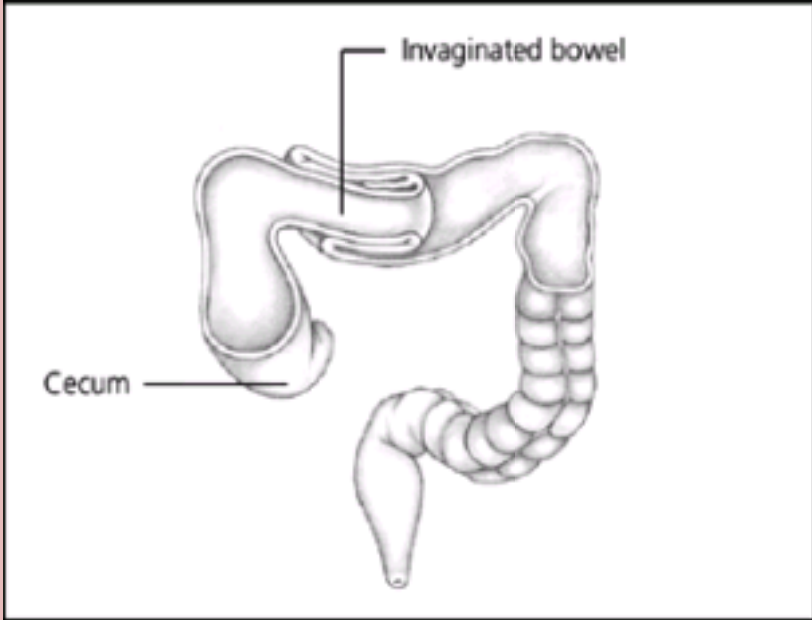

Intussusception is most common in infants and occurs three times more often in males than in females. About 87% of children with intussusception are under age 2; about 70% of these children are between 4 and 11 months old.

Causes

In infants, intussusception usually arises from unknown causes. In older children, polyps, hemangioma, lymphosarcoma, lymphoid hyperplasia, Meckel's diverticulum, or alterations in intestinal motility may trigger the process. In adults, intussusception most commonly results from benign or malignant tumors (65% of patients); other possible causes include polyps, Meckel's diverticulum, gastroenterostomy with herniation, and an appendiceal stump.

Understanding intussusception

In intussusception, a bowel section invaginates and is propelled along by peristalsis, pulling in more bowel. In this illustration, a portion of the cecum invaginates and is propelled into the large intestine. Intussusception typically produces edema, hemorrhage from venous engorgement, incarceration, and obstruction.

The diagram illustrates the process of intussusception. It shows a cross-section of the large intestine. A portion of the cecum, labeled 'Cecum', is shown invaginating into the large intestine, labeled 'Invaginated bowel'. The invaginated portion is shown as a coiled mass within the larger bowel lumen.

In addition, studies suggest that intussusception may be linked to viral infections because seasonal peaks are noted—in the spring and summer, coinciding with peak incidence of enteritis, and in midwinter, coinciding with peak incidence of respiratory tract infections.

Complications

Without prompt treatment, strangulation of the intestine may occur, with gangrene, shock, perforation, and peritonitis. These complications can be fatal.

Assessment findings

If the patient is an infant or a child, the history may reveal intermittent attacks of colicky pain. Typically, this pain causes the child to scream, draw his legs up to his abdomen, turn pale and diaphoretic and, possibly, grunt. Parents may report that the child initially vomits stomach contents and, later, bile-stained or fecal material. Parents may describe the child's “currant jelly” stools, which contain a mixture of blood and mucus.

Inspection and palpation may reveal a distended, tender abdomen, with some guarding over the intussusception site. A sausage-shaped abdominal mass may be palpable in the right upper quadrant or in the midepigastria area if the transverse colon is involved. Rectal examination may show bloody mucus.

In an adult patient, the history may reveal nonspecific, chronic, and intermittent symptoms, such as colicky abdominal pain and tenderness, vomiting, diarrhea (occasionally constipation), bloody stools, and weight loss. The patient may describe abdominal pain that is localized in the right lower quadrant, radiates to the back, and increases with eating. The abdomen may be distended. Palpation may help pinpoint the tender area in the right lower quadrant.

In the adult patient, excruciating pain, abdominal distention, and tachycardia are signs that severe intussusception has led to strangulation.

Diagnostic tests

Various tests help to confirm the diagnosis: Barium enema confirms colonic intussusception when it shows the characteristic coiled-spring sign; it also delineates the extent of intussusception. Upright abdominal X-rays may show a soft-tissue mass and signs of complete or partial obstruction, with dilated loops of bowel. White blood cell count up to 15,000/μl indicates obstruction; more than 15,000/μl, strangulation; and more than 20,000/μl, bowel infarction.

Treatment

In children, therapy may include hydrostatic reduction or surgery. Surgery is indicated for children with recurrent intussusception, for those who show signs of shock or peritonitis, and for those in whom symptoms have been present longer than 24 hours. In adults, surgery is always the treatment of choice.

During hydrostatic reduction, the radiologist drips a barium solution into the rectum through a catheter from a height of not more than 3' (0.9 m); fluoroscopy is used to trace the progress of the barium. If the procedure is successful, the barium backwashes into the ileum and the mass disappears. If not, the procedure is stopped, and the patient is prepared for surgery.

During surgery, manual reduction is attempted first. After compressing the bowel above the intussusception, the doctor attempts to milk the intussusception back through the bowel. However, if manual reduction fails, or if the bowel is gangrenous or strangulated, the doctor performs a resection of the affected bowel segment.

Nursing diagnoses

u Altered tissue perfusion (GI) u Anxiety u Fear u Fluid volume deficit u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will avoid complications.
- u The patient's fluid volume will remain within normal parameters.
- u Family members will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Offer reassurance and emotional support to the patient and, if the patient is a child, to his parents. Because this condition is considered a pediatric emergency, parents are often unprepared for their child's hospitalization and possible surgery. Similarly, the child is unprepared for an abrupt separation from his parents and familiar environment.
- u Monitor vital signs before and after surgery. A change in temperature can indicate sepsis; infants may become hypothermic at the onset of infection. Increasing pulse rate and decreasing blood pressure may signal peritonitis.
- u Check intake and output. Administer I.V. fluids as ordered. Watch for signs of dehydration and bleeding. If the patient is in shock, give blood or plasma as ordered.
- u A nasogastric (NG) tube is inserted to decompress the intestine and minimize vomiting. Monitor tube drainage, and replace volume lost, as ordered.

u Monitor the patient who has undergone hydrostatic reduction for passage of stools and barium, a sign that the reduction has been successful. Keep in mind that a few patients have a recurrence of intussusception; this usually occurs within the first 36 to 48 hours after the hydrostatic reduction.

After surgery:

- u Monitor NG tube drainage for color, consistency, and amount; check fluid and electrolyte balance. Frequently assess the patient for return of bowel sounds. Administer analgesics, broad-spectrum antibiotics, and I.V. fluids as ordered.
- u Provide meticulous wound care. Most incisions heal without complications. However, closely check the incision for inflammation, drainage, or suture separation. Encourage the patient to cough productively by turning him from side to side. Take care to splint the incision when he coughs and, if appropriate, teach him to do so himself. Make sure he takes 10 deep breaths per hour.
- u Oral fluids may be reintroduced postoperatively when bowel sounds and peristalsis resume, NG tube drainage is minimal, the abdomen remains soft, and vomiting doesn't occur when the NG tube is clamped briefly for a trial period. When the patient tolerates oral fluids well, the tube can be removed and the patient's diet gradually returned to normal as tolerated.
- u Check for abdominal distention after the patient resumes a normal diet.

Patient teaching

- u Depending on the patient's age, explain to him or his parents what happens in intussusception. Review required diagnostic tests and treatments. If hydrostatic reduction by barium enema will be attempted, be sure the patient or his parents understand the procedure. Let them know that surgery will be necessary if the procedure isn't successful.
- u If surgery is required, provide preoperative teaching. Reinforce the doctor's explanation of the surgery and its possible complications.
- u To minimize the stress of hospitalization, encourage parents to participate in their child's care as much as possible. Be flexible about visiting hours.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (also called spastic colon, spastic colitis, mucous colitis) is a common condition marked by chronic or periodic diarrhea alternating with constipation. It's accompanied by straining and abdominal cramps.

Irritable bowel syndrome occurs mostly in women, with symptoms first emerging before age 40. The prognosis is good.

Causes and pathophysiology

Although the precise etiology is unclear, irritable bowel syndrome involves a change in bowel motility, reflecting an abnormality in the neuromuscular control of intestinal smooth muscle. (See [Understanding irritable bowel syndrome.](#))

Contributing or aggravating factors include anxiety and stress. Initial episodes occur early in life; psychological stress probably causes most exacerbations. Irritable bowel syndrome may also result from dietary factors, such as fiber, fruits, coffee, alcohol, and foods that are cold, highly seasoned, or laxative in nature. Other possible triggers include hormones, laxative abuse, and allergy to certain foods or drugs.

PATHOPHYSIOLOGY

Understanding irritable bowel syndrome

Typically, the patient with irritable bowel syndrome has a GI tract that appears normal. However, careful examination of the colon may reveal functional irritability, an abnormality in colonic smooth-muscle function marked by excessive peristalsis and spasms, even during remission.

Intestinal function

To understand what happens in irritable bowel syndrome, consider how smooth muscle controls bowel function. Normally, segmental muscle contractions mix intestinal contents while peristalsis propels the contents through the GI tract. Motor activity is most propulsive in the proximal (stomach) and the distal (sigmoid) portions of the intestine. Activity in the rest of the intestine is slower, permitting nutrient and water absorption.

In irritable bowel syndrome, the autonomic nervous system, which innervates the large intestine, fails to produce the alternating contractions and relaxations that propel stools smoothly toward the rectum. The result is constipation, diarrhea, or both.

Constipation

Some patients have spasmodic intestinal contractions, which set up a partial obstruction by trapping gas and stools. This causes distention, bloating, gas pain, and constipation.

Diarrhea

Other patients have dramatically increased intestinal motility. Usually triggered by eating or by cholinergic stimulation, the small intestine's contents speed into the large intestine, dumping watery stools and causing mucosal irritation, which results in diarrhea.

Mixed symptoms

If further spasms trap liquid stools, the intestinal mucosa absorbs water from the stools, leaving them dry, hard, and difficult to pass. The result is a pattern of alternating diarrhea and constipation.

Complications

Irritable bowel syndrome is associated with a higher-than-normal incidence of diverticulitis and colon cancer. Although complications are usually few, the disorder may lead (rarely) to chronic inflammatory bowel disease.

Because symptoms mimic those of acute abdomen, misdiagnosis occasionally results in unnecessary surgery.

Assessment findings

Typically, the patient reports a history of chronic constipation, diarrhea, or both. She may complain of lower abdominal pain (usually in the left lower quadrant) that is often relieved by defecation or passage of gas. She may report bouts of diarrhea, which typically occur during the day. This symptom alternates with constipation or normal bowel function.

The patient may describe her stools as small with visible mucus. Or she may have small, pasty, and pencil-like stools instead of diarrhea. Other common complaints

include dyspepsia, abdominal bloating, heartburn, faintness, and weakness.

During the patient history, investigate possible contributing psychological factors such as a recent stressful life change that may have triggered or aggravated symptoms.

On inspection, the patient may seem anxious and fatigued, but otherwise normal. Auscultation may reveal normal bowel sounds. Palpation typically discloses a relaxed abdomen. Occasionally, percussion reveals tympany over a gas-filled bowel.

Diagnostic tests

Because no definitive test exists to confirm irritable bowel syndrome, the diagnosis typically involves studies to rule out other, more serious disorders, such as diverticulitis or colon cancer. The most frequently performed tests include barium enema, sigmoidoscopy, and stool examination.

Barium enema may reveal colonic spasm and a tubular appearance of the descending colon. It's also used to rule out certain other disorders, such as diverticula, tumors, and polyps.

Sigmoidoscopy may disclose spastic contractions.

Stool examination for occult blood, parasites, and pathogenic bacteria is negative.

Treatment

The goal of therapy is to control symptoms through dietary changes, stress management, and lifestyle modifications. Medications are reserved for severe symptoms and, if used, are discontinued as the patient learns to control her symptoms through diet and stress reduction.

The type of dietary therapy depends on the patient's symptoms. If she has diarrhea, an elimination diet may help determine whether her symptoms result from food intolerance. In this type of diet, certain foods, such as citrus fruits, coffee, corn, dairy products, tea, and wheat, are sequentially eliminated. Then, each food is gradually reintroduced to identify which foods, if any, trigger the patient's symptoms.

Other dietary changes include elimination of sorbitol, an artificial sweetener that may cause diarrhea, abdominal distention, and bloating. Also helpful is dietary elimination of nonabsorbable carbohydrates, such as beans and cabbage, and lactose-containing foods, all of which can cause flatulence.

To control diarrhea, bran may be added to increase dietary bulk. By increasing the time the stool remains in the bowel, bran helps to promote stool formation.

If the patient has constipation and abdominal pain, her diet should contain at least 15 g per day of bulky foods, such as wheat bran, oatmeal, oat bran, rye cereals, prunes, dried apricots, and figs. These foods help to minimize the effect of nonpropulsive colonic contractions that may trap stool or retard its passage, causing abdominal pain. The patient should also increase her water intake to at least eight glasses per day.

Counseling to help the patient understand the relationship between stress and her illness is essential, as is instruction in stress-management techniques.

Drug therapy, if required, may include:

- u anticholinergic, antispasmodic drugs such as propantheline bromide to reduce intestinal hypermotility
- u antidiarrheals, such as diphenoxylate and atropine, to control diarrhea
- u laxatives for constipation
- u antiemetics such as metoclopramide to relieve heartburn, epigastric discomfort, and after-meal fullness
- u simethicone to relieve belching and bloating from gas in the stomach and intestines
- u mild tranquilizers such as diazepam prescribed for a short time to reduce psychological stress associated with irritable bowel syndrome
- u tricyclic antidepressants, if depression accompanies the disorder.

Nursing diagnoses

- u Body image disturbance u Constipation u Diarrhea u Ineffective individual coping u Knowledge deficit u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will maintain adequate caloric intake.
- u The patient's bowel function will return to normal.
- u The patient will express positive feelings about herself.
- u The patient's laboratory values will return to normal.
- u The patient will express an understanding of the disease process and treatment regimen.

Nursing interventions

Because the patient with irritable bowel syndrome isn't hospitalized, nursing interventions almost always focus on patient teaching.

Patient teaching

- u Explain irritable bowel syndrome to the patient, and reassure her that it can be relieved. Point out, however, that the condition is chronic with no known cure.
- u Help the patient understand ordered diagnostic tests. Review all pretest guidelines. Explain that diagnostic tests can't specifically diagnose irritable bowel syndrome but do rule out other disorders.
- u Help the patient develop a dietary plan and suggest ways to implement it. Help her schedule meals; the GI tract works best if meals are eaten at regular intervals. Show her how to keep a daily record of her symptoms and food intake, carefully noting which foods trigger symptoms. Advise her to eat slowly and carefully to prevent swallowing air, which causes bloating, and to increase her intake of dietary fiber.
- u Encourage the patient to drink 8 to 10 glasses of fluid per day. Point out that this will help regulate the consistency of her stools and promote balanced hydration. Caution her to avoid beverages associated with GI discomfort, such as carbonated or caffeine-containing drinks, fruit juices, and alcohol.
- u Discuss the proper use of prescribed drugs, reviewing their desired effects and possible adverse reactions.
- u Help the patient to implement lifestyle changes that reduce stress. Teach her to set priorities in her daily activities and, if possible, to delegate some responsibilities to other family members. Encourage her to schedule more time for rest and relaxation. Provide instruction in such relaxation techniques as guided imagery and deep-breathing exercises, and advise her to perform them regularly. If appropriate, instruct her to seek professional counseling for stress management.
- u Remind the patient that regular exercise is important to relieve stress and promote regular bowel function; even a 20- or 30-minute walk each day is helpful.
- u Discourage smoking. If the patient smokes, warn her that this habit can aggravate her symptoms by altering bowel motility.
- u Explain the need for regular physical examinations. For patients over age 40, emphasize the need for colorectal cancer screening, including annual proctosigmoidoscopy and rectal examinations.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis is characterized by diffuse or patchy intestinal necrosis. It's accompanied by sepsis in about one-third of cases. Sepsis usually involves

Escherichia coli, *Clostridium*, *Salmonella*, *Pseudomonas*, or *Klebsiella*. Initially, necrosis is localized, occurring anywhere along the intestine, but most often it's right-sided (in the ileum, ascending colon, or rectosigmoid). With early detection, the survival rate is 60% to 80%. If diffuse bleeding occurs, the disorder usually results in disseminated intravascular coagulation.

Necrotizing enterocolitis is most common in premature infants (less than 34 weeks' gestation) and those of low birth weight (less than 5 lb [2.3 kg]). It's related to 2% of all infant deaths, with onset usually occurring 1 to 14 days after birth.

Necrotizing enterocolitis has become more prevalent in some areas, possibly because of the higher incidence and survival of premature infants and neonates who have low birth weights. One in 10 infants who develops this disorder is full-term.

Causes

The exact cause of necrotizing enterocolitis is unknown. Possible predisposing factors include birth asphyxia, postnatal hypotension, respiratory distress, hypothermia, umbilical vessel catheterization, and patent ductus arteriosus. The disorder may also be a response to significant prenatal stress, such as premature rupture of membranes, placenta previa, maternal sepsis, toxemia of pregnancy, and breech or cesarean birth.

According to a current theory, necrotizing enterocolitis develops when the infant suffers perinatal hypoxemia that results when blood from the gut is shunted to more vital organs. Subsequent mucosal ischemia provides an ideal medium for bacterial growth. Hypertonic formula may increase bacterial activity because—unlike breast milk—it lacks protective immune activity and contributes to the production of hydrogen gas. As the bowel swells and breaks down, gas-forming bacteria invade damaged areas, producing free air in the intestinal wall and resulting in perforation and peritonitis.

Complications

Perforation, the major complication of necrotizing enterocolitis, requires surgery. Infants who survive acute necrotizing enterocolitis may develop recurrent disease or mechanical and functional abnormalities of the intestine. In surgical patients, these complications may develop as late as 3 months postoperatively.

Assessment findings

The maternal and patient histories may reveal one or more predisposing factors. Just before the onset of necrotizing enterocolitis, the infant may experience temperature instability, bradycardia, apnea, and lethargy or irritability. You may notice an increase in gastric aspirates, bile-stained vomitus, or bloody diarrhea. On inspection, the abdomen may appear distended. Suspect gastric retention if the abdomen feels tense or rigid on palpation. A taut abdomen, with red or shiny skin, may indicate peritonitis.

Diagnostic tests

Stool cultures may be used to identify the infecting organism, and stool analysis to identify occult blood.

Anteroposterior and lateral abdominal X-rays are used to confirm the diagnosis. These X-rays show nonspecific intestinal dilation and, in later stages of necrotizing enterocolitis, pneumatosis cystoides intestinalis (gas or air in the intestinal wall).

Blood studies show several abnormalities. Platelet count may fall below 50,000/μl, and serum sodium levels are decreased. Arterial blood gas levels show metabolic acidosis, indicating sepsis. Bilirubin levels are elevated because of infection-induced breakdown of erythrocytes. Blood cultures are used to identify the infecting organism. Clotting studies and hemoglobin levels show disseminated intravascular coagulation.

Abdominal X-rays are used to monitor the progress of the disorder.

Treatment

Medical management is supportive, with successful treatment dependent on early detection. At the first signs of necrotizing enterocolitis, oral feedings are discontinued for about 7 to 10 days to rest the injured bowel. I.V. fluids, including total parenteral nutrition, maintain fluid and electrolyte balance and nutrition during this time. To aid bowel decompression, a nasogastric (NG) tube is placed and connected to suction. If coagulation studies indicate a need for transfusion, the infant usually receives dextran to promote hemodilution, increase mesenteric blood flow, and reduce platelet aggregation.

Antibiotic therapy consists of parenteral administration of an aminoglycoside or ampicillin to suppress bacterial flora and prevent bowel perforation. (These drugs can also be administered through an NG tube, if necessary.)

Surgery is indicated if the patient develops any of the following: signs of perforation (free intraperitoneal air on X-ray or symptoms of peritonitis), respiratory insufficiency (caused by severe abdominal distention), progressive and intractable acidosis, or disseminated intravascular coagulation.

Surgery is used to remove all necrotic and acutely inflamed bowel, then creates a temporary colostomy or ileostomy. The procedure must leave at least 12" (30 cm) of bowel, or the infant may suffer from malabsorption or chronic vitamin B₁₂ deficiency.

Nursing diagnoses

⌚ Altered growth and development ⌚ Altered nutrition: Less than body requirements ⌚ Fluid volume deficit ⌚ Ineffective family coping ⌚ Pain⌚ Risk for altered parenting ⌚ Risk for infection

Key outcomes

- ⌚ The patient will express feelings of comfort.
- ⌚ The patient's fluid volume will remain within normal parameters.
- ⌚ The patient will remain free from signs and symptoms of infection.
- ⌚ The patient will maintain current weight without evidence of further loss.
- ⌚ The patient will exhibit adequate coping mechanisms and seek appropriate sources of support.

Nursing interventions

- ⌚ Provide psychological support for the parents, and remain with them during stressful periods. Answer their questions about their child's condition.
- ⌚ Monitor the patient continuously. Administer I.V. fluids and, if necessary, total parenteral nutrition as ordered. Monitor fluid and electrolyte levels, acid-base balance, and intake and output.
- ⌚ Administer prescribed antibiotics; observe the infant for adverse reactions.
- ⌚ Take axillary temperatures to avoid perforating the bowel.
- ⌚ Promptly dispose of soiled diapers to prevent cross-contamination. Wash your hands with soap and water after diaper changes.
- ⌚ Be alert for signs and symptoms of gastric distention and perforation, including apnea, bradycardia, cardiovascular shock, edema, erythema, increasing abdominal tenderness, involuntary abdominal rigidity, rag-doll limpness, a sudden drop in body temperature, or sudden listlessness. If any of these signs or symptoms occur, notify the doctor immediately.
- ⌚ If surgery is necessary, provide appropriate preoperative care.

After surgery:

- u Gently suction secretions, and frequently assess respirations.
- u Replace fluids lost through drainage from the NG tube and stoma. Include drainage losses in output records.
- u Weigh the infant daily. A daily weight gain of 0.35 to 0.7 oz (9.9 to 19.8 g) indicates a good response to therapy.
- u Because of the infant's small abdomen, the suture line is near the stoma; therefore, keeping the suture line clean can be a problem. Good skin care is essential because the immature infant's skin is fragile and vulnerable to excoriation, and the active enzymes in bowel secretions are corrosive.
- u Improvise tiny colostomy bags from urine collection bags, medicine cups, or condoms. Karaya gum may be used to make a seal.
- u Watch for wound disruption, infection, and excoriation. Monitor for signs and symptoms of intestinal malfunction from stricture or short-gut syndrome. Such complications usually develop 1 month after the infant resumes normal feedings.

Patient teaching

- u Explain necrotizing enterocolitis to the infant's parents, helping them to understand necessary tests and treatments. Try to prepare them for potential deterioration in their infant's condition. Be honest and explain all treatments, such as why feedings are withheld.
- u If the infant is scheduled for a temporary colostomy or ileostomy, reinforce the doctor's explanation of the surgery and explain why it's necessary. Reassure the parents that they'll be able to participate in their infant's physical care after his condition is no longer critical, and encourage them to do so.
- u Before discharge, refer the parents to community resources and home health care agencies as needed.
- u Encourage mothers whose infants are at risk for development of necrotizing enterocolitis to breast-feed. Point out that breast milk contains live macrophages that fight infection, and its low pH inhibits the growth of many organisms. Ideally, breast-feeding should begin immediately postpartum because colostrum (fluid secreted before the milk) contains high concentrations of maternal immunoglobulin A, which directly protects the infant gut from infection and which the infant lacks for several days postpartum.
- u If the mother plans to express breast milk for later use, instruct her to store it in plastic—not glass—containers because leukocytes adhere to glass. Tell the mother she may refrigerate her milk for 48 hours but shouldn't freeze or heat it because doing so destroys antibodies.

PANCREATITIS

Inflammation of the pancreas, or pancreatitis, occurs in acute and chronic forms. It's associated with biliary tract disease, alcoholism, trauma, and certain drugs, and it can be idiopathic. Acute pancreatitis generally resolves clinically and histologically but is serious in nature and has a 10% mortality. Chronic pancreatitis causes irreversible tissue damage and tends to progress to significant loss of pancreatic function.

Causes and pathophysiology

The most common causes of pancreatitis are biliary tract disease and alcoholism, but the disorder can also result from abnormal organ structure, metabolic or endocrine disorders (such as hyperlipidemia or hyperparathyroidism), pancreatic cysts or tumors, penetrating peptic ulcers, or trauma (blunt or iatrogenic, resulting from surgical manipulation). This disorder can develop after the use of certain drugs, such as glucocorticoids, sulfonamides, thiazides, and oral contraceptives.

Pancreatitis may result as a complication of renal failure and kidney transplantation or endoscopic retrograde cholangiopancreatography (ERCP). Heredity may be a predisposing factor and, in some patients, emotional or neurogenic factors are involved.

Regardless of the cause, pancreatitis involves autodigestion: The enzymes normally excreted into the duodenum by the pancreas are activated within the pancreas or its ducts and begin autodigestion of the pancreatic tissue. The consequent inflammation causes intense pain, third spacing of large volumes of fluids, pancreatic fat necrosis with accompanying consumption of serum calcium, and, occasionally, hemorrhage.

Complications

If pancreatitis damages the islets of Langerhans, diabetes mellitus may occur. Fulminant pancreatitis causes massive hemorrhage and total destruction of the pancreas, resulting in diabetic acidosis, shock, or coma. Respiratory complications include adult respiratory distress syndrome, atelectasis, pleural effusion, and pneumonia. Proximity of the inflamed pancreas to the bowel may cause paralytic ileus. Other complications include GI bleeding, pancreatic abscess, pseudocysts and, rarely, cancer.

Assessment findings

Commonly, the patient describes intense epigastric pain centered close to the umbilicus and radiating to the back, between the 10th thoracic and 6th lumbar vertebrae. He typically reports that eating fatty foods, consuming alcohol, or lying in a recumbent position aggravates this pain. He may also complain of weight loss with nausea and vomiting.

Investigation may uncover predisposing factors, such as alcoholism, biliary tract disease, and pancreatic disease. Other medical problems, such as peptic ulcer disease and hyperlipidemia, may be discovered.

Assessment of vital signs may reveal decreased blood pressure, tachycardia, and fever. These signs, if present, indicate respiratory complications. Other signs of respiratory complications are dyspnea and orthopnea. Observe the patient for changes in behavior and sensorium; these signs may be related to alcohol withdrawal or may indicate hypoxia or impending shock.

Abdominal inspection may disclose generalized jaundice, Cullen's sign (bluish periumbilical discoloration), and Turner's sign (bluish flank discoloration). Inspection of stools may reveal steatorrhea, a sign of chronic pancreatitis.

During abdominal palpation, you may note tenderness, rigidity, and guarding. If you hear a dull sound while percussing, suspect pancreatic ascites. If bowel sounds are absent or decreased on abdominal auscultation, suspect paralytic ileus.

Diagnostic tests

Elevated serum amylase and lipase levels are the diagnostic hallmarks that confirm acute pancreatitis. Characteristically, serum amylase reaches peak levels 24 hours after onset of pancreatitis, then returns to normal within 48 to 72 hours, despite continued symptoms. Amylase levels are also dramatically elevated in urine, ascites, and pleural fluid. Urine amylase levels and serum lipase levels remain elevated longer than serum amylase levels.

Supportive laboratory studies include elevated white blood cell count and serum bilirubin level. In many patients, hypocalcemia occurs and appears to be associated with the severity of the disease. Blood and urine glucose tests may reveal transient glucosuria and hyperglycemia. In chronic pancreatitis, significant laboratory findings include elevations in serum alkaline phosphatase, amylase, and bilirubin levels. Serum glucose levels may be transiently elevated. Stools contain elevated lipid and trypsin levels.

Abdominal and chest X-rays differentiate pancreatitis from other diseases that cause similar symptoms and detect pleural effusions.

Computed tomography scanning and ultrasonography reveal an increased pancreatic diameter. These tests also reveal pancreatic cysts and pseudocysts.

ERCP shows the anatomy of the pancreas. It's used to identify ductal system abnormalities, such as calcification and strictures, and to differentiate pancreatitis from other disorders such as pancreatic cancer.

Treatment

The goals of treatment are to maintain circulation and fluid volume, relieve pain, and decrease pancreatic secretions. Emergency treatment for shock (the most common cause of death in early stage pancreatitis) consists of vigorous I.V. replacement of electrolytes and proteins. Metabolic acidosis secondary to hypovolemia and impaired cellular perfusion requires vigorous fluid volume replacement. Blood transfusions may be needed if hemorrhage occurs. Food and fluids are withheld to allow the pancreas to rest and to reduce pancreatic enzyme secretion.

In acute pancreatitis, nasogastric (NG) tube suctioning is usually required to decrease gastric distention and suppress pancreatic secretions. Prescribed medications may include:

- u meperidine to relieve abdominal pain (this drug causes less spasm at the ampulla of Vater than do opiates such as morphine)
- u antacids to neutralize gastric secretions
- u histamine antagonists, such as cimetidine or ranitidine, to decrease hydrochloric acid production
- u antibiotics, such as clindamycin or gentamicin, to fight bacterial infections
- u anticholinergics to reduce vagal stimulation, decrease GI motility, and inhibit pancreatic enzyme secretion
- u total parenteral nutrition to maintain positive nitrogen balance
- u pancreatic enzymes if enzyme secretion is impaired
- u insulin to correct hyperglycemia, if present.

When the crisis begins to resolve, oral low-fat, low-protein feedings are gradually implemented. Alcohol and caffeine are eliminated from the diet. If the crisis occurred during treatment with glucocorticoids, oral contraceptives, or thiazide diuretics, these drugs are discontinued.

Surgery usually isn't indicated in acute pancreatitis. However, if complications occur, such as pancreatic abscess or pseudocyst, surgical drainage may be necessary. If biliary tract obstruction causes acute pancreatitis, a laparotomy may be required.

For chronic pancreatitis, treatment depends on the cause. Nonsurgical measures are appropriate if the patient isn't a suitable candidate for surgery or if he refuses this treatment. Measures to prevent and relieve abdominal pain are similar to those used in acute pancreatitis. Meperidine usually is the drug of choice; however, pentazocine also effectively relieves pain. Treatments for diabetes mellitus may include dietary modification, insulin replacement, or antidiabetic agents. Malabsorption and steatorrhea are treated with pancreatic enzyme replacement.

Surgical intervention relieves abdominal pain, restores pancreatic drainage, and reduces the frequency of acute pancreatic attacks. Surgical drainage is required for an abscess or a pseudocyst. If biliary tract disease is the underlying cause, cholecystectomy or choledochotomy is performed. A sphincterotomy is indicated to enlarge a pancreatic sphincter that has become fibrotic. To relieve obstruction and allow drainage of pancreatic secretions, pancreaticojejunostomy (anastomosis of the jejunum with the opened pancreatic duct) may be required.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Fluid volume deficit
- u Hopelessness
- u Ineffective breathing pattern
- u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's airway will remain patent.
- u The patient will express positive feelings about himself.
- u The patient's breathing pattern will remain within ± 5 of baseline.
- u The patient will avoid complications.
- u The patient's bowel function will return to normal.
- u The patient's skin integrity will remain intact.

Nursing interventions

- u Assess the patient's level of pain. As ordered, administer meperidine or other analgesics. Evaluate and document effectiveness of pain medications; watch for adverse reactions.
- u Maintain the NG tube for drainage or suctioning.
- u Restrict the patient to bed rest, and provide a quiet and restful environment.
- u Place the patient in a comfortable position that also allows maximal chest expansion, such as Fowler's position.
- u Assess pulmonary status at least every 4 hours to detect early signs of respiratory complications.
- u Monitor fluid and electrolyte balance and report any abnormalities. Maintain an accurate record of intake and output. Weigh the patient daily and record his weight.
- u Evaluate the patient's present nutritional status and metabolic requirements.
- u Provide I.V. fluids and parenteral nutrition as ordered. As soon as the patient can tolerate it, provide a diet high in carbohydrates, low in protein, and low in fat.
- u Monitor serum glucose levels and administer insulin as ordered.

ALERT Watch for signs of calcium deficiency: tetany, cramps, carpopedal spasm, and seizures. If you suspect hypocalcemia, keep airway and suction apparatus handy and pad the side rails of the bed.

- u Don't confuse thirst due to hyperglycemia (indicated by serum glucose levels up to 350 mg/dl and glucose and acetone in the urine) with dry mouth due to NG intubation and anticholinergics.
- u If the patient has chronic pancreatitis, allow him to express feelings of anger, depression, and sadness related to his condition, and help him to cope with these feelings. Encourage him to use appropriate physical outlets to express his emotions, such as pounding a punching bag and throwing pillows.
- u Counsel the patient to contact a self-help group, such as Alcoholics Anonymous, if needed.

Patient teaching

- u Emphasize the importance of avoiding factors that precipitate acute pancreatitis, especially alcohol.
- u Refer the patient and family members to the dietitian. Stress the need for a diet high in carbohydrates and low in protein and fats. Caution the patient to avoid beverages with caffeine and irritating foods.
- u Point out the need to comply with pancreatic enzyme replacement therapy. Instruct the patient to take the enzymes with meals or snacks to help digest food and to promote fat and protein absorption. Advise him to watch for and report any of the following signs and symptoms: fatty, frothy, foul-smelling stools; abdominal distention; cramping; and skin excoriation.

PEPTIC ULCERS

Peptic ulcers, which are circumscribed lesions in the mucosal membrane, can develop in the lower esophagus, stomach, duodenum, or jejunum. The major forms are duodenal ulcer and gastric ulcer; both are chronic conditions.

Duodenal ulcers, which account for about 80% of peptic ulcers, affect the proximal part of the small intestine. These ulcers, which occur most commonly in men between ages 20 and 50, follow a chronic course characterized by remissions and exacerbations. About 5% to 10% of patients with duodenal ulcers develop

complications that necessitate surgery.

Gastric ulcers, which affect the stomach mucosa, are most common in middle-aged and elderly men, especially among those who are poor and undernourished. This kind of ulcer also tends to occur in chronic users of aspirin or alcohol.

Causes and pathophysiology

Researchers have identified a bacterial infection with *Helicobacter pylori* (formerly known as *Campylobacter pylori*) as a leading cause of peptic ulcer disease. They also found that *H. pylori* releases a toxin that promotes mucosal inflammation and ulceration.

In a peptic ulcer resulting from *H. pylori*, acid seems to be mainly a contributor to the consequences of the bacterial infection rather than its dominant cause. Other risk factors include the use of certain medications—nonsteroidal anti-inflammatory drugs (NSAIDs), for example—and pathologic hypersecretory states, such as Zollinger-Ellison syndrome.

Investigators think drug therapy, particularly with salicylates and other NSAIDs, reserpine, or caffeine, may erode the mucosal lining. They believe that NSAIDs can cause a gastric ulcer by inhibiting prostaglandins (the fatty acids that mediate and suppress ulceration).

These substances are present in large quantities in the gastric mucosa, where they inhibit injury by stimulating secretion of gastric mucus and gastric and duodenal mucosal bicarbonate.

Prostaglandins also promote gastric mucosal blood flow, maintain the integrity of the gastric mucosal barrier, and help renew the epithelium after a mucosal injury. When an agent, such as an NSAID, inhibits prostaglandin production, ulceration can occur.

Glucocorticoids also predispose the patient to ulcer formation. These drugs inhibit prostaglandin synthesis, increase gastric acid and pepsin secretion, reduce gastric mucosal blood flow, and decrease cytoprotective mucus production. Because these drugs also decrease gastric pain, they can mask signs of ulcer development until hemorrhage or perforation occurs.

Certain illnesses—particularly pancreatitis, hepatic disease, Crohn's disease, preexisting gastritis, and Zollinger-Ellison syndrome—are believed to have a strong association with ulcer development.

Researchers continue to unveil the exact mechanisms of ulcer formation; several predisposing factors are known. These include:

- u *Blood type*. For unknown reasons, gastric ulcers commonly strike people who have type A blood. Duodenal ulcers tend to afflict people who have type O blood.
- u *Genetic factors*. Duodenal ulcers are about three times more common in first-degree relatives of duodenal ulcer patients than they are in the general population.
- u *Exposure to irritants*. Like certain other drugs, alcohol inhibits prostaglandin secretion, triggering a mechanism much like the one caused by NSAIDs.
- u *Cigarette smoking*. Smoking also appears to encourage ulcer formation. It evidently inhibits pancreatic secretion of bicarbonate by a mechanism involving nicotine. It may also accelerate the emptying of gastric acid into the duodenum and promote mucosal breakdown.
- u *Trauma*. Critical illness, shock, or severe tissue injury from extensive burns or intracranial surgery may lead to a stress ulcer.
- u *Psychogenic factors*. Emotional stress may stimulate long-term overproduction of gastric secretions that aid in ulcer production by eroding stomach, duodenal, and esophageal tissue.
- u *Normal aging*. The pyloric sphincter may wear down in the course of normal aging, which, in turn, permits the reflux of bile into the stomach. This appears to be a common contributor to the development of gastric ulcers in elderly people.

Complications

Erosion of the mucosa can cause GI hemorrhage, which can progress to hypovolemic shock, perforation, and obstruction. Obstruction of the pylorus may cause the stomach to distend with food and fluid and result in abdominal or intestinal infarction.

Penetration, in which the ulcer crater extends beyond the duodenal walls into attached structures, such as the pancreas, biliary tract, liver, and gastrohepatic omentum, occurs fairly frequently in duodenal ulcer.

Assessment findings

Typically, the patient describes periods of exacerbation and remission of his symptoms, with remissions lasting longer than exacerbations. Investigation of the patient's history may reveal possible causes or predisposing factors, such as smoking, use of aspirin or other medications, and associated disorders.

The patient with a gastric ulcer may report a recent loss of weight or appetite. He may explain that he doesn't feel like eating or that he has developed an aversion to food because eating causes discomfort. He may have pain in the left epigastrium, which he describes as heartburn or indigestion. His discomfort may be accompanied by a feeling of fullness or distention. Commonly, the onset of pain signals the start of an attack.

Symptoms of the two types of ulcers are often so similar that the source of the ulcer isn't discernible by examination. The patient's history helps distinguish between a gastric and a duodenal ulcer. Ask the patient whether his pain worsens after eating or is relieved by it. In the patient with a gastric ulcer, eating often triggers or aggravates pain. Conversely, food often relieves the pain of a duodenal ulcer. Also inquire whether the patient has experienced nocturnal pain that disrupts his sleep. The patient with a duodenal ulcer reports waking up because of pain; the patient with a gastric ulcer doesn't.

The patient with a duodenal ulcer may have epigastric pain that he describes as sharp, gnawing, or burning. Alternatively, he may describe the pain as boring or aching and poorly defined. Or he may liken it to a sensation of hunger, abdominal pressure, or fullness. Typically, pain occurs 90 minutes to 3 hours after eating. Because eating often reduces the pain of a duodenal ulcer, the patient may report a recent weight gain. Vomiting and other digestive disturbances are rare in these patients.

If the patient is anemic from blood loss, you may notice pallor on inspection. Palpation in the midline and midway between the umbilicus and the xiphoid process may disclose epigastric tenderness. Auscultation may reveal hyperactive bowel sounds.

Diagnostic tests

Barium swallow or upper GI and small-bowel series may reveal the presence of the ulcer. This is the initial test performed on a patient whose symptoms aren't severe.

Upper GI endoscopy or esophagogastroduodenoscopy confirms the presence of an ulcer and permits cytologic studies and biopsy to rule out *H. pylori* or cancer. Endoscopy is the major diagnostic test for peptic ulcers.

Upper GI tract X-rays reveal mucosal abnormalities.

Laboratory analysis may disclose occult blood in stools.

IgA anti-*H. pylori* test on a venous blood sample can be used to detect antibodies to *H. pylori* accurately.

Serologic testing may disclose clinical signs of infection such as an elevated white blood cell count.

Gastric secretory studies show hyperchlorhydria.

Carbon 13 (¹³C) urea breath test results reflect activity of *H. pylori*. (*H. pylori* contains the enzyme urease, which breaks down orally administered urea containing the radioisotope ¹³C before it's absorbed systemically. Low levels of ¹³C in exhaled breath point to *H. pylori* infection.)

Treatment

Medical management is essentially symptomatic, emphasizing drug therapy, physical rest, dietary changes, and stress reduction. For patients with severe symptoms or complications, surgery may be required.

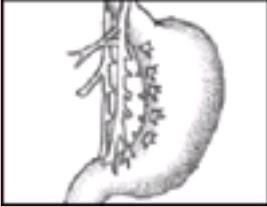

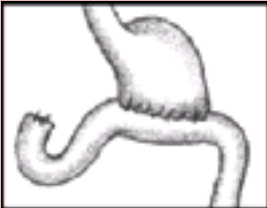

The goal of drug therapy is to eradicate *H. pylori*, reduce gastric secretions, protect the mucosa from further damage, and relieve pain. Medications may include:

- bismuth and two other antimicrobial agents, usually tetracycline or amoxicillin and metronidazole
- antacids to reduce gastric acidity
- histamine-2 receptor antagonists, such as cimetidine or ranitidine, to reduce gastric secretion for short-term therapy (up to 8 weeks), or gastric acid pump inhibitor (lansoprazole) for 4 weeks
- coating agents, such as sucralfate, for duodenal ulcers (Sucralfate forms complexes with proteins at the base of an ulcer, making a protective coat that prevents further digestive action of acid and pepsin.)
- antisecretory agents, such as misoprostol, if the ulceration resulted from NSAID use and the NSAID must be continued for another condition such as arthritis
- sedatives and tranquilizers, such as chlordiazepoxide and phenobarbital, for patients with gastric ulcers
- anticholinergics, such as propantheline, to inhibit the vagus nerve effect on the parietal cells and reduce gastrin production and excessive gastric activity in duodenal ulcers. (These drugs are usually contraindicated in gastric ulcers.)

Standard therapy also includes physical rest and decreased activity, which help decrease the amount of gastric secretion. Diet therapy may consist of eating six small meals daily (or small hourly meals) rather than three regular meals. Some doctors prescribe a milk and cream or bland diet, but the value of these measures is controversial.

If GI bleeding occurs, emergency treatment begins with passage of a nasogastric (NG) tube to allow iced saline lavage, possibly containing norepinephrine. Gastrosocopy allows visualization of the bleeding site and coagulation by laser or cautery to control bleeding. This therapy allows surgery to be postponed until the patient's condition stabilizes.

Surgery is indicated for perforation, unresponsiveness to conservative treatment, suspected cancer, and other complications. The type of surgery chosen for peptic ulcers depends on the location and extent of the disorder. Major operations include bilateral vagotomy, pyloroplasty, and gastrectomy. (See [Types of peptic ulcer surgery.](#))

Types of peptic ulcer surgery			
SURGERY		INDICATIONS	EFFECTS
Vagotomy			
Truncal (total abdominal vagotomy)		<ul style="list-style-type: none">▫ Recurrent ulcer disease▫ Acid reduction	<ul style="list-style-type: none">▫ Completely severs both vagus nerves at the esophageal base▫ Destroys gastric, intestinal, and gallbladder motility▫ Stops acid production▫ Causes impaired emptying and diarrhea
Selective vagotomy		<ul style="list-style-type: none">▫ Recurrent ulcer disease▫ Acid reduction	<ul style="list-style-type: none">▫ Severs vagus nerve▫ Destroys vagal innervation of stomach (but retains abdominal innervation)▫ Reduces acid production▫ Impairs gastric motility
Highly selective (parietal cell vagotomy)		<ul style="list-style-type: none">▫ Recurrent ulcer disease▫ Acid reduction	<ul style="list-style-type: none">▫ Severs only the parietal cell branches of vagus nerve▫ Denervates acid-producing cells but doesn't affect motility
Pyloroplasty			
		<ul style="list-style-type: none">▫ Pyloric stricture or obstruction (may be combined with vagotomy to reduce gastric secretion and motility)	<ul style="list-style-type: none">▫ Enlarges pylorus by removing sphincter▫ Improves drainage; eliminates obstruction▫ Facilitates neutralization without inhibiting gastric secretion▫ Increases gastric emptying
Gastrectomy			
Billroth I (gastroduodenostomy, hemigastrectomy)		<ul style="list-style-type: none">▫ Gastric ulcer▫ Pyloric obstruction▫ Hemorrhage	<ul style="list-style-type: none">▫ Resects antrum and connects gastric remnant to proximal duodenum▫ Destroys antral function and pyloric sphincter▫ Reduces gastric secretion; increases emptying▫ May cause bile reflux, steatorrhea, dumping syndrome, weight loss, vomiting, and anemia
Billroth II (gastrojejunostomy)		<ul style="list-style-type: none">▫ Duodenal ulcer▫ Pyloric obstruction	<ul style="list-style-type: none">▫ Resects antrum▫ Attaches gastric remnant to proximal jejunum (retains duodenum)▫ Destroys antral function▫ Allows digestive secretions of liver and pancreas to mix in duodenum▫ Reduces gastric secretion; increases emptying▫ Commonly causes steatorrhea, dumping

			(retains duodenum) <ul style="list-style-type: none"> Destroys antral function Allows digestive secretions of liver and pancreas to mix in duodenum Reduces gastric secretion; increases emptying Commonly causes steatorrhea, dumping syndrome, weight loss, vomiting, and anemia
Total gastrectomy (esophagojejunostomy)		<ul style="list-style-type: none"> Ulcer disease Perforation Gastric cancer 	<ul style="list-style-type: none"> Resects stomach from lower esophageal sphincter to duodenal bulb; anastomoses duodenum and esophagus Destroys gastric function; ingested materials pass from esophagus to duodenum
Gastric resection (antrectomy)		<ul style="list-style-type: none"> Recurrent ulcers Perforation 	<ul style="list-style-type: none"> Removes stomach portion Varies, depending on stomach portion removed (for example, antrectomy alters digestive function)

Nursing diagnoses

- Altered nutrition: Less than body requirements
- Anxiety
- Fluid volume deficit
- Knowledge deficit
- Pain
- Risk for injury
- Sleep pattern disturbance

Key outcomes

- The patient will maintain adequate fluid volume.
- The patient will express feelings of comfort.
- The patient will avoid complications.
- The patient will resume regular sleep patterns.
- The patient will express an understanding of the disorder and comply with the treatment regimen.

Nursing interventions

- Support the patient emotionally and offer reassurance.
- Administer prescribed medications. Monitor the patient for the desired effects and watch for adverse reactions. Most medications should alleviate the patient's discomfort, so ask whether his pain is relieved.
- Provide six small meals or small hourly meals as ordered. Advise the patient to eat slowly, chew thoroughly, and have small snacks between meals.
- Schedule the patient's care so that he can get plenty of rest.

ALERT Continuously monitor the patient for complications: hemorrhage (sudden onset of weakness, fainting, chills, dizziness, thirst, the desire to defecate, and passage of loose, tarry, or even red stools); perforation (acute onset of epigastric pain followed by lessening of the pain and the onset of a rigid abdomen, tachycardia, fever, or rebound tenderness); obstruction (feeling of fullness or heaviness, copious vomiting containing undigested food after meals); and penetration (pain radiating to the back, night distress). If any of the above occurs, notify the doctor immediately.

After surgery:

- Keep the NG tube (that was inserted in the operating room) patent. If the tube isn't functioning, don't reposition it; you could damage the suture line or anastomosis. Notify the surgeon promptly.
- Monitor intake and output, including NG tube drainage. Also, check bowel sounds. Allow the patient nothing by mouth until peristalsis resumes and the NG tube is removed or clamped.
- Replace fluids and electrolytes. Assess for signs of dehydration, sodium deficiency, and metabolic alkalosis, which can occur secondary to gastric suction. Provide parenteral nutrition, if ordered. This is usually given if the patient isn't allowed to eat for 1 week or more.
- Control postoperative pain with narcotics and analgesics as ordered.
- Watch for complications: hemorrhage; shock; iron, folate, or vitamin B₁₂ deficiency anemia; and dumping syndrome.

Patient teaching

- Teach the patient about peptic ulcer disease, and help him to recognize its signs and symptoms. Explain scheduled diagnostic tests and prescribed therapies. Review symptoms associated with complications, and urge him to notify the doctor if any of these occur. Emphasize the importance of complying with treatment, even after his symptoms are relieved.
- Review the proper use of prescribed medications, discussing the desired actions and possible adverse reactions of each drug.
- Instruct the patient to take antacids 1 hour after meals. If he follows a sodium-restricted diet, advise him to take only low-sodium antacids. Caution him that antacids may cause changes in bowel habits (diarrhea with magnesium-containing antacids, constipation with aluminum-containing antacids).
- Check all medications the patient is using. Antacids inhibit the absorption of many other drugs, including digoxin. Work out a schedule for taking medications.
- Warn against excessive intake of coffee and alcoholic beverages during exacerbations.
- Encourage the patient to make appropriate lifestyle changes. Explain that emotional tension can precipitate an ulcer attack and prolong healing. Help the patient identify anxiety-producing situations, and teach him to perform relaxation techniques, such as distraction and meditation.
- If the patient smokes, urge him to stop because smoking stimulates gastric acid secretion. Refer him to a smoking-cessation program.
- Tell the patient to read labels of nonprescription medications and to avoid preparations that contain corticosteroids, aspirin, or other NSAIDs such as ibuprofen. Explain that these drugs inhibit mucus secretion and therefore leave the GI tract vulnerable to injury from gastric acid. Advise him to use alternative analgesics such as acetaminophen. Caution him to avoid systemic antacids such as sodium bicarbonate, because they're absorbed into the circulation and can cause an acid-base imbalance.
- Tell the patient that, although cimetidine, famotidine, and other histamine-receptor antagonists are available over-the-counter, he shouldn't take them without consulting his doctor. These drugs may duplicate prescribed medications or suppress important symptoms.
- To avoid dumping syndrome after gastric surgery, advise the patient to lie down after meals, drink fluids between meals rather than with meals, avoid eating large amounts of carbohydrates and eat four to six small high-protein, low-carbohydrate meals daily.

PERITONITIS

Peritonitis—an acute or chronic disorder—is an inflammation of the peritoneum, the membrane that lines the abdominal cavity and covers the visceral organs. Such inflammation may extend throughout the peritoneum or be localized as an abscess. Peritonitis commonly decreases intestinal motility and causes intestinal distention with gas. Mortality is about 10%; bowel obstruction is the usual cause of death.

Causes

The GI tract normally contains bacteria, but the peritoneum is sterile. In peritonitis, bacteria invade the peritoneum; generally, such infection results from inflammation and perforation of the GI tract, allowing bacterial invasion. Usually, this is a result of appendicitis, diverticulitis, peptic ulcer, ulcerative colitis, volvulus, strangulated obstruction, abdominal neoplasm, or a stab wound. Peritonitis can also result from chemical inflammation after rupture of a fallopian tube, ovarian cyst, or the bladder; perforation of a gastric ulcer; or released pancreatic enzymes.

In both bacterial and chemical inflammation, fluid containing protein and electrolytes accumulates in the peritoneal cavity and makes the transparent peritoneum opaque, red, inflamed, and edematous. Because the peritoneal cavity is so resistant to contamination, such infection is often localized as an abscess rather than

disseminated as a generalized infection.

Complications

Peritonitis can lead to abscess, septicemia, respiratory compromise, bowel obstruction, and shock.

Assessment findings

The patient's symptoms depend on when the disorder is assessed, early or late in its course. In the early phase, the patient may report vague, generalized abdominal pain. If peritonitis is localized, he may describe pain over a specific area (usually over the site of inflammation); if the peritonitis is generalized, he may complain of diffuse pain over the abdomen.

As the disorder progresses, the patient typically reports increasingly severe and constant abdominal pain. Pain often increases with movement and respirations. Occasionally, pain may be referred to the shoulder or the thoracic area. Other signs and symptoms include abdominal distention, anorexia, nausea, vomiting, and an inability to pass stools and flatus.

Assessment of vital signs may reveal fever, tachycardia (a response to the fever), and hypotension. On inspection, the patient usually appears acutely distressed. He may lie very still in bed, often with his knees flexed to try to alleviate abdominal pain. He tends to breathe shallowly and move as little as possible to minimize pain. If he loses excessive fluid, electrolytes, and proteins into the abdominal cavity, you may observe excessive sweating, cold skin, pallor, abdominal distention, and signs of dehydration such as dry mucous membranes.

Early in peritonitis, auscultation usually discloses bowel sounds; as the inflammation progresses, these sounds tend to disappear. Abdominal rigidity is usually felt on palpation. If peritonitis spreads throughout the abdomen, palpation may disclose general tenderness; if peritonitis stays in a specific area, you may detect local tenderness. Rebound tenderness may also be present.

Diagnostic tests

The following tests support the diagnosis:

White blood cell count shows leukocytosis (commonly more than 20,000/ μ l).

Abdominal X-rays demonstrate edematous and gaseous distention of the small and large bowel. With perforation of a visceral organ, the X-ray shows air in the abdominal cavity. Chest X-ray may reveal elevation of the diaphragm.

Paracentesis discloses the nature of the exudate and permits bacterial culture so appropriate antibiotic therapy can be instituted.

Treatment

To prevent peritonitis, early treatment of GI inflammatory conditions and preoperative and postoperative antibiotic therapy are important. After peritonitis develops, emergency treatment is instituted to combat infection, restore intestinal motility, and replace fluids and electrolytes.

Antibiotic therapy depends on the infecting organism but usually includes administration of cefoxitin with an aminoglycoside or penicillin G and clindamycin with an aminoglycoside. To decrease peristalsis and prevent perforation, the patient should receive nothing by mouth; instead, he requires supportive fluids and electrolytes parenterally.

Supplementary treatment includes administration of an analgesic such as meperidine, nasogastric (NG) intubation to decompress the bowel, and possible use of a rectal tube to facilitate the passage of flatus.

Surgery, the treatment of choice, eliminates the cause of peritonitis. As soon as the patient's condition is stable enough to tolerate surgery, the source of infection is eliminated by evacuating the spilled contents and inserting drains.

The surgical procedure varies with the cause of peritonitis. For example, if appendicitis is the cause, an appendectomy is performed; if the colon is perforated, a colon resection may be performed. Occasionally, abdominocentesis may be necessary to remove accumulated fluid. Irrigation of the abdominal cavity with antibiotic solutions during surgery may be appropriate.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered tissue perfusion (GI) u Anxiety u Fear u Fluid volume deficit u Pain

Key outcomes

- u The patient's vital signs will return to within normal parameters.
- u The patient will express feelings of comfort.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's bowel function will return to normal.
- u The patient will maintain adequate caloric intake.

Nursing interventions

- u Provide psychological support, and offer encouragement when appropriate.
- u Administer prescribed medications, such as analgesics and antibiotics, as ordered; monitor the patient for desired effects and possible adverse reactions.
- u Maintain parenteral fluid and electrolyte administration as ordered. Monitor fluid volume by checking skin turgor, mucous membranes, urine output, weight, vital signs, amount of NG tube drainage, and amount of I.V. infusion. Accurately record intake and output, including NG tube drainage.
- u Maintain bed rest, and place the patient in semi-Fowler's position to help him breathe deeply with less pain, preventing pulmonary complications.
- u Counteract mouth and nose dryness due to fever, dehydration, and NG intubation with regular hygiene and lubrication.

After surgery:

- u Place the patient in Fowler's position to promote drainage (through a drainage tube) by gravity. Move him carefully because the slightest movement will intensify the pain. Keep the side rails up, and implement other safety measures if fever and pain disorient the patient.
- u Immediately after surgery, monitor the patient's pain, vital signs, level of consciousness, respiratory status, bowel signs and abdominal distention, incisional drainage, urine output, NG tube drainage, and I.V. fluid intake at least once every hour or as ordered.
- u Allow the patient nothing by mouth, as ordered, until NG tube suction is discontinued. Administer parenteral feedings as ordered.
- u If necessary, administer ordered blood transfusions.
- u Encourage and assist ambulation, as ordered, usually on the first postoperative day.
- u Frequently assess for peristaltic activity by listening for bowel sounds and checking for flatus, bowel movements, and a soft abdomen. When peristalsis resumes, and temperature and pulse rate become normal, gradually decrease parenteral fluids and increase oral fluids. If the patient has an NG tube in place, clamp it for short intervals. If nausea or vomiting doesn't result, begin oral fluids as ordered and tolerated.

ALERT Watch for signs of dehiscence (the patient may complain that “something gave way”) and abscess formation (continued abdominal tenderness and fever).

u If necessary, refer the patient to the facility's social service department or a home health care agency that can help him obtain needed services during convalescence.

Patient teaching

- u Teach the patient about peritonitis, its cause (in his case), and necessary treatments. If time allows before surgery, reinforce the doctor's explanation of the procedure and its possible complications. Tell him how long he can expect to be hospitalized; many patients remain hospitalized for 2 weeks or more after surgery.
- u Provide teaching before surgery. Include coughing and deep-breathing instructions. Review postoperative care procedures.
- u Instruct the patient to report any swelling, drainage, bleeding, redness, warmth, or odor from the incision. Teach him how to care for the incision, including how to change the dressing and how to irrigate the wound, if necessary.
- u Discuss the proper use of prescribed medications, reviewing their correct administration, desired effects, and possible adverse reactions.
- u Review diet and activity limitations (depending on the type of surgery). Typically, the patient must avoid lifting for at least 6 weeks postoperatively.

PSEUDOMEMBRANOUS ENTEROCOLITIS

Pseudomembranous enterocolitis is an acute inflammation and necrosis of the small and large intestines. It usually affects the mucosa but may extend into the submucosa and, rarely, other layers. This rare condition, marked by severe diarrhea, can be fatal in 1 to 7 days from severe dehydration and from toxicity, peritonitis, or perforation.

Causes

What triggers the acute inflammation and necrosis characteristic of this disorder is unknown; however, *Clostridium difficile* may produce a toxin that plays a role in its development. The disease typically occurs in patients who are undergoing treatment with broad-spectrum antibiotics or who received such therapy in the previous 4 weeks. Nearly all broad-spectrum antibiotics, especially clindamycin, ampicillin, and the cephalosporins, have been linked with its onset. Possible exceptions are vancomycin, metronidazole, and aminoglycosides.

Pseudomembranous enterocolitis may also occur postoperatively in debilitated patients undergoing abdominal surgery. Whatever the cause, the necrosed mucosa is replaced by a pseudomembrane filled with staphylococci, leukocytes, mucus, fibrin, and inflammatory cells.

Complications

Severe dehydration, electrolyte imbalance, hypotension, shock, colonic perforation, and peritonitis are among the potentially fatal complications associated with this disorder.

Assessment findings

The patient's history usually reveals current or recent antibiotic treatment. Typically, the patient reports the sudden onset of copious, watery or, rarely, bloody diarrhea; abdominal pain; and fever. Palpation may reveal abdominal tenderness.

Careful consideration of the patient's history is essential because the abrupt onset of enterocolitis and the emergency situation it creates can make diagnosis difficult.

Diagnostic tests

A rectal biopsy through sigmoidoscopy confirms pseudomembranous enterocolitis. Stool cultures can be used to identify *C. difficile*.

Treatment

If the patient is receiving broad-spectrum antibiotic treatment, the first priority is immediate discontinuation of the offending drug. Usually, the patient is then treated with oral metronidazole or oral vancomycin. Metronidazole generally is used first; if it's ineffective, vancomycin is given.

Supportive treatments include maintaining fluid and electrolyte balance and combatting hypotension and shock with vasopressors, such as dopamine and norepinephrine.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Altered tissue perfusion (GI) u Diarrhea u Fluid volume deficit u Pain u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will maintain adequate caloric intake.
- u The patient's bowel function will return to normal.
- u The patient's laboratory values will return to normal.
- u The patient's vital signs will remain stable.
- u The patient will express an understanding of the disease process and treatment regimen.

Nursing interventions

- u Monitor vital signs, skin color, and level of consciousness. Immediately report signs of shock.
- u Record fluid intake and output, including fluid lost in stools. Watch for dehydration (poor skin turgor, sunken eyes, and decreased urine output). If ordered, administer I.V. therapy to maintain fluid and electrolyte balance.
- u Check serum electrolyte levels daily, and watch for clinical signs of hypokalemia (especially malaise) and a weak, rapid, irregular pulse.
- u Administer medications as ordered. Monitor for their desired effects and for adverse reactions.
- u Keep the patient as comfortable as possible. Administer analgesics, if necessary, to decrease abdominal pain and antipyretics to control high fever. Teach the patient how to perform such relaxation techniques as distraction and guided imagery to help him cope with abdominal pain.
- u Keep a bedpan within the patient's reach to help prevent embarrassing accidents.
- u Use standard precautions to prevent the spread of the infecting organism to other patients.

Patient teaching

- u Teach the patient about pseudomembranous enterocolitis and its possible causes; discuss signs and symptoms, diagnostic tests, and treatments.
- u Review prescribed medications, explaining their desired effects, potential adverse reactions, and proper administration.
- u Point out that because pseudomembranous enterocolitis recurs in about 20% of cases, the patient must immediately report symptoms of recurrence. Reassure him that a second course of therapy resolves the disorder.

u If the disorder was antibiotic-related, instruct the patient to caution doctors who might prescribe similar medications in the future.

ULCERATIVE COLITIS

Ulcerative colitis is an inflammatory, commonly chronic disease that causes ulcerations of the mucosa in the colon. It usually begins in the rectum and sigmoid colon and may extend upward into the entire colon; it rarely affects the small intestine, except for the terminal ileum. Ulcerative colitis produces congestion, edema (leading to mucosal friability), and ulcerations. Severity ranges from a mild, localized disorder to a fulminant disease that can cause many complications.

Ulcerative colitis occurs primarily in young adults, especially women; it's also more prevalent among Jewish people and higher socioeconomic groups. The incidence of the disease is unknown, but some studies indicate that as many as 1 out of 1,000 persons are affected. Onset of symptoms seems to peak between ages 15 and 30 and again between ages 50 and 70.

Causes

Although the etiology of ulcerative colitis is unknown, it may be related to an abnormal immune response in the GI tract, possibly associated with genetic factors. Stress was once thought to be a cause of ulcerative colitis. Studies have since shown that although it isn't a cause, it can increase the severity of an attack. Although no specific organism has been linked to the disease, infection hasn't been ruled out as a cause.

Complications

Ulcerative colitis can lead to a variety of complications, depending on the severity and site of inflammation. Nutritional deficiencies are the most common complication, but the disease can also lead to perineal sepsis with anal fissure, anal fistula, perirectal abscess, hemorrhage, and toxic megacolon. A patient with ulcerative colitis has an increased risk of various arthritis types (40 times more prevalent in this group than in the general population) and cancer (if the disease has persisted more than 10 years since childhood).

Other complications include coagulation defects resulting from vitamin K deficiency, erythema nodosum on the face and arms, pyoderma gangrenosum on the legs and ankles, uveitis, pericholangitis, sclerosing cholangitis, cirrhosis, possible cholangiocarcinoma, ankylosing spondylitis, loss of muscle mass, strictures, pseudopolyps, stenosis, and perforated colon, leading to peritonitis and toxemia.

Assessment findings

Usually, the patient's history reveals periods of remission and exacerbation of symptoms. During an exacerbation, the patient generally reports mild cramping, lower abdominal pain, and recurrent bloody diarrhea as often as 10 to 25 times per day. She may also experience nocturnal diarrhea. During these periods, she may complain of fatigue, weakness, anorexia, weight loss, nausea, and vomiting.

On inspection, the patient's stools may appear liquid, with visible pus and mucus. Check for blood in the stools, a cardinal sign of ulcerative colitis. Abdominal distention may be present in fulminant disease. Palpation may disclose abdominal tenderness. A rectal examination may reveal perianal irritation, hemorrhoids, and fissures. Rarely, rectal fistulas and abscesses are evident.

Diagnostic tests

Sigmoidoscopy confirms rectal involvement in most cases by showing increased mucosal friability, decreased mucosal detail, and thick inflammatory exudate.

Colonoscopy may be used to determine the extent of the disease and to evaluate the areas of stricture and pseudopolyps. This test isn't performed when the patient has active signs and symptoms.

Biopsy, performed during colonoscopy, can help confirm the diagnosis.

Barium enema is used to evaluate the extent of the disease and to detect complications, such as strictures and carcinoma. This study isn't performed in a patient with active signs and symptoms.

Stool specimen analysis reveals blood, pus, and mucus, but no pathogenic organisms.

Other supportive laboratory tests show decreased serum levels of potassium, magnesium, hemoglobin, and albumin, as well as leukocytosis and increased prothrombin time. An elevated erythrocyte sedimentation rate correlates with the severity of the attack.

Treatment

The goals of treatment are to control inflammation, replace nutritional losses and blood volume, and prevent complications. Supportive treatment includes dietary therapy, bed rest, I.V. fluid replacement, and medications. Blood transfusions or iron supplements may be needed to correct anemia.

Dietary measures depend on the severity of the disease. Patients with severe disease usually receive total parenteral nutrition and are allowed nothing by mouth. Parenteral nutrition is also used for patients awaiting surgery or showing signs of dehydration and debilitation from excessive diarrhea. The goals of parenteral nutrition are to rest the intestinal tract, decrease stool volume, and restore positive nitrogen balance.

The patient with moderate signs and symptoms may receive Ensure or another brand of elemental feeding to provide adequate nutrition with minimal bowel stimulation. A low-residue diet may be ordered for the patient with mild signs and symptoms. As signs and symptoms subside, the diet may gradually advance to include a greater variety of foods.

Drug therapy to control inflammation includes corticotropin and adrenal corticosteroids, such as prednisone, prednisolone, and hydrocortisone; sulfasalazine, which has anti-inflammatory and antimicrobial properties; and mesalamine, given rectally or orally. Antispasmodics, such as belladonna tincture, and antidiarrheals, such as diphenoxylate and atropine, are used only for the patient with frequent, troublesome diarrhea whose ulcerative colitis is otherwise under control. These drugs may precipitate massive dilation of the colon (toxic megacolon) and are generally contraindicated.

Surgery, the treatment of last resort, is performed if the patient has toxic megacolon, if she fails to respond to drugs and supportive measures, or if she finds signs and symptoms unbearable.

The most common surgical technique is proctocolectomy with ileostomy. Total colectomy and ileorectal anastomosis is done less often because of its mortality (2% to 5%). This procedure is done to remove the entire colon and anastomose the rectum and terminal ileum. It requires observation of the remaining rectal stump for any signs of cancer or colitis.

Pouch ileostomy, in which a pouch is created from a small loop of the terminal ileum and a nipple valve is formed from the distal ileum, is gaining popularity. The resulting stoma opens just above the pubic hairline; the pouch empties through a catheter inserted in the stoma several times a day. In ulcerative colitis, colectomy to prevent colon cancer is controversial.

Ileoanal reservoir is a surgery that preserves the anal sphincter and provides the patient with a reservoir made from the ileum and attached to the anal opening. The procedure is performed in two steps. First, the rectal mucosa is excised. An abdominal colectomy is performed; then a reservoir is constructed and attached. After that, a temporary loop ileostomy is created to allow the new rectal reservoir to heal. Finally, the loop ileostomy is closed after a 3- or 4-month waiting period. Stools

from the reservoir are similar to stools from an ileostomy.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Body image disturbance u Diarrhea u Ineffective individual coping u Knowledge deficit u Pain u Risk for fluid volume deficit u Risk for impaired skin integrity u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's skin integrity will remain intact.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will avoid or minimize complications.
- u The patient will maintain adequate caloric intake.

Nursing interventions

- u Support the patient emotionally. Stay with her when she's acutely distressed. Listen to her concerns, and offer reassurance when appropriate.
- u Provide diet therapy as ordered. Monitor the fluid and electrolyte status of the patient on total parenteral nutrition. Change dressings, and assess for inflammation at the insertion site. Check urine every 6 hours for glucose and acetone.
- u Provide frequent mouth care for the patient who's allowed nothing by mouth. Regardless of the prescribed diet, monitor intake and calorie count. Record intake and output, noting the frequency and number of stools.
- u Monitor hemoglobin level and hematocrit and give blood transfusions as ordered.
- u Administer medications as ordered, and monitor for desired effects. Note any adverse reactions such as those from prolonged corticosteroid therapy. Be aware that such therapy can mask infection.
- u Watch for signs of dehydration (poor skin turgor, furrowed tongue) and electrolyte imbalances, especially signs of hypokalemia (muscle weakness, paresthesia) and hypernatremia (tachycardia, fever, dry tongue).
- u Schedule care to allow for frequent rest periods. These patients are often very tired and weak.
- u After each bowel movement, thoroughly clean the skin around the rectum and apply a soothing and protective agent, such as petroleum jelly, to the irritated area. Provide an air mattress to help prevent skin breakdown.

ALERT Watch closely for signs and symptoms of complications, such as a perforated colon and peritonitis (fever, severe abdominal pain, abdominal rigidity and tenderness, cool clammy skin), and toxic megacolon (abdominal distention, decreased bowel sounds). Report these immediately.

- u If surgery is to be performed, provide preoperative care as required. Do a bowel preparation, if ordered. This usually involves keeping the patient on a clear-liquid diet, using cleansing enemas, and administering an antimicrobial agent such as neomycin.
- u After surgery, provide all necessary postoperative care. Monitor vital signs, intake and output, fluid and electrolyte levels, and respiratory status. Change dressings and maintain skin integrity. Provide comfort measures.
- u If the postoperative patient has a nasogastric tube, keep the tube patent. After removal of the tube, provide a clear-liquid diet as ordered, and gradually advance to a low-residue diet as tolerated.

Patient teaching

- u Teach the patient about ulcerative colitis, and review its signs and symptoms. Explain diagnostic tests and ordered treatments.
- u Discuss all prescribed dietary changes, and help the patient understand how these measures will decrease her symptoms. If she's placed on parenteral nutrition or a very restricted diet, reassure her that she'll progress to a more advanced diet as her symptoms resolve. In general, caution the patient to avoid GI stimulants, such as caffeine, alcohol, and smoking.
- u Review the patient's medications with her. Explain the desired actions, dosage, and adverse reactions.
- u If the patient is scheduled for surgery, reinforce the doctor's explanation of the procedure and its possible complications. As part of preoperative teaching, describe the stoma and explain how it differs from normal anatomy. Provide additional patient information as needed (available from the United Ostomy Association). Arrange for a visit by an enterostomal therapist and, ideally, a recovered ileostomy patient.
- u After a proctocolectomy and ileostomy, teach stoma care. After a pouch ileostomy, demonstrate procedures to insert the catheter and care for the stoma.
- u Emphasize the need for regular physical examinations because of the increased risk of colorectal cancer.

VOLVULUS

Volvulus is a twisting of the intestine at least 180 degrees on itself. It's marked by sudden onset of severe abdominal pain. Volvulus results in blood vessel compression and causes obstruction both proximal and distal to the twisted loop. (See [What happens in volvulus.](#))

Volvulus occurs in a bowel segment long enough to twist. The most common area, particularly in adults, is the sigmoid colon; the small bowel is a common site in children. Other common sites include the stomach and cecum.

Causes

In volvulus, twisting may result from an anomaly of bowel rotation in utero, an ingested foreign body, or an adhesion. Volvulus secondary to meconium ileus may occur in patients with cystic fibrosis. In some patients, the cause is unknown.

Complications

Without immediate treatment, volvulus can lead to strangulation of the twisted bowel loop, ischemia, infarction, perforation, and fatal peritonitis.

Assessment findings

The patient with volvulus complains of severe abdominal pain and may report bilious vomiting. If the patient is an infant, the parents may report increased vomiting of feedings. The history may also reveal the passage of bloody stools.

On inspection, the patient appears to be in pain. Abdominal inspection and palpation may reveal distention and a palpable mass.

Diagnostic tests

Abdominal X-rays may show multiple distended bowel loops and a large bowel without gas. In midgut volvulus, abdominal X-rays may be normal.

In cecal volvulus, barium from a barium enema fills the colon distal to the section of cecum; in sigmoid volvulus, barium may twist to a point and, in adults, take on an “ace of spades” configuration.

White blood cell count, in strangulation, is greater than 15,000/µl. In bowel infarction, it's greater than 20,000/µl.

Treatment

The severity and location of the volvulus are considered when determining therapy. For children with midgut volvulus, surgery is required. For adults with sigmoid volvulus, nonsurgical treatment includes proctoscopy to check for infarction and reduction by careful insertion of a flexible sigmoidoscope to deflate the bowel. Expulsion of flatus and immediate relief of abdominal pain indicate success of nonsurgical reduction.

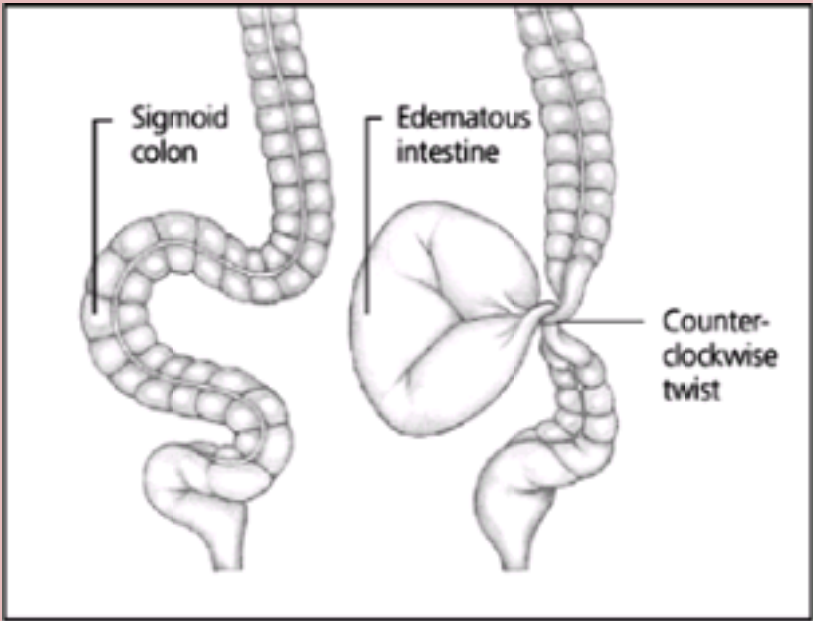

If the bowel is distended but viable, surgery consists of detorsion (untwisting); if the bowel is necrotic, surgery includes resection and anastomosis. Prolonged total parenteral nutrition and I.V. administration of antibiotics are usually necessary. Sedatives may be needed.

What happens in volvulus

Although volvulus may occur anywhere in a bowel segment long enough to twist, the most common site, as this illustration depicts, is the sigmoid colon, causing edema within the closed loop and obstruction at both its proximal and distal ends.

NORMAL BOWEL SEGMENT

VOLVULUS

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (GI)
- u Fluid volume deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's vital signs will remain stable.
- u The patient will avoid complications.
- u The patient's bowel function will return to normal.
- u Family members will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Provide psychological support. Listen to the patient's concerns, and offer reassurance; take time to answer his questions.
- u Administer analgesics and broad-spectrum antibiotics as ordered. Monitor the patient for desired effects and potential adverse reactions before and after surgery.
- u Monitor vital signs, intake and output, and fluid and electrolyte balance.
- u Administer I.V. fluids as ordered.
- u Insert a nasogastric (NG) tube and connect to low-pressure, intermittent suction, if ordered, to relieve abdominal distention.
- u Provide appropriate preoperative care, if surgery is to be performed.

After surgical correction of volvulus:

- u Monitor vital signs, watching for temperature changes (a sign of sepsis) and a rapid pulse rate and decreasing blood pressure (signs of shock and peritonitis). If ordered, administer total parenteral nutrition. Carefully monitor fluid intake and output (including stools), electrolyte levels, and complete blood count. Be sure to measure and record drainage from the NG tube and any surgical drains.
- u When bowel sounds and peristalsis resume, begin oral feedings with clear liquids as ordered. Before removing the NG tube, clamp it for a trial period, and watch for abdominal distention. When solid food can be tolerated, gradually expand the diet.
- u Encourage frequent coughing and deep breathing. Reposition the patient often, and suction him as needed.
- u Keep the dressings clean and dry. Record any excessive or unusual drainage. Later, check for incisional inflammation and suture separation.

Patient teaching

- u Explain what happens in volvulus, using teaching aids, if available. Review the signs and symptoms and possible complications. Discuss necessary diagnostic procedures and treatments.
- u Reinforce the doctor's explanation of scheduled surgery and its possible complications. Provide preoperative teaching.
- u If the patient is a child, encourage the parents to participate in his care to minimize the stress of hospitalization.
- u If surgery was extensive, or if the patient's condition requires it, refer the patient and his family members to the social service department and a local home health care agency.

Liver disorders

Because the liver performs more than 100 functions, many of them essential for life, hepatic diseases and their complications tend to be life-threatening, especially in advanced cases of cirrhosis, hepatic encephalopathy, and liver abscess.

CIRRHOSIS

Cirrhosis is a chronic hepatic disease characterized by diffuse destruction and fibrotic regeneration of hepatic cells. As necrotic tissue yields to fibrosis, this disease alters liver structure and normal vasculature, impairs blood and lymph flow, and ultimately causes hepatic insufficiency.

Cirrhosis is the 10th most common cause of death in the United States and is most common among people ages 45 to 75. Most cases are a result of alcoholism, but toxins, biliary destruction, hepatitis, and a number of metabolic conditions may stimulate the destruction process.

Causes

There are several types of cirrhosis:

- u Laënnec's or micronodular cirrhosis (alcohol or portal cirrhosis) stems from chronic alcoholism and malnutrition.
- u Postnecrotic, or macronodular, cirrhosis is usually a complication of viral hepatitis. This type may also occur after exposure to such liver toxins as arsenic, carbon tetrachloride, and phosphorus.
- u Biliary cirrhosis results from prolonged biliary tract obstruction or inflammation.
- u Some patients develop idiopathic cirrhosis, which has no known cause.

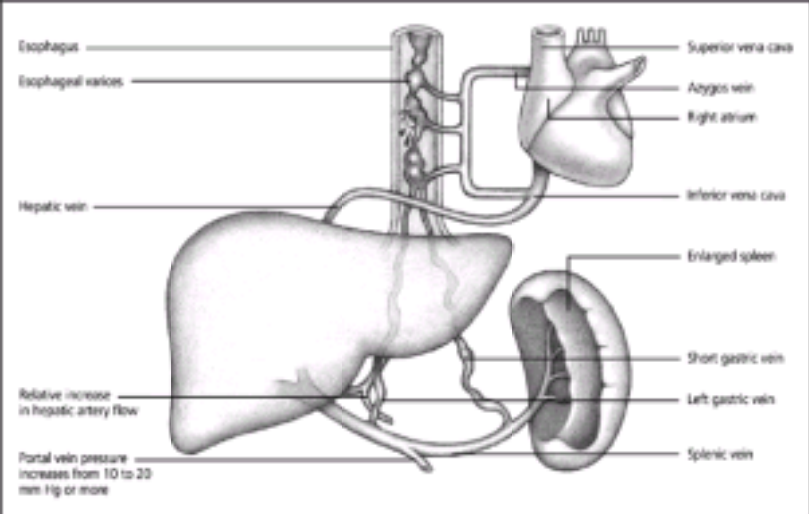

Complications

Depending on the amount of liver damage, cirrhosis can lead to such complications as portal hypertension, bleeding esophageal varices, hepatic encephalopathy, hepatorenal syndrome, and death. (See [Understanding portal hypertension.](#))

Assessment findings

Signs and symptoms are similar for all types, regardless of the cause. However, clinical manifestations vary depending on when in the course of the disease the patient seeks treatment.

PATHOPHYSIOLOGY

Understanding portal hypertension

Portal hypertension—elevated pressure in the portal vein—occurs when blood flow meets increased resistance. The disorder, a common result of cirrhosis, may also stem from mechanical obstruction and occlusion of the hepatic veins (Budd-Chiari syndrome).

As pressure in the portal vein increases, blood backs up into the spleen and flows through collateral channels to the venous system, bypassing the liver. Consequently, portal hypertension produces splenomegaly with thrombocytopenia, dilated collateral veins (esophageal varices, hemorrhoids, or prominent abdominal veins), and ascites.

Bleeding esophageal varices: The first sign

In many patients, the first sign of portal hypertension is bleeding from esophageal varices (dilated tortuous veins in the submucosa of the lower esophagus). Esophageal varices commonly cause massive hematemesis, requiring emergency care to control hemorrhage and prevent hypovolemic shock.

Care for the patient who has portal hypertension with esophageal varices focuses on careful monitoring for signs and symptoms of hemorrhage and subsequent hypotension, compromised oxygen supply, and altered level of consciousness.

In the early stage, the patient may experience only vague signs and symptoms, but typically he complains of abdominal pain, diarrhea, fatigue, nausea, and vomiting. Later, as the disease progresses, he may complain of chronic dyspepsia, constipation, pruritus, and weight loss. He may report a tendency for easy bleeding, such as frequent nosebleeds, easy bruising, and bleeding gums.

The history may reveal alcoholism or other diseases or conditions, such as acute viral hepatitis, biliary tract disorders, heart failure, recent blood transfusions, and viral infections.

In a head-to-toe approach, inspection reveals these common signs: telangiectasis on the cheeks; spider angiomas on the face, neck, arms, and trunk; gynecomastia; umbilical hernia; distended, abdominal blood vessels; ascites; testicular atrophy; palmar erythema; clubbed fingers; thigh and leg edema; ecchymosis; and jaundice.

In the early phase of the disease, palpation reveals that the liver is large and firm with a sharp edge. Later, scar tissue causes the liver to decrease in size; at this point, if the liver is palpable, its edge is nodular. Palpation also reveals an enlarged spleen.

Diagnostic tests

A thorough workup consisting of diagnostic and laboratory tests is required to confirm the diagnosis, establish the type of cirrhosis, and pinpoint complications.

Liver biopsy is the definitive test for cirrhosis, revealing hepatic tissue destruction and fibrosis.

Abdominal X-rays show liver size and cysts or gas in the biliary tract or liver; liver calcification; and massive ascites. Computed tomography and liver scans are used to determine liver size, identify liver masses, and visualize hepatic blood flow and obstruction. Esophagogastroduodenoscopy reveals bleeding esophageal varices, stomach irritation or ulceration, and duodenal bleeding and irritation.

Blood studies show elevated levels of liver enzymes (alanine aminotransferase, aspartate aminotransferase, total serum bilirubin, and indirect bilirubin). Total serum albumin and protein levels decrease; prothrombin time is prolonged. Hemoglobin, hematocrit, and serum electrolyte levels decrease. Vitamins A, C, and K are deficient.

Urine and stool studies disclose increased urine levels of bilirubin and urobilinogen; fecal urobilinogen levels decrease.

Treatment

The goal of therapy is to remove or alleviate the underlying cause of cirrhosis, prevent further liver damage, and prevent or treat complications. Vitamins and nutritional supplements promote healing of damaged hepatic cells and improve the patient's nutritional status. Sodium consumption is usually restricted to 500 mg/day and liquid intake is limited to 1,500 ml/day to help manage ascites and edema.

Drug therapy requires special caution because the cirrhotic liver can't detoxify harmful substances efficiently. Antacids may be prescribed to reduce gastric distress and decrease the potential for GI bleeding. Potassium-sparing diuretics, such as furosemide, may be used to reduce ascites and edema. However, diuretics require careful monitoring because fluid and electrolyte imbalance may precipitate hepatic encephalopathy. Vasopressin may be indicated for esophageal varices. Alcohol is prohibited, and sedatives should be avoided.

In patients with ascites, paracentesis may be used as a palliative treatment to relieve abdominal pressure. Surgical intervention may be required to divert ascites into venous circulation; if so, a peritoneovenous shunt is used. Shunt insertion results in weight loss, decreased abdominal girth, increased sodium excretion from the kidneys, and improved urine output.

To control bleeding from esophageal varices or other GI hemorrhage, nonsurgical measures are attempted first. These include gastric intubation and esophageal balloon tamponade. In gastric intubation, a tube is inserted and the stomach is lavaged until the contents are clear. If the bleeding is assessed as a gastric ulcer, antacids and histamine antagonists are administered.

In esophageal balloon tamponade, bleeding vessels are compressed to stanch blood loss from esophageal varices. Several forms of balloon tamponade are available, including the Sengstaken-Blakemore tube method, the esophagogastric tube method, and the Minnesota tube method.

Sclerotherapy is performed if the patient continues to experience repeated hemorrhagic episodes despite conservative treatment. A sclerosing agent is injected into the oozing vessels. This agent traumatizes epithelial tissue, which causes thrombosis and leads to sclerosis. If bleeding from the varices doesn't stop within 2 to 5 minutes, a second injection is given below the bleeding site. Sclerotherapy may also be performed prophylactically on nonbleeding varices.

As a last resort, portal-systemic shunts may be used for patients with bleeding esophageal varices and portal hypertension. Surgical shunting procedures decrease portal hypertension by diverting a portion of the portal vein blood flow away from the liver. These procedures are seldom performed because they can result in bleeding, infection, and shunt thrombosis.

Massive hemorrhage requires blood transfusions. To maintain blood pressure, crystalloid or colloid volume expanders are administered until the blood is available.

Nursing diagnoses

u Activity intolerance u Altered nutrition: Less than body requirements u Fluid volume excess u Hopelessness u Risk for fluid volume deficit u Risk for impaired skin integrity u Risk for injury u Sensory or perceptual alterations

Key outcomes

u The patient will maintain adequate caloric intake.
u The patient's fluid volume will remain within normal parameters.
u The patient's skin integrity will remain intact.
u The patient will remain oriented to his environment.
u The patient won't incur injury.

Nursing interventions

u Monitor vital signs, intake and output, and electrolyte levels to determine fluid volume status.
u To assess fluid retention, measure and record abdominal girth every shift. Weigh the patient daily and document his weight.
u Administer diuretics, potassium, and protein or vitamin supplements as ordered. Restrict sodium and fluid intake as ordered.
u Provide or assist with oral hygiene before and after meals.
u Determine food preferences and provide them within the patient's prescribed diet limitations. Offer frequent, small meals.
u Observe and document the degree of sclerae and skin jaundice.
u Give the patient frequent skin care, bathe him without soap, and massage him with emollient lotions. Keep his fingernails short. Handle him gently; turn and reposition him often to keep the skin intact.
u Observe for bleeding gums, ecchymoses, epistaxis, and petechiae. Constantly remain with the patient during hemorrhagic episodes.
u Inspect stools for amount, color, and consistency. Test stools and vomitus for occult blood.
u Increase the patient's exercise tolerance by decreasing fluid volumes and providing rest periods before exercise.
u Address the patient by name and tell him your name. Mention time, place, and date frequently throughout the day. Place a clock and a calendar where he can easily see them.
u Use appropriate safety measures to protect the patient from injury. Avoid physical restraints, if possible.
u Watch for signs of anxiety, epigastric fullness, restlessness, and weakness.
u Observe closely for signs of behavioral or personality changes. Report increasing stupor, lethargy, hallucinations, or neuromuscular dysfunction. Arouse the patient periodically to determine level of consciousness. Watch for asterixis, a sign of developing encephalopathy.
u Allow the patient to express his feelings about having cirrhosis. Offer psychological support and encouragement, when appropriate. Offer him and family members a realistic evaluation of his present health status, and communicate hope for the immediate future.

Patient teaching

u To minimize the risk of bleeding, warn the patient against taking nonsteroidal anti-inflammatory drugs, straining to defecate, and blowing his nose or sneezing too vigorously. Suggest using an electric razor and a soft toothbrush.
u Advise the patient that rest and good nutrition conserve energy and decrease metabolic demands on the liver. Urge him to eat frequent, small meals. Teach him to alternate periods of rest and activity to reduce oxygen demand and prevent fatigue.
u Tell the patient how he can conserve energy while performing activities of daily living. For example, suggest that he sit on a bench while bathing or dressing.
u Stress the need to avoid infections and abstain from alcohol. Refer the patient to Alcoholics Anonymous, if appropriate.

FATTY LIVER

Fatty liver (also called steatosis), a common clinical finding, is the accumulation of triglycerides and other fats in hepatic cells. In severe fatty liver, fat constitutes as much as 40% of the liver's weight (as opposed to 5% in a normal liver), and the weight of the liver may increase from 3 ¹/₃ lb (1.5 kg) to as much as 11 lb (5 kg).

Minimal fatty changes are temporary and asymptomatic; severe or persistent changes may cause liver dysfunction. Fatty liver is usually reversible simply by eliminating the cause; however, this disorder can result in recurrent infection or sudden death from fat emboli in the lungs.

Causes

Chronic alcoholism is the most common cause of fatty liver in the United States and Europe, with the severity of hepatic disease directly related to the amount of alcohol consumed. Other causes include malnutrition (especially protein deficiency), obesity, diabetes mellitus, jejunoileal bypass surgery, Cushing's syndrome, Reye's syndrome, pregnancy, large doses of hepatotoxins (such as I.V. tetracycline), carbon tetrachloride intoxication, prolonged I.V. total parenteral nutrition (TPN), and dichlorodiphenyltrichloroethane (DDT) poisoning.

Whatever the cause, fatty infiltration of the liver probably results from mobilization of fatty acids from adipose tissues or altered fat metabolism.

Complications

Without treatment, fatty liver can lead to permanent liver damage, portal hypertension, metabolic disturbances, disseminated intravascular coagulation, renal failure, coma, and death.

Assessment findings

Clinical features of fatty liver vary with the degree of lipid infiltration; many patients are asymptomatic.

The patient's history may uncover predisposing factors, such as alcoholism, malnutrition, biliary stasis, hepatic necrosis, diabetes mellitus, and obesity.

The patient may complain of right upper quadrant pain (with massive or rapid infiltration). Less common symptoms are nausea or vomiting and, rarely, menstrual disorders.

Inspection may reveal jaundice, edema, and ascites. With ascites, the patient may also have an emaciated chest and thin extremities. Rarely, inspection may disclose transient gynecomastia or spider angiomas. Abdominal palpation may reveal a large, tender liver (hepatomegaly) and splenomegaly, indicating cirrhosis.

Diagnostic tests

A liver biopsy confirms excessive fat in the liver.

The following results in liver function studies support the diagnosis:

- u albumin — low
- u globulin — usually elevated
- u cholesterol — usually elevated
- u total bilirubin — elevated
- u alkaline phosphatase — elevated
- u aminotransferase — usually low
- u prothrombin time — may be prolonged.

Other diagnostic findings may include anemia, leukocytosis, elevated white blood cell count, albuminuria, hyperglycemia or hypoglycemia, and deficiencies of iron, folic acid, and vitamin B₁₂.

Treatment

Management is essentially supportive and consists of correcting the underlying condition or eliminating its cause. For instance, when fatty liver results from I.V. TPN, decreasing the rate of carbohydrate infusion may correct the disease. In alcoholic fatty liver, abstinence from alcohol and a proper diet can begin to correct liver changes within 4 to 8 weeks. Such correction requires comprehensive patient teaching.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Anxiety u Fear u Fluid volume excess u Knowledge deficit u Pain

Key outcomes

- u The patient and family members will express an understanding of the disorder and treatment regimen.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will express feelings of comfort.
- u The patient will maintain adequate caloric intake.

Nursing interventions

- u Assess the patient's pain and administer analgesics as ordered. Monitor and record the drug's effectiveness and watch for adverse effects.
- u Apply heat or cold as ordered to minimize or relieve pain.
- u Help the patient into a comfortable position, and use pillows to splint or support the painful areas.
- u Assess for malnutrition, especially protein deficiency, in the patient with chronic illness. Encourage the patient to eat a nutritious diet.
- u Weigh the patient at the same each day to determine weight loss. Restrict oral liquid intake to 2 qt (2 L) per day. Provide sugarless hard candies to decrease thirst and improve taste.

Patient teaching

- u Suggest counseling for alcoholics. Provide emotional support for their families as well. If necessary, refer them to support groups, such as Alcoholics Anonymous and Al-Anon.
- u Teach the diabetic patient and family members about proper care, such as the purpose of insulin injections, diet, and exercise. Refer the patient to a public health nurse or to group classes, as necessary, to promote compliance with treatment. Emphasize the need for long-term medical supervision, and urge the patient to immediately report any changes in his health.
- u Instruct the obese patient and his family members about proper diet. Warn against fad diets, which often are nutritionally unsound. Recommend medical supervision for those more than 20% overweight. Encourage attendance at group diet and exercise programs and, if necessary, suggest behavior modification programs to correct eating habits. Be sure to follow up on your patient's progress, and provide positive reinforcement for any weight loss.
- u Explain the reasons for liquid and dietary restrictions to help the patient comply.

ALERT Advise the patient receiving hepatotoxins and those who risk occupational exposure to DDT to watch for and immediately report signs of toxicity.

- u Emphasize that fatty liver is reversible only if the patient strictly follows the therapeutic program; otherwise, he risks permanent liver damage.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy (also called hepatic coma, portal-systemic encephalopathy) is a neurologic syndrome that develops as a complication of aggressive fulminant hepatitis or chronic hepatic disease. This syndrome is most common in patients with cirrhosis. It may be acute and self-limiting or chronic and progressive. In advanced stages, the prognosis is extremely poor despite vigorous treatment.

Causes and pathophysiology

Most experts attribute hepatic encephalopathy to ammonia intoxication of the brain, but the precise etiology is unknown. Normally, the ammonia produced by protein breakdown in the bowel is metabolized to urea in the liver. When portal blood shunts past the liver, ammonia directly enters the systemic circulation and is carried to

the brain. Such shunting may result from the collateral venous circulation that develops in portal hypertension or from surgically created portal-systemic shunts. Cirrhosis further compounds this problem because impaired hepatocellular function prevents conversion of ammonia that reaches the liver.

Other factors that may lead to increasing ammonia levels include excessive protein intake, sepsis, excessive accumulation of nitrogenous body wastes (from constipation or GI hemorrhage), and bacterial action on protein and urea to form ammonia.

Certain other factors heighten the brain's sensitivity to ammonia intoxication: fluid and electrolyte imbalance (especially metabolic alkalosis), hypoxia, azotemia, impaired glucose metabolism, infection, and administration of sedatives, narcotics, and general anesthetics.

Complications

Hepatic encephalopathy can lead to irreversible coma and death.

Assessment findings

Clinical features vary, depending on the severity of neurologic involvement. The disorder usually progresses through four stages, but the patient's symptoms can fluctuate from one stage to another.

In the prodromal stage, early symptoms are typically overlooked because they're so subtle. The patient's history obtained from the patient or from a family member or caregiver may reveal slight personality changes, such as agitation, belligerence, disorientation, and forgetfulness. The patient may also have trouble concentrating or thinking clearly. He may report feeling fatigued or drowsy. He may have slurred or slowed speech. On inspection, you may observe a slight tremor.

In the impending stage, the patient undergoes continuing mental changes. He may be confused and disoriented as to time, place, and person. Inspection continues to reveal tremors that have progressed to asterixis (also called liver flap and flapping tremor). Asterixis—the hallmark of hepatic encephalopathy—refers to quick, irregular extensions and flexions of the wrists and fingers, when the wrists are held out straight and the hands flexed upward. On inspection, you may observe lethargy and aberrant behavior. Some patients demonstrate apraxia. When asked, the patient is unable to reproduce a simple design such as a star.

In the stuporous stage, the patient shows marked mental confusion. On inspection, he appears drowsy and stuporous. Yet he can still be aroused and is often noisy and abusive. Hyperventilation, muscle twitching, and asterixis are also evident.

In the comatose stage, the patient can't be aroused and is obtunded with no asterixis. Seizures, though uncommon, may occur. Palpation may reveal hyperactive reflexes and a positive Babinski's sign. The patient often has fetor hepaticus (musty odor of the breath and urine). Fetor hepaticus may occur in other stages also. Eventually this stage progresses to coma; it's usually fatal.

Diagnostic tests

Serum ammonia levels in venous and arterial samples are elevated and, together with characteristic clinical features, highly suggest hepatic encephalopathy.

An EEG shows slowing waves as the disease progresses.

Treatment

The goal of therapy is to eliminate the underlying cause of the disorder and to lower serum ammonia levels to stop progression of encephalopathy. In mild cases, treating the underlying cause of encephalopathy may reverse the symptoms. In most patients, the toxic products, often ammonia, must also be eliminated from the body.

Treatments to eliminate ammonia from the GI tract include sorbitol-induced catharsis to produce osmotic diarrhea, continuous aspiration of blood from the stomach, reduction of dietary protein intake, and administration of lactulose to reduce serum ammonia levels.

Lactulose traps ammonia in the bowel and promotes its excretion. It's effective because bacterial enzymes change lactulose to lactic acid, thereby rendering the colon too acidic for bacterial growth. At the same time, the resulting increase in free hydrogen ions prevents diffusion of ammonia through the mucosa; lactulose promotes conversion of systemically absorbable ammonia to ammonium, which is poorly absorbed and can be excreted. Lactulose syrup may be given orally. In acute hepatic coma, lactulose may be administered by retention enema. Lactulose therapy requires careful monitoring of fluid and electrolyte balance.

Although it's now considered a second-line treatment because of potential toxicity, neomycin may be given to suppress bacterial flora (preventing them from converting amino acids into ammonia). Neomycin is administered orally or by retention enema. Although neomycin is nonabsorbable at recommended dosages of 3 to 4 g/day, an amount that exceeds 4 g/day may produce irreversible hearing loss and nephrotoxicity.

Treatment may also include potassium supplements (80 to 120 mEq/day given by mouth or I.V.) to correct alkalosis (from increased ammonia levels), especially if the patient is taking diuretics. Salt-poor albumin may be used to maintain fluid and electrolyte balance, replace depleted albumin levels, and restore plasma.

Other treatments that have been tried, usually with little success, are hemodialysis and exchange transfusions.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered tissue perfusion (GI, neurologic) u Anxiety u Diarrhea u Fear u Fluid volume deficit u Pain u Risk for injury u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain orientated to his environment.
- u The patient's vital signs will remain stable.
- u The patient's laboratory values will return to normal.
- u The patient won't injure himself.
- u The patient's fluid volume will return to normal parameters.

Nursing interventions

- u Frequently assess and record the patient's level of consciousness. Continually orient him to time, place, and person. Keep a daily record of the patient's handwriting to monitor neurologic involvement.
- u Promote rest, comfort, and a quiet atmosphere. Discourage stressful exercise.
- u Monitor intake, output, and fluid and electrolyte balance. Check the patient's weight, and measure abdominal girth daily. Watch for, and immediately report, signs of anemia (decreased hemoglobin), alkalosis (increased serum bicarbonate), GI bleeding (melena, hematemesis), and infection. Monitor the serum ammonia level for signs of improvement.
- u Administer medications as ordered. Monitor for the desired effects, and watch for adverse reactions.
- u Ask the dietary department to provide the specified low-protein diet, with carbohydrates supplying most of the calories. Provide good mouth care. As ordered, provide parenteral nutrition to the semicomatose or comatose patient.
- u Use appropriate safety measures to protect the patient from injury. Avoid physical restraints, if possible.

ALERT Don't give a semicomatose or comatose patient sedatives because they deepen the coma. Protect the comatose patient's eyes from corneal injury by using artificial tears or eye patches.

u Provide emotional support for the patient's family in the terminal stage of encephalopathy.

Patient teaching

- u Teach the patient, if he's still able to understand, and family members about hepatic encephalopathy and its treatment. Repeat explanations of each treatment before you perform them. Be sure to explain all procedures even if the patient is comatose.
- u If the patient has chronic encephalopathy, be sure that he and his family members understand the mental and physical effects that the illness will eventually have on the patient. Alert them to signs of complications or worsening symptoms. Advise them when to notify the doctor.
- u As the patient begins to recover, inform him about the low-protein diet. Emphasize that recovery from a severe illness takes time. Review how to use medications.

LIVER ABSCESS

Liver abscess is a relatively uncommon but life-threatening disorder that occurs when bacteria or protozoa destroy hepatic tissue. The damage produces a cavity, which fills with infectious organisms, liquefied hepatic cells, and leukocytes. Necrotic tissue then walls off the cavity from the rest of the liver.

Liver abscess carries a mortality of 30% to 50%, which soars to more than 80% with multiple abscesses and to more than 90% with complications. Liver abscess affects both sexes and all age-groups, although it's slightly more prevalent in hospitalized children (because of a high rate of immunosuppression) and in women (most commonly those between ages 40 and 60).

Causes and pathophysiology

An amoebic abscess (the most common cause) results from infection with *Entamoeba histolytica*, the organism that causes amebic dysentery. Amoebic liver abscesses usually occur singly, in the right lobe.

In pyogenic liver abscesses, the common infecting organisms are *Escherichia coli*, *Klebsiella*, *Salmonella*, *Staphylococcus*, and enterococcus. Such organisms may invade the liver directly after a liver wound, or they may spread from the lungs, skin, or other organs by the hepatic artery, portal vein, or biliary tract. Multiple pyogenic abscesses are usual, but a single abscess can occur. (See [How liver abscess develops.](#))

PATHOPHYSIOLOGY

How liver abscess develops

With its rich vasculature and lymphatic supply, the liver offers several routes of entry for infectious bacteria. Pathogenic invaders, which may arise from distant infections in the GI tract or elsewhere, can spread to the liver by way of the biliary tract, the portal venous system, or the hepatic arterial or lymphatic systems.

Abscess formation

Usually, the liver destroys these bacteria but, occasionally, some infiltrate hepatic defenses. As these bacteria multiply and release toxins, they destroy adjacent hepatocytes. A necrotic wall forms, enclosing and protecting the bacteria.

At the same time, leukocytes swarm into the infected area, creating an abscess. The abscessed cavity fills with fluid containing living and dead leukocytes, liquefied hepatic cells, and bacteria, causing a life-threatening disease.

Lower mortality

In the past, liver abscess was virtually always fatal. It was hard to diagnose because of its vague clinical features and ineffective diagnostic tools. It was also difficult to treat because surgical techniques to drain the abscess were inadequate.

With the recent advent of sophisticated liver-scanning techniques, including computed tomography, and more effective surgical drainage procedures, survival rates have greatly improved.

Certain illnesses or conditions also may lead to abscess development; these include cholecystitis, colon cancer, diverticulitis, peritonitis, regional enteritis, infective endocarditis, pelvic inflammatory disease, pneumonia, trauma, and septicemia.

Complications

Without treatment, liver abscess usually leads to death. Complications include abscess rupture into the peritoneum, pleura, or pericardium.

Assessment findings

The clinical manifestations of a liver abscess depend on the degree of involvement. Some patients are acutely ill; in others, the abscess is recognized only at autopsy, after death from another illness. Onset of symptoms of a pyogenic abscess is usually sudden; in an amoebic abscess, onset is more insidious.

The patient may report right abdominal and shoulder pain, chills, fever, diaphoresis, nausea, vomiting, and weight loss. If the abscess extends through the diaphragm, he may complain of dyspnea and chest pain (symptoms of pleural effusion); if he has developed anemia, he may report fatigue.

Inspection may disclose jaundice, a sign of liver damage. On palpation, the liver may feel enlarged, indicating hepatic disease.

Diagnostic tests

Liver scan showing filling defects at the abscess area more than ¾" (2 cm), together with characteristic clinical features, confirms the diagnosis.

Hepatic ultrasonography may indicate defects caused by the abscess but is less definitive than a liver scan. Computed tomography (CT) scanning verifies the diagnosis after a liver scan or hepatic ultrasonography.

Chest X-ray shows the diaphragm on the right side as raised and fixed.

Blood tests demonstrate elevated levels of serum aspartate aminotransferase, serum alanine aminotransferase, alkaline phosphatase, and bilirubin. Serum albumin level is decreased. White blood cell count is elevated (usually more so in pyogenic than in amoebic abscess).

Blood cultures and percutaneous liver aspiration may help identify the causative organism in pyogenic abscess.

Stool cultures and serologic and hemagglutination tests can isolate *Entamoeba histolytica* in amoebic abscess.

Treatment

If the organism causing the liver abscess is unknown, long-term antibiotic therapy begins immediately with aminoglycosides, cephalosporins, clindamycin, or chloramphenicol. If cultures demonstrate that the infectious organism is *E. coli*, treatment includes ampicillin. If the infectious organism is *E. histolytica*, treatment includes emetine, chloroquine hydrochloride, chloroquine phosphate, or metronidazole. The therapy continues for 2 to 4 months. Surgery is usually avoided, but it may be required for a single pyogenic abscess or for an amoebic abscess that fails to respond to antibiotics. Placement of drains (using CT scanning or ultrasonography), particularly in large abscesses, reduces the need for abdominal surgery.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Knowledge deficit
- u Pain
- u Risk for impaired skin integrity
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's vital signs will remain stable.
- u The patient and family members will express an understanding of the disease process and treatment.
- u The patient's skin integrity will remain intact.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Provide supportive care, monitor vital signs (especially respirations), and maintain fluid and nutritional intake.
- u Assess the patient's pain level and administer analgesics as ordered. Monitor and document the drug's effectiveness and adverse reactions (if any occur). Apply heat or cold, as ordered, to minimize or relieve pain. Help the patient into a comfortable position, using pillows to splint or support painful areas.
- u Administer anti-infectives and antibiotics, as ordered, and watch for possible adverse effects.
- u Wash your hands before and after providing patient care. Wear gloves to maintain asepsis when providing direct care such as dressing changes.
- u Obtain and record the patient's weight at the same time every day to ensure the most accurate readings.
- u Inspect the patient's skin daily; document skin condition and report any changes.
- u Watch carefully for complications of abdominal surgery, such as hemorrhage and infection.

Patient teaching

- u Explain all diagnostic and surgical procedures to the patient.
- u Stress the importance of compliance with antibiotic drug therapy. Review the medication's purpose, correct use, potential adverse effects, and any special considerations.
- u Teach the patient how to perform skin care. Advise him to use nonirritating soap; pat rather than rub his skin dry; inspect skin on a regular basis; and avoid prolonged exposure to environmental elements, such as the sun and wind.

VIRAL HEPATITIS

Viral hepatitis is a fairly common systemic disease. It's marked by hepatic cell destruction, necrosis, and autolysis, leading to anorexia, jaundice, and hepatomegaly. In most patients, hepatic cells eventually regenerate with little or no residual damage, allowing recovery. However, old age and serious underlying disorders make complications more likely. The prognosis is poor if edema and hepatic encephalopathy develop.

More than 70,000 cases of viral hepatitis are reported annually in the United States. Today, six types of viral hepatitis are recognized, and a seventh is suspected.

Causes

The six major forms of viral hepatitis—A, B, C, D, E, and G—result from infection with causative viruses.

Type A hepatitis is highly contagious and is usually transmitted by the fecal-oral route, commonly within institutions or families. However, it may also be transmitted parenterally. Hepatitis A usually results from ingestion of contaminated food, milk, or water. Outbreaks of this type are often traced to ingestion of seafood from polluted water.

Type B hepatitis, once thought to be transmitted only by the direct exchange of contaminated blood, is now known to be transmitted also by contact with contaminated human secretions and stools. As a result, nurses, doctors, laboratory technicians, and dentists are frequently exposed to type B hepatitis, often as a result of wearing defective gloves. Transmission of this type also occurs during intimate sexual contact and through perinatal transmission.

Type C hepatitis is a blood-borne illness transmitted primarily by sharing of needles by I.V. drug users and through blood transfusions. This causes 80% of posttransfusion hepatitis. Although it seldom causes an acute disease, 90% of infected persons develop chronic infection. This type was formerly labeled non-A, non-B hepatitis.

Type D hepatitis is found only in patients with an acute or a chronic episode of hepatitis B. Type D infection requires the presence of the hepatitis B surface antigen; the type D virus depends on the double-shelled type B virus to replicate. For this reason, type D infection can't outlast a type B infection.

Type E hepatitis is transmitted enterically and is often waterborne. Because this virus is inconsistently shed in stools, detection is difficult. Outbreaks of Type E hepatitis have occurred in developing countries.

Hepatitis G is a newly identified virus. It's thought to be blood-borne, with transmission similar to that of hepatitis C.

Complications

Life-threatening fulminant hepatitis—the most feared complication—develops in about 1% of patients, causing unremitting liver failure with encephalopathy. It progresses to coma and commonly leads to death within 2 weeks.

Complications may be specific to the type of hepatitis:

- u Chronic active hepatitis may occur as a late complication of hepatitis B.
- u During the prodromal stage of acute hepatitis B, a syndrome resembling serum sickness, characterized by arthralgia or arthritis, rash, and angioedema, may occur. This syndrome can lead to misdiagnosis of hepatitis B as rheumatoid arthritis or lupus erythematosus.
- u Primary liver cancer may develop after infection with hepatitis B or C.
- u Type D hepatitis can cause a mild or asymptomatic form of type B hepatitis to flare into severe, progressive chronic active hepatitis and cirrhosis.

- u Weeks to months after apparent recovery from acute hepatitis A, relapsing hepatitis may develop.

Rarely, hepatitis leads to pancreatitis, myocarditis, typical pneumonia, aplastic anemia, transverse myelitis, or peripheral neuropathy.

Assessment findings

Investigate the patient's history for the source of transmission. For example, you may learn that he was recently exposed to individuals with hepatitis A or B, underwent recent blood transfusions, used I.V. drugs, or had hemodialysis for renal failure.

ASSESSMENT TIP Look for evidence of recent ear piercing or tattooing (significant because contaminated instruments can transmit hepatitis), travel to a foreign country where hepatitis is endemic, or living conditions that are, or were, overcrowded.

Be sure to ask about alcohol consumption, which is especially significant in suspected cirrhosis. An alcoholic patient often deliberately underestimates how much he drinks, so you may need to interview family members as well.

Check the patient's employment history for occupational exposure. For instance, the patient may work in a hospital or laboratory, where the risk of viral exposure from contaminated instruments or waste could be high. Also probe the patient's background for possible exposure to toxic chemicals, such as carbon tetrachloride, which can cause nonviral hepatitis.

Assessment findings are similar for the different types of hepatitis. Typically, signs and symptoms progress in several stages. In the prodromal (preictal) stage, the patient generally complains of easy fatigue and anorexia, possibly with mild weight loss. He may also report generalized malaise, depression, headache, weakness, arthralgia, myalgia, photophobia, and nausea with vomiting. He may describe changes in his senses of taste and smell.

Assessment of vital signs may reveal fever, with a temperature of 100° to 102° F (37.8° to 38.9° C). As the prodromal stage draws to a close, usually within 1 to 5 days before the onset of the clinical jaundice stage, inspection of urine and stool specimens may reveal dark-colored urine and clay-colored stools.

If the patient has progressed to the clinical jaundice stage, he may report pruritus, abdominal pain or tenderness, and indigestion. Early in this stage, he may complain of anorexia; later, his appetite may return. Inspection of the sclerae, mucous membranes, and skin may show jaundice, which can last for 1 to 2 weeks. Jaundice indicates that the damaged liver is unable to remove bilirubin from the blood; it doesn't indicate disease severity. Occasionally, hepatitis occurs without jaundice.

During the clinical jaundice stage, skin inspection may reveal rashes, erythematous patches, or hives, especially if the patient has hepatitis B or C. Palpation may disclose abdominal tenderness in the right upper quadrant, an enlarged and tender liver and, in some cases, splenomegaly and cervical adenopathy.

If you assess the patient during the recovery or posticteric stage, you find most symptoms are decreasing or have subsided. On palpation, you may notice a decrease in liver enlargement. The recovery phase generally lasts from 2 to 12 weeks, sometimes longer in patients with hepatitis B, C, or E.

Diagnostic tests

In suspected viral hepatitis, a hepatitis profile is routinely performed. This study identifies antibodies specific to the causative virus, establishing the type of hepatitis:

- u Type A. Detection of an antibody to hepatitis A virus (anti-HAV) confirms the diagnosis.
- u Type B. The presence of hepatitis B surface antigens (HBsAg) and hepatitis B antibodies (anti-HBs) confirms the diagnosis.
- u Type C. Diagnosis depends on serologic testing for the specific antibody 1 or more months after the onset of acute illness. Until then, the diagnosis is principally established by obtaining negative test results for hepatitis A, B, and D.
- u Type D. Detection of intrahepatic delta antigens or immunoglobulin (Ig) M antidelta antigens in acute disease (or IgM and IgG in chronic disease) establishes the diagnosis.
- u Type E. Detection of hepatitis E antigens supports the diagnosis; however, the diagnosis may also consist of ruling out hepatitis C.
- u Type G. Detection of hepatitis G ribonucleic acid supports diagnosis. Serologic assays are being developed.

Additional findings from liver function studies support the diagnosis:

- u Serum aspartate aminotransferase and serum alanine aminotransferase levels are increased in the prodromal stage of acute viral hepatitis.
- u Serum alkaline phosphatase levels are slightly increased.
- u Serum bilirubin levels are elevated. Levels may continue to be high late in the disease, especially if the patient has severe disease.
- u Prothrombin time is prolonged. (Prothrombin time more than 3 seconds longer than normal indicates severe liver damage.)
- u White blood cell counts commonly reveal transient neutropenia and lymphopenia followed by lymphocytosis.
- u Liver biopsy is performed if chronic hepatitis is suspected. (This study is performed for acute hepatitis only if the diagnosis is questionable.)

Treatment

Persons believed to have been exposed to hepatitis A and the household contacts of patients with confirmed cases should be treated with standard immunoglobulin. Travelers planning visits to areas known to harbor such viruses should receive hepatitis A vaccine.

Hepatitis B globulin is given to individuals exposed to blood or body secretions of infected individuals. The immunoglobulin is effective but very expensive. Hepatitis B vaccine should be given to people at risk for exposure. This group includes neonates of hepatitis B virus (HBV)-positive mothers, sexual contacts of HBV-positive individuals, hemodialysis patients, health care workers, and male homosexuals. There is no vaccine against hepatitis C, but it has been treated with alfa interferon.

In the early stages of the disease, the patient is advised to rest and combat anorexia by eating small, high-calorie, high-protein meals. (Protein intake should be reduced if signs of precoma—lethargy, confusion, mental changes—develop.) Large meals are usually better tolerated in the morning because many patients experience nausea late in the day.

In acute viral hepatitis, hospitalization usually is required only for those patients with severe symptoms or complications. Parenteral nutrition may be required if the patient has persistent vomiting and is unable to maintain oral intake.

Antiemetics (trimethobenzamide or benzquinamide) may be given half an hour before meals to relieve nausea and prevent vomiting; phenothiazines have a cholestatic effect and should be avoided. For severe pruritus, the resin cholestyramine, which sequesters bile salts, may be given.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Anxiety
- u Fear
- u Knowledge deficit
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient won't develop complications.
- u The patient will remain free from signs and symptoms of infection.
- u The patient's vital signs will remain stable.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient and family members will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Observe standard precautions to prevent transmission of the disease. Make sure that visitors also observe these precautions.
- u Provide rest periods throughout the day. Schedule treatments and tests so that the patient can rest between activities.
- u Because inactivity may make the patient anxious, include diversional activities as part of his care. Suggest television programs of interest to him. Gradually add activities to his schedule as he begins to recover.
- u To help the patient maintain an adequate diet, don't overload his meal tray. Too much food may only diminish his appetite. Take care not to overmedicate him, which may also cause loss of appetite. Determine his food preferences and try to include his favorite foods in the meal plan.
- u Administer supplemental vitamins and commercial feedings as ordered. If symptoms are severe and the patient can't tolerate oral intake, provide I.V. therapy and parenteral nutrition as ordered.
- u Provide adequate fluid intake. The patient should consume at least 4 L of liquid per day to maintain adequate hydration. To help him meet or exceed this goal, provide him with fruit juices, soft drinks, ice chips, and water.
- u Administer antiemetics as ordered. Observe the patient for the desired effects, and note any adverse reactions.
- u Record weight daily, and keep accurate intake and output records. Observe the stools for color, consistency, and amount. Also note the frequency of defecation.
- u Watch for signs of complications, such as changes in level of consciousness, ascites, edema, dehydration, respiratory problems, myalgia, and arthralgia.
- u Report all cases of hepatitis to health officials. Ask the patient to name anyone he came in contact with recently.

Patient teaching

- u Teach the patient about viral hepatitis, its signs and symptoms, and recommended treatments.
- u Explain all necessary diagnostic tests. Review any special preparation that may be required. Point out that the findings from these tests, together with the patient's symptoms, help to establish his diagnosis.
- u Educate the patient about the importance of rest and a proper diet to help the liver heal and minimize complications.
- u Stress that complete recovery takes time. Point out that the liver takes 3 weeks to regenerate and up to 4 months to return to normal functioning. Advise the patient to avoid contact sports until his liver returns to its normal size. Instruct him to check with his doctor before performing any strenuous activity. (See [Preventing the spread of viral hepatitis.](#))
- u Emphasize the importance of good nutrition in promoting liver regeneration. Instruct the patient to eat a high-calorie, high-protein diet. Advise him to eat several small meals rather than three large meals. Also stress the importance of drinking adequate fluids every day.

PREVENTION

Preventing the spread of viral hepatitis

In your teaching, review the following measures to prevent the spread of viral hepatitis:

- u Stress the importance of thorough and frequent hand washing.
- u Tell the patient not to share food, eating utensils, or toothbrushes.
- u If the patient has hepatitis A or E, warn him not to contaminate food or water with fecal matter, because the disease is transmitted by the fecal-oral route.
- u If the patient has hepatitis B, C, D, or G, explain that transmission occurs through exchange of blood or body fluids that contain blood. While infected, he shouldn't donate blood or have sexual relations.
- u Advise the patient to take extra care to avoid cutting himself.

- u Tell the patient recuperating at home to weigh himself every day and to report any weight loss greater than 5 lb (2.3 kg) to his doctor.
- u Warn the patient to abstain from alcohol while he has this disease. If necessary, explain that, because alcohol is detoxified in the liver, its consumption could put undue stress on the liver during the illness.
- u Explain to the patient and family members that anyone exposed to the disease through contact with the patient should receive prophylaxis as soon as possible after exposure.
- u Tell the patient to check with the doctor before taking any medication—even nonprescription drugs—because some medications can precipitate a relapse.
- u Stress the need for continued medical care. Advise the patient to see the doctor again about 2 weeks after the diagnosis is made. Mention the probable need for follow-up visits every month for up to 6 months after diagnosis. Also explain that if chronic hepatitis develops, he'll always have to visit the doctor regularly so that the disease can be monitored.

Gallbladder and duct disorders

Diseases of the gallbladder and biliary tract are common and often painful conditions that usually require surgery and may be life-threatening. They are often associated with inflammation and deposition of calculi.

CHOLELITHIASIS, CHOLECYSTITIS, AND RELATED DISORDERS

Cholelithiasis—the leading biliary tract disease—is the formation of stones or calculi (also called gallstones) in the gallbladder. (See [How gallstones form.](#)) The prognosis is usually good with treatment unless infection occurs. Then the prognosis depends on the infection's severity and its response to antibiotics.

The formation of gallstones can give rise to a number of related disorders:

- u In cholecystitis, the gallbladder becomes acutely or chronically inflamed, usually because a gallstone becomes lodged in the cystic duct, causing painful gallbladder distention. The acute form is most common during middle age; the chronic form, among elderly people. The prognosis is good with treatment.
- u In choledocholithiasis, gallstones pass out of the gallbladder and lodge in the common bile duct, causing partial or complete biliary obstruction. The prognosis is good unless infection occurs.
- u In cholangitis, the bile duct becomes infected; this disorder is commonly associated with choledocholithiasis and may follow percutaneous transhepatic cholangiography. Nonsuppurative cholangitis usually responds rapidly to antibiotic treatment. Suppurative cholangitis has a poor prognosis unless surgery to correct the obstruction and drain the infected bile is performed promptly.
- u In gallstone ileus, a gallstone obstructs the small bowel. Typically, the gallstone travels through a fistula between the gallbladder and small bowel and lodges at the ileocecal valve. This condition is most common in elderly people. The prognosis is good with surgery.

Generally, gallbladder and duct diseases occur during middle age. Between ages 20 and 50, they're six times more common in women, but the incidence in men and women equalizes after age 50. The incidence increases with each succeeding decade.

PATHOPHYSIOLOGY

How gallstones form

Bile is made continuously by the liver and is concentrated and stored in the gallbladder until needed by the duodenum to help digest fat. Changes in the composition of bile or in the absorptive ability of the gallbladder epithelium allow gallstones to form. The following explains the physiology of gallstone formation and tells you what to look for.

1 Certain conditions (such as age, obesity, and estrogen imbalance) cause the liver to secrete bile that is abnormally high in cholesterol or lacking the proper concentration of bile salts.

Signs and symptoms are undetectable at this stage.

2 When the gallbladder concentrates this bile, inflammation may occur. Excessive water and bile salts are reabsorbed, making the bile less soluble. Cholesterol, calcium, and bilirubin precipitate into gallstones.

Look for nausea, belching, and pain in the right upper quadrant, especially after a fatty meal.

3 Fat entering the duodenum causes the intestinal mucosa to secrete the hormone cholecystokinin, which stimulates the gallbladder to contract and empty. If a calculus lodges in the cystic duct, the gallbladder contracts but can't empty.

Look for severe pain, nausea, and vomiting.

4 If a calculus lodges in the common bile duct, the flow of bile into the duodenum becomes obstructed. Bilirubin is absorbed into the blood, causing jaundice.

Look for jaundice, biliary colic, clay-colored stools, and fat intolerance.

5 Biliary stasis and ischemia of the tissue surrounding the calculus can also cause irritation and inflammation of the common bile duct.

Look for jaundice, high fever, chills, and an increased eosinophil count.

6 Inflammation can progress up the biliary tree and lead to infection of any of the bile ducts. This causes scar tissue, edema, cirrhosis, portal hypertension, and variceal hemorrhage.

Look for fever, an increased white blood cell count, ascites, increased prothrombin time, bleeding tendencies, confusion, and coma.

Possible locations for calculi include these sites.

Causes

These related disorders all stem from a common cause: calculi formation. The exact cause of gallstone formation is unknown, but abnormal metabolism of cholesterol and bile salts clearly plays an important role.

A number of risk factors that predispose a person to calculi formation have been identified. These include:

- u a high-calorie, high-cholesterol diet, associated with obesity
- u elevated estrogen levels from oral contraceptive use, postmenopausal hormone-replacement therapy, or pregnancy
- u diabetes mellitus, ileal disease, hemolytic disorders, hepatic disease, or pancreatitis.

The type of disorder that develops depends on where in the gallbladder or biliary tract the calculi collect. For example, cholelithiasis results when gallstones form and remain in the gallbladder. Cholecystitis, choledocholithiasis, cholangitis, and gallstone ileus usually develop after a gallstone lodges in a duct or in the small bowel, causing an obstruction. (See [Where calculi collect.](#))

Acute cholecystitis also may result from conditions that alter the gallbladder's ability to fill or empty. These conditions include trauma, reduced blood supply to the gallbladder, prolonged immobility, chronic dieting, adhesions, prolonged anesthesia, and narcotic abuse.

Complications

Each of these disorders produces a set of complications:

- u Cholelithiasis may lead to any of the disorders associated with gallstone formation: cholangitis, cholecystitis, choledocholithiasis, and gallstone ileus.
- u Cholecystitis can progress to gallbladder complications, such as empyema, hydrops or mucocele, and gangrene. Gangrene may lead to perforation, resulting in peritonitis, fistula formation, pancreatitis, limy bile, and porcelain gallbladder. Other complications include chronic cholecystitis and cholangitis.
- u Choledocholithiasis may lead to cholangitis, obstructive jaundice, pancreatitis, and secondary biliary cirrhosis.
- u Cholangitis may progress to septic shock and death, especially in the suppurative form.
- u Gallstone ileus may cause bowel obstruction, which can lead to intestinal perforation, peritonitis, septicemia, secondary infection, and septic shock.

Assessment findings

Gallbladder disease may produce no symptoms (even when X-rays reveal gallstones). Acute cholelithiasis, acute cholecystitis, and choledocholithiasis produce symptoms of a classic gallbladder attack. (See [Differentiating cholangitis and gallstones.](#))

In a gallbladder attack, the patient typically complains of sudden onset of severe steady or aching pain in the midepigastriac region or the right upper abdominal quadrant. He may describe pain that radiates to the back, between the shoulder blades or over the right shoulder blade, or just to the shoulder area. This type of pain is known as biliary colic and is the most characteristic symptom of gallbladder disease. It's often severe enough to send the patient to the emergency department.

Often, the patient reports that the attack followed eating a fatty meal or a large meal after fasting for an extended time. The attack may have occurred in the middle of the night, suddenly awakening him. He may also report nausea, vomiting, and chills; a low-grade fever may be assessed.

The patient may report a history of milder GI symptoms that preceded the acute attack. He may have experienced these symptoms for some time before seeking treatment. Such symptoms may include indigestion, vague abdominal discomfort, belching, and flatulence after eating meals or snacks high in fat.

During an acute attack, inspection confirms that the patient is in severe pain and reveals pallor, diaphoresis, and exhaustion. If he has chronic cholecystitis, inspection of the skin, sclerae, and oral mucous membranes may confirm jaundice; inspection of urine and stool specimens may reveal dark-colored urine and clay-colored stools.

Tachycardia may be noted on palpation. Light palpation of the abdomen may disclose tenderness over the gallbladder, which increases on inspiration. If a calculus-filled gallbladder without ductal obstruction is palpated, a painless, sausage-like mass can be felt.

Auscultation may reveal hypoactive bowel sounds if the patient has acute cholecystitis.

Diagnostic tests

Ultrasonography and X-rays reveal gallstones. Plain abdominal X-rays identify gallstones if they contain enough calcium to be radiopaque. X-rays are also helpful in identifying porcelain gallbladder, limy bile, and gallstone ileus. Ultrasonography of the gallbladder confirms cholelithiasis in most patients and distinguishes between obstructive and nonobstructive jaundice; calculi as small as 2 mm can be detected.

Oral cholecystography confirms the presence of gallstones, although this test is gradually being replaced by ultrasonography.

Technetium-labeled iminodiacetic acid scan of the gallbladder indicates cystic duct obstruction and acute or chronic cholecystitis if the gallbladder can't be seen.

Percutaneous transhepatic cholangiography, imaging performed under fluoroscopic control, supports the diagnosis of obstructive jaundice and is used to visualize calculi in the ducts.

Blood studies may reveal elevated levels of serum alkaline phosphatase, lactate dehydrogenase, aspartate aminotransferase, icteric index, and total bilirubin. The white blood cell count is slightly elevated during a cholecystitis attack.

Treatment

Surgery, usually elective, remains the most common treatment for gallbladder and duct disease. Surgery is usually recommended if the patient has symptoms frequent enough to interfere with his regular routine, if he has any complications of gallstones, or if he has had a previous attack of cholecystitis.

ADVANCED PRACTICE

Differentiating cholangitis and gallstones

If the patient has cholangitis, he may report a history of choledocholithiasis and classic symptoms of biliary colic. On inspection, jaundice and pain may be evident. He may also have a spiking fever with chills.

In gallstone ileus, the patient may complain of colicky pain, which may persist for several days, sometimes with nausea and vomiting. You may note abdominal distention on inspection. Auscultation may reveal absent bowel sounds if the patient has a complete bowel obstruction.

Procedures may include cholecystectomy (laparoscopic or abdominal), cholecystectomy with operative cholangiography, choledochostomy, or exploration of the common bile duct.

If the patient's gallstones are radiolucent and consist all or in part of cholesterol, he may undergo gallstone dissolution therapy. In this procedure, the doctor uses oral chenodeoxycholic acid or ursodeoxycholic acid to partially or completely dissolve gallstones. This treatment has several limitations, including the need for prolonged treatment, the ability to dissolve only small calculi, the high incidence of adverse reactions, and the frequency of calculus reformation after treatment ends.

Other, more direct methods may be used to remove the gallstones. One of these is insertion of a percutaneous transhepatic biliary catheter under fluoroscopic guidance, which permits visualization of the calculi and their removal using a basket-shaped tool, called a Dormia basket. Another calculus-removal technique is endoscopic retrograde cholangiopancreatography (ERCP). In this procedure, the calculi are removed with a balloon or basketlike tool passed through an endoscope. Both of these techniques permit decompression of the biliary tree, allowing bile to flow.

Another technique, lithotripsy, breaks up gallstones using ultrasonic waves. It's been used successfully in some patients with radiolucent calculi. This outpatient procedure is contraindicated in patients with a pacemaker or an automatic implantable defibrillator.

If the patient is asymptomatic or has recovered from a first attack of biliary colic, noninvasive treatment may be attempted. This treatment includes a low-fat diet with replacement of the fat-soluble vitamins A, D, E, and K, and administration of bile salts to facilitate digestion and vitamin absorption.

During an acute attack, narcotics relieve pain. (Meperidine is preferred over morphine, which may constrict the sphincter and cause biliary spasm.) Antispasmodics and anticholinergics relax smooth muscles and decrease ductal tone and spasm, and antiemetics reduce nausea and vomiting. A nasogastric (NG) tube may also be inserted and connected to intermittent, low-pressure suction to relieve vomiting.

In patients with severe acute cholecystitis, I.V. fluids and I.V. antibiotic therapy are often given before surgery. Cholestyramine may be given if the patient has obstructive jaundice with severe itching from accumulation of bile salts in the skin.

Nonsuppurative cholangitis usually responds quickly to antibiotic therapy. Suppurative cholangitis requires antibiotic therapy, prompt surgical correction of the obstruction, and drainage of the infected bile.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (GI)
- u Knowledge deficit
- u Pain
- u Risk for fluid volume deficit
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient's laboratory values will return to normal.
- u The patient will avoid complications.
- u The patient's fluid volume will remain within normal parameters.

Nursing interventions

- u If the patient will be managed without invasive procedures, provide a low-fat diet and small, frequent meals to help prevent attacks of biliary colic. Also replace vitamins A, D, E, and K, and administer bile salts as ordered.
- u As ordered, administer narcotics and anticholinergics if the patient has pain, and antiemetics if he has nausea and vomiting. Monitor him for the desired effects, and watch for possible adverse reactions.
- u If the patient vomits or has nausea, stay with him, assess his vital signs, monitor intake and output, and withhold food and fluids.
- u If the patient has cholangitis, give antibiotics as ordered and watch for desired effects and adverse reactions. Also monitor vital signs, and watch for signs of severe toxicity, including confusion, septicemia, and septic shock.
- u After percutaneous transhepatic biliary catheterization or ERCP to remove gallstones, assess vital signs. Allow the patient nothing by mouth until the gag reflex returns. Monitor intake and output, keeping in mind that urine retention can be a problem. Observe the patient for complications, including cholangitis and pancreatitis.
- u If surgery is scheduled, provide appropriate preoperative care. Usually, this includes insertion of an NG tube.

After surgery:

- u Be alert for signs of bleeding, infection, or atelectasis. Evaluate the incision site for bleeding. Serosanguineous and bile drainage is common during the first 24 to 48 hours if the patient has a wound drain, such as a Jackson-Pratt or Penrose drain. If, after a choledochostomy, a T tube drain is placed in the duct and attached to a drainage bag, make sure the drainage tube has no kinks. Also make sure the connecting tubing from the T tube is well secured to the patient to prevent dislodgment. Measure and record drainage daily (200 to 300 ml is normal).
- u If the patient underwent laparoscopic cholecystectomy, assess for “free-air” pain caused by carbon dioxide insufflation. Encourage ambulation soon after the procedure to promote gas absorption.
- u Monitor intake and output. Provide appropriate I.V. fluid intake. Allow the patient nothing by mouth for 24 to 48 hours or until bowel sounds resume and nausea and vomiting cease (postoperative nausea may indicate a full urinary bladder). Administer antiemetics, as ordered, for postoperative nausea and vomiting. Monitor NG tube drainage for color, amount, and consistency.
- u When peristalsis resumes, remove the NG tube and begin a clear liquid diet. Advance the diet as tolerated by the patient. If he doesn't void within 8 hours (or if he voids an inadequate amount based on I.V. fluid intake), percuss over the symphysis pubis for bladder distention (especially in patients receiving anticholinergics). Avoid catheterization, if possible.

u Encourage leg exercises every hour. The patient should ambulate in the evening after surgery. Encourage hourly coughing and deep breathing. Discourage sitting in a chair. Provide elastic stockings to support leg muscles and promote venous blood flow, thus preventing stasis and possible clot formation. Have the patient rest in semi-Fowler's position as much as possible to direct any abdominal drainage into the pelvic cavity rather than allowing it to accumulate under the diaphragm.

Patient teaching

- u Teach the patient about the disease and the reasons for his symptoms.
- u Explain scheduled diagnostic tests, reviewing pretest instructions and necessary aftercare.
- u If a low-fat diet is prescribed, suggest ways to implement it. If necessary, ask the dietitian to reinforce your instructions. Make sure the patient understands how dietary changes help to prevent biliary colic.
- u Review the proper use of prescribed medications, explaining their desired effects. Point out possible adverse effects, especially those that warrant a call to the doctor.
- u Reinforce the doctor's explanation of the ordered treatment, such as surgery, ERCP, or lithotripsy. Make sure the patient fully understands the possible complications, if any, associated with his treatment.

Before and after surgery:

- u Teach the patient to breathe deeply, cough, expectorate, and perform leg exercises that are necessary after surgery. Also teach splinting, repositioning, and ambulation techniques.
- u Explain the procedures that will be performed before, during, and after surgery to help ease the patient's anxiety and ensure his cooperation. Teach the patient who will be discharged with a T tube how to empty it, change the dressing, and provide skin care.
- u On discharge (usually 4 to 7 days after traditional surgery), advise the patient against heavy lifting or straining for 6 weeks. Urge him to walk daily. Tell him that food restrictions are unnecessary unless he has intolerance to a specific food or some underlying condition (diabetes, atherosclerosis, or obesity) that requires such restriction.
- u After laparoscopic surgery, tell the patient he may return to work within 3 to 7 days if no complications develop.

Anorectal disorders

Anorectal disorders, which commonly cause pain and bleeding, include anal fissure, anorectal abscess, anorectal stricture, hemorrhoids, pilonidal disease, and proctitis, among others.

ANAL FISSURE

An anal fissure is a laceration or crack in the lining of the anus that extends to the circular muscle. Acute fissures usually heal spontaneously or with minimal treatment. Chronic fissures recur and may require surgery. The prognosis is good, especially with fissurectomy and good anal hygiene.

Posterior fissure, the most common form, is equally prevalent in males and females. Anterior fissure, the rarer type, is 10 times more common in females.

Causes

Posterior fissure results from the passage of large, hard stools that stretch the anal lining beyond its limits. Anterior fissure usually results from strain on the perineum during childbirth or, rarely, from stricture caused by scar tissue. Diarrhea and spasm can cause anal fissures. Some anal fissures develop secondary to proctitis, Crohn's disease, trauma, anal tuberculosis, or cancer.

Complications

Rare complications include abscess, fistula, septicemia, and hemorrhage. Chronic fissure can produce scar tissue that hampers normal bowel evacuation.

Assessment findings

Typically, the patient complains of pain, which he describes as tearing, cutting, or burning, during or immediately after a bowel movement. He may also report blood on his underclothes or toilet paper.

In the patient with chronic fissure, additional signs and symptoms may include dysuria, pruritus, and urinary frequency or urine retention. The patient may also complain of painful anal sphincter spasms that result from ulceration of “sentinel pile” (swelling at the lower end of the fissure).

Gentle traction on the perianal skin can create sufficient eversion to visualize the fissure directly. Digital examination permits palpation of the fissure. Keep in mind that a digital examination can elicit pain and bleeding.

Diagnostic tests

Anoscopy showing longitudinal tears helps to confirm the diagnosis.

Barium enema and sigmoidoscopy are performed to rule out inflammatory bowel disease if the patient has painless or multiple fissures.

Treatment

Management of an acute fissure provides local pain relief with analgesics, sitz baths, and bulk-producing agents, such as psyllium. Soft stools prevent further tearing and decrease pain associated with defecation. Intra-anal application of isosorbide dinitrate ointment over 6 to 12 weeks is successful in most patients. If further treatment is required, the fissure may be removed by surgical excision (fissurectomy).

Nursing diagnoses

- u Anxiety u Diarrhea u Knowledge deficit u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's bowel movements will return to normal.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Provide warm sitz baths, warm soaks, and local anesthetic ointment to relieve pain.
- u Administer pain medications, stool softeners, and bulk-forming laxatives as ordered. Monitor the patient for the desired effects and potential adverse reactions.
- u In addition to stool softeners and laxatives, provide the patient with a low-residue diet and adequate fluids to soften stools and prevent straining during defecation.
- u If diarrhea occurs, control it with diphenoxylate or other antidiarrheals.
- u If surgery is necessary, provide preoperative care as appropriate. Postoperatively, monitor the patient's vital signs and continue with the regimen (including sitz

baths) established before surgery.

Patient teaching

- u Teach about anal fissure, explaining how a fissure develops and what can be done to prevent recurrence.
- u If rectal examination will be performed, discuss the procedure with the patient. Help him to understand that, although the examination may be painful, it will help the doctor confirm the presence of a fissure.
- u Stress the need to drink fluids to prevent hard stools.
- u If surgery is needed, reinforce the doctor's explanation of the procedure and review any possible complications. Provide appropriate preoperative teaching.

ANORECTAL ABSCESS AND FISTULA

Anorectal abscess is a localized infection that appears as a collection of pus due to inflammation of the soft tissue. As the abscess produces more pus, a fistula can form, creating an abnormal opening in the anal skin.

A fistula usually forms in the soft tissue beneath the muscle fibers of the sphincters (especially the external sphincter), extending into the perianal skin. The internal (primary) opening of the abscess or fistula is usually near the anal glands and crypts; the external (secondary) opening, in the perianal skin. In severe cases, this opening may communicate with the rectum.

Causes

The inflammatory process that leads to abscess may begin with an abrasion or tear in the lining of the anal canal, rectum, or perianal skin and subsequent infection with *Escherichia coli*, staphylococci, or streptococci. Such trauma may result from abrasive contact with objects such as enema tips, ingested eggshells or fish bones, or very hard stools. An abscess may also develop after infection of submucosal hematomas, sclerosed hemorrhoids, or anal fissures.

Other causes include obstruction of glands in the anal area, extension of cryptitis, infection in the apocrine glands, or folliculitis in the perianal region. Certain systemic illnesses, including ulcerative colitis and Crohn's disease, may also lead to abscess formation.

Complications

Anorectal abscess may lead to anorectal fistula. Either disorder can cause perineal cellulitis, scar tissue formation, and anal stricture. Rarely, peritonitis develops from internal abscess rupture.

Assessment findings

Signs and symptoms depend on the infection's severity and whether or not the abscess is a chronic condition. Assessment findings also vary according to the type of abscess. (See [Types of anorectal abscess.](#))

Usually, the first symptom the patient reports is rectal pain, which he usually describes as throbbing. Occasionally, diarrhea precedes the onset of rectal pain. The patient may state that he can't sit comfortably because of the development of a hard, painful lump on one side.

If the anorectal abscess is a chronic condition, the patient may report discharge or bleeding and anal pruritus. If he also has an anal fistula, anal pruritus and purulent discharge are commonly reported.

Depending on the severity of the infection, the patient may also complain of fever, chills, nausea, vomiting, and malaise.

Inspection may reveal an erythematous lump or swelling in the anal area. If the patient has a fistula, its external opening may be visible as a pink or red, elevated, discharging sinus or ulcer on the skin near the anus. Palpation usually reveals tenderness over the reddened or swollen area.

Digital examination of the patient with a fistula may disclose a palpable, indurated tract and a depression or ulcer in the midline anteriorly or at the dentate line posteriorly.

Diagnostic tests

Sigmoidoscopy, barium enema, and colonoscopy may be performed to rule out other conditions.

Treatment

Anorectal abscesses require surgical incision and drainage, usually under caudal anesthesia. Fistulas require fistulotomy (removal of the fistula and associated granulation tissue) under caudal anesthesia. If the fistula tract is epithelialized, treatment requires fistulectomy (removal of the fistulous tract) followed by insertion of drains, which remain in place for 48 hours. Fistulas that result from an intestinal disorder, such as Crohn's disease, are usually treated conservatively because surgery is often not successful.

Nursing diagnoses

- u Anxiety
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.

ADVANCED PRACTICE

Types of anorectal abscess

Although perianal abscess is the most common form of anorectal abscess, don't overlook the possibility of other types. Assessment findings usually help to distinguish among the four types of anorectal abscesses.

Perianal abscess

This abscess, which occurs in 80% of patients, appears on inspection as a red, tender, localized oval swelling close to the anus. Pus may drain from the abscess. The patient may report that sitting or coughing increases his pain. Digital examination reveals no abnormalities.

Ischiorectal abscess

This abscess, which affects 15% of patients, involves the entire perianal region on the affected side of the anus. Palpation reveals tenderness. The abscess may not produce drainage. Digital examination reveals a tender induration bulging into the anal canal.

Submucosal or high intermuscular abscess

About 5% of patients have this form of abscess, which may cause a dull, aching pain in the rectum. The abscess may produce tenderness and, occasionally, induration. Digital examination reveals a smooth swelling of the upper part of the anal canal or lower rectum.

Pelvirectal abscess

The patient with this rare abscess typically reports malaise and myalgia. He also has a fever, but no local anal or external rectal signs or pain. Digital examination reveals a tender mass high in the pelvis, perhaps extending into one of the ischiorectal fossae.

- u The patient's vital signs will return to normal.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express an understanding of the disease process and treatment regimen.

Nursing interventions

- u Before surgery, apply ice and witch hazel soaks, and provide sitz baths to ease the patient's discomfort.
- u After the incision is made to drain the anorectal abscess, provide adequate medication for pain relief as ordered. Examine the wound frequently to assess proper healing. Healing should be complete in 4 to 5 weeks for perianal fistulas and 12 to 16 weeks for deeper wounds.
- u Dispose of soiled dressings properly.
- u Note the time of the first postoperative bowel movement. Anticipating pain, the patient may suppress the urge to defecate; the resulting constipation increases pressure at the wound site. Such a patient benefits from a stool-softening laxative such as psyllium.

Patient teaching

- u Explain the disorder to the patient. If diagnostic tests are scheduled, review their purpose and required preparation and aftercare.
- u Emphasize that complete recovery takes time. Offer encouragement.
- u Teach the patient that a diet high in fiber and fluids promotes regular bowel movements, which helps to prevent irritation of an existing abscess. Explain that straining during a bowel movement can increase abscess discomfort.
- u Stress the importance of perianal cleanliness at all times, especially after bowel movements or any contact with a foreign body. Tell the patient that good hygiene helps prevent infection.
- u Provide appropriate preoperative teaching if surgery will be performed. Be sure the patient understands the procedure and its possible complications.
- u After surgery, reinforce the importance of diet and perianal cleanliness. Teach the patient about prescribed medications, such as analgesics and stool softeners. Show him how to prepare sitz baths if they are ordered to promote comfort.

ANORECTAL STRICTURE, STENOSIS, OR CONTRACTURE

Anorectal stricture is a narrowing of the anal canal that results from intraluminal inflammation or scarring. Stenosis or contracture prevents sphincter dilation.

Causes

Anorectal stricture results from scarring after anorectal surgery or inflammation, radiation to the pelvic area, inadequate postoperative care, or laxative abuse.

Complications

Severe bleeding and infection are the most common complications.

Assessment findings

The patient typically reports a history of anorectal surgery, radiation to the pelvic area, or laxative abuse. He may describe excessive straining to have a bowel movement and a feeling of incomplete bowel evacuation. Other clinical features are pain, bleeding, and pruritus.

Inspection reveals narrowing of the anal canal; digital examination discloses anal tenderness and tightness.

Diagnostic tests

Visual inspection and digital examination are used to confirm the diagnosis. No diagnostic tests are performed for this disorder.

Treatment

The goal of therapy is to alleviate the underlying cause. For example, if inflammation is the cause of stricture, correction of the underlying inflammatory process is necessary. If laxative abuse is the cause, this habit must be corrected to prevent recurrence.

Surgical removal of scar tissue is usually the most effective treatment. Digital or instrumental dilatation may be beneficial; however, it may cause additional tears and splits of the anal mucosa. Balloon dilatation may also be successful.

Nursing diagnoses

- u Anxiety
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.

- u The patient's vital signs will return to normal.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Provide psychological support. The patient with elimination problems is often very anxious. Listen to the patient's fears and concerns.
- u After dilatation, provide the patient with a high-fiber diet to help keep the sphincter dilated.
- u If surgery is scheduled, provide appropriate preoperative care.

After surgery:

- u Check vital signs often until the patient is stable. Watch for signs of hemorrhage (excessive bleeding on the perianal dressing). If surgery was performed under spinal anesthesia, record the first leg movement, and keep the patient lying flat for 6 to 8 hours after surgery.
- u When the patient's condition is stable, resume a normal diet, and record the time of the first bowel movement. Administer stool softeners as ordered. Give analgesics, provide sitz baths, and change the perianal dressing as ordered.

Patient teaching

- u Teach the patient about the disorder, explaining its probable cause and the treatment plan. If he's to undergo dilatation, point out that this procedure may need to be repeated. If he's scheduled for surgery to remove adhesions, provide appropriate preoperative teaching.
- u Review the proper use of prescribed medications, focusing on their desired effects and possible adverse reactions.
- u Stress the benefits of a high-fiber diet. Have the dietitian review the dietary plan with the patient.
- u Discuss proper perineal care with the patient, stressing the importance of good hygiene.

HEMORRHOIDS

Hemorrhoids are varicosities in the superior or inferior hemorrhoidal venous plexus; they're commonly painful. Dilation and enlargement of the superior plexus produce mucus-covered, internal hemorrhoids that bulge into the rectal lumen and may prolapse during defecation. Dilation and enlargement of the inferior plexus produce skin-covered, external hemorrhoids that may protrude from the rectum. External hemorrhoids are more likely to be thrombotic than internal hemorrhoids. Generally, the incidence of hemorrhoids peaks between ages 20 and 50 and affects both sexes.

Causes

Hemorrhoids probably result from increased intravenous pressure in the hemorrhoidal plexus. Predisposing factors include occupations that require prolonged standing or sitting; straining due to constipation, diarrhea, coughing, sneezing, or vomiting; heart failure; hepatic disease, such as cirrhosis, amoebic abscesses, and hepatitis; alcoholism; anorectal infections; loss of muscle tone due to old age, rectal surgery, or episiotomy; anal intercourse; and pregnancy.

Complications

Local infection or thrombosis of hemorrhoids can occur. Rarely, hemorrhoids cause severe or recurrent bleeding, leading to secondary anemia with significant pallor, fatigue, and weakness.

Assessment findings

Typically, the patient notices and reports intermittent rectal bleeding after defecation. He may report bright red blood on his stools or toilet paper, a sign that the fragile mucosa covering the hemorrhoid was injured during defecation. He also may complain of anal itching (the result of poor anal hygiene) or describe a vague feeling of anal discomfort when bleeding occurs.

If the hemorrhoids are thrombosed, the patient usually complains of rectal pain, which may be accompanied by anal pruritus and mucus discharge. If external hemorrhoids are thrombosed, he may be aware of a large subcutaneous lump in the anal area.

Inspection of the anal area confirms the presence of external hemorrhoids. If the external hemorrhoids are thrombosed, they appear on inspection as blue swellings at the anus. Although internal hemorrhoids usually aren't seen on inspection, they're obvious if they have prolapsed.

Palpation reveals anal tenderness. Digital rectal examination may disclose internal hemorrhoids.

Diagnostic tests

Anoscopy and flexible sigmoidoscopy are used to confirm internal hemorrhoids and rule out other possible causes of symptoms, such as rectal polyps and anal fistulas.

Treatment

Hemorrhoids generally require only conservative treatment designed to ease pain, combat swelling and congestion, and regulate bowel habits. To reduce local pain and swelling, local anesthetic agents (lotions, creams, or suppositories), astringents, or cold compresses may be applied, followed by warm sitz baths or thermal packs. A steroid preparation, such as hydrocortisone, can relieve itching or inflammation.

Stool softeners help prevent straining during defecation. If the patient has a mildly prolapsed internal hemorrhoid, manual reduction may be attempted. Rarely, the patient with chronic, profuse bleeding may require a blood transfusion.

Several outpatient procedures may be used to treat hemorrhoids. A sclerosing solution may be injected to induce scar formation and decrease prolapse. Elastic band ligation is even more effective than sclerotherapy.

Hemorrhoidectomy, still the most effective method with less need for further therapy, is indicated for patients with severe bleeding, intolerable pain, pruritus, and large prolapse. This surgery, by which the hemorrhoid is removed through cauterization or excision, can be performed on an outpatient basis.

Nursing diagnoses

- u Constipation u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient's bowel movements will return to normal.
- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

u If hemorrhoidectomy is scheduled, prepare the patient for surgery. Administer an enema as ordered (usually 2 to 4 hours before surgery), and record the results. Shave and clean the perianal area.

Postoperative care:

- u Watch the patient closely for signs of prolonged rectal bleeding, acute hemorrhage, and hypovolemic shock. Monitor the patient's vital signs every 2 to 4 hours while he's in the facility. Also monitor and record intake and output. Assess for signs of fluid volume deficit, such as dry mucous membranes and feelings of faintness or weakness.
- u Check the dressing regularly, and immediately report any excessive bleeding or drainage. If bleeding is excessive, you may be asked to insert a balloon-tipped catheter into the patient's rectum and inflate the balloon. This exerts pressure on the hemorrhagic area and reduces blood loss.
- u Make sure the patient voids within 24 hours after surgery. If necessary, help stimulate voiding with massage and warm sitz baths; catheterize him only if other measures fail to induce urination.
- u Clean the perianal area with warm water and a mild soap to prevent infection and irritation, then gently pat the area dry. After spreading petroleum jelly on the wound site to prevent skin irritation, apply a wet dressing (a 1:1 solution of cold water and witch hazel) to the perianal area.
- u As necessary, provide the patient with analgesics and sitz baths or hot compresses, which can help prevent rectoanal spasms and reduce local pain, swelling, and inflammation.
- u As soon as the patient can resume oral feeding, administer a bulk-forming or stool-softening laxative as ordered to ease defecation and ensure the passage of stools shortly after surgery.

Patient teaching

- u Teach the patient about hemorrhoidal development, predisposing factors, and tests.
- u If conservative treatment is ordered, teach the patient measures to relieve hemorrhoidal discomfort. Suggest applying cold packs to the anorectal region for 3 to 4 hours at the onset of pain, followed by warm sitz baths. Recommend nonprescription remedies, such as witch hazel soaks and dibucaine ointment. Advise the patient to use dibucaine ointment only temporarily; if pain continues for more than 5 days, tell him to notify the doctor. Tell him that this ointment can mask worsening symptoms and cause delay in seeking attention for a more serious disorder.
- u Encourage the patient to eat a high-fiber diet to promote regular bowel movements. To avoid venous congestion, remind him not to sit on the toilet longer than necessary.
- u If the patient has had surgery, provide tips on avoiding constipation. Encourage adequate intake of dietary fiber and fluids. Advise the patient to increase the amount of raw vegetables, fruits, and whole-grain cereals in his diet.
- u Instruct the patient to check with his doctor about when to begin using stool softeners to prevent constipation. To prevent anal stricture from scar tissue, warn against using a stool softener too soon after hemorrhoidectomy because a firm stool acts as a natural anal dilator.
- u Emphasize the need for good anal hygiene. Caution against vigorous wiping with washcloths and using harsh soaps. Encourage the use of medicated astringent pads and toilet paper made without dyes or perfumes.

ALERT To reduce postoperative pain and swelling, encourage the use of sitz baths. Instruct the patient to watch for and report increased rectal bleeding, purulent drainage, fever, constipation, or rectal spasm.

- u Prepare the patient emotionally for the first bowel movement after surgery. Explain that it will be painful and can be very frightening to some patients.

PILONIDAL DISEASE

In pilonidal disease, a lesion called a coccygeal or pilonidal cyst develops in the sacral area. The cyst—which usually contains hair—becomes infected and commonly produces an abscess, a draining sinus, or a fistula. Generally, a pilonidal cyst produces no symptoms until it becomes infected. The incidence is highest among hirsute, white men ages 18 to 30.

Causes

Pilonidal disease may develop congenitally from a tendency to hirsutism, or it may be acquired from stretching or irritation of the sacrococcygeal area (intergluteal fold) from prolonged rough exercise (such as horseback riding), heat, excessive perspiration, or constricting clothing.

Complications

Pain and discomfort associated with pilonidal disease can cause psychosocial complications for the patient, such as impaired social interaction and difficulty performing work-related activities. This is most likely if his lifestyle or occupation involves vigorous activity that irritates the cyst, causing increased pain.

Assessment findings

Investigation of the patient's history may turn up one or more predisposing factors for pilonidal disease. Typically, the patient complains of localized pain, tenderness, swelling, and heat over the affected area. He may also describe continuous or intermittent purulent drainage. If the infection is severe enough, signs and symptoms include chills, fever, headache, and malaise.

On inspection, you may detect a series of openings along the midline, with thin, brown, foul-smelling drainage or a protruding tuft of hair. Palpation of the area may produce purulent drainage, if the drainage isn't already continuous.

Diagnostic tests

Cultures of discharge from the infected cyst may show staphylococci or skin bacteria; the discharge doesn't usually contain bowel bacteria.

Treatment

Conservative measures consist of incision and drainage of abscesses, regular extraction of protruding hairs, and sitz baths (four to six times per day). However, persistent infections may result in abscess formation and require surgical excision of the infected area.

After excision of a pilonidal abscess, the patient requires regular follow-up care to monitor wound healing. The surgeon may periodically palpate the wound during healing with a cotton-tipped applicator, curette excess granulation tissue, and extract loose hairs to promote wound healing from the inside out and to prevent dead cells from collecting in the wound. Complete healing can take several months.

Nursing diagnoses

- u Anxiety u Impaired social interaction u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express an understanding of the disorder and treatment regimen.

- u The patient's vital signs will remain stable.

Nursing interventions

- u Before incision and drainage of a pilonidal abscess, reassure the patient that he'll receive analgesics to ease discomfort. If surgery will be performed, provide appropriate preoperative care.

After surgery:

- u Monitor vital signs often until the patient is stable; check compression dressings for signs of excessive bleeding, such as large amounts of blood on the perianal dressing. Change the dressing as directed, using aseptic technique to avoid infection.
- u Administer analgesics and provide sitz baths, as needed, to relieve discomfort and maintain hygiene.
- u Provide stool softeners as ordered, and record the time of the first bowel movement. When the patient's condition is stable, resume a normal diet.
- u Encourage the patient to walk within 24 hours.

Patient teaching

- u Teach the patient about pilonidal disease, and explain his treatment plan. Reassure him that the disorder usually resolves completely with proper treatment.
- u Before surgery, reinforce the doctor's explanation of the procedure and answer the patient's questions.
- u After surgery or incision and drainage, instruct the patient to wear a gauze sponge over the site after the dressing has been removed. Explain that the protective covering provides ventilation and prevents friction from clothing from irritating the wound. Recommend the continued use of sitz baths, followed by air-drying instead of towel drying.
- u Review the proper use of prescribed medications, usually analgesics and antibiotics. Teach the patient about the desired action of each drug and any adverse reactions that he should report to his doctor.

POLYPS

Polyps—arising as masses of tissue above the mucosal membrane—may develop in the rectum or colon, where they protrude into the GI tract. Polyps are classified according to tissue type: They include common polypoid adenomas, villous adenomas, familial polyposis, focal polypoid hyperplasia, and juvenile polyps (hamartomas). Polyps also may be described by their appearance: They may be pedunculated (attached by a stalk to the intestinal wall) or sessile (attached to the intestinal wall with a broad base and no stalk).

Most polyps are benign. However, villous and familial polyps show a marked inclination to become malignant. A striking feature of familial polyposis is its frequent association with rectosigmoid adenocarcinoma.

Villous adenomas are most prevalent in men over age 55; common polypoid adenomas, in white women between ages 45 and 60. The incidence in both sexes increases after age 70. Juvenile polyps occur most commonly in children under age 10 and are characterized by rectal bleeding.

Causes

Polyps are caused by unrestrained cell growth in the upper epithelium. Risk factors include heredity, age, infection, and diet.

Complications

Slow bleeding from polyps can result in anemia. Occasionally, a polyp may grow large enough to cause bowel obstruction. Polyps can also be complicated by gross rectal bleeding or intussusception. Polypoid adenomas are believed to give rise to most colorectal cancers.

Assessment findings

In many patients, assessment findings are minimal because these patients have no obvious symptoms. Usually, polyps are discovered incidentally during a digital examination or rectosigmoidoscopy. Rarely, the patient history reveals obvious rectal bleeding and diarrhea.

Diagnostic tests

Proctosigmoidoscopy or colonoscopy with biopsy confirms the diagnosis.

Stool analyses detect occult blood in the stools of about 5% of patients with polyps.

Hemoglobin (Hb) level and hematocrit (HCT) may decrease with rectal bleeding.

Treatment

The therapeutic regimen depends on the type and size of the polyps and their location in the rectum or colon. Polypectomy may be performed if the polyp is pedunculated. This procedure uses an electrocautery snare inserted through a sigmoidoscope or a colonoscope. Even large, pedunculated polyps can be removed by this method. Sessile polyps usually require abdominal surgery for removal. Some benign polyps aren't removed but are monitored periodically for changes by routine sigmoidoscopy or colonoscopy.

Depending on the extent of GI involvement, familial polyposis requires total abdominoperineal resection with a permanent ileostomy or subtotal colectomy with an ileoproctostomy. Juvenile polyps are prone to autoamputation; if this doesn't occur, snare removal during colonoscopy is the treatment of choice.

Nursing diagnoses

- u Anxiety
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's vital signs will return to normal.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Offer psychological support to the patient, as necessary, because he probably fears a diagnosis of cancer. Listen to his concerns and offer reassurance.
- u After polypectomy, monitor the patient for signs of complications, such as bleeding, infection, and perforation. Watch for decreased Hb level and HCT, rectal bleeding, mucopurulent rectal drainage, and abdominal pain and discharge. If the patient is hospitalized, watch for and record the first bowel movement, which may not occur for 2 to 3 days. Provide sitz baths for 3 days.
- u If abdominal surgery is necessary, prepare the patient for the type of scheduled surgery.
- u After abdominal surgery, provide appropriate postoperative care. Monitor vital signs, intake and output, and fluid and electrolyte balance. Provide I.V. therapy, and

administer pain medications as needed. Monitor the surgical site for healing, and change the dressing as ordered.

- u If the patient has an ileostomy or another type of stoma, provide stoma care, and arrange for an enterostomal therapist to visit the patient.

Patient teaching

- u Teach the patient about polyps. Explain monitoring procedures, such as sigmoidoscopy and colon-oscopy, that will be performed periodically. Stress the need for periodic monitoring of benign polyps. Instruct him to report any rectal bleeding.
- u If polypectomy is scheduled, explain the procedure and its possible complications. Emphasize the need for follow-up care to monitor for any new growth.
- u If abdominal surgery is scheduled, provide appropriate preoperative teaching. Show the patient how to cough and deep-breathe. Teach him how to splint his incision. Review his postoperative plan of care, including the use of analgesics to relieve pain. Discuss the proper use of other medications, including their desired effects and possible adverse reactions. If necessary, teach him how to perform stoma care.

PROCTITIS

Proctitis—an inflammation of the rectal mucosa—has a good prognosis unless massive bleeding occurs.

Causes

Proctitis may develop secondary to rectal gonorrhea, candidiasis, syphilis, or nonspecific sexually transmitted infections. The most common causative pathogens are *Neisseria gonorrhoeae*, chlamydiae, and herpesvirus.

Other causes include chronic constipation, habitual laxative use, emotional upset, radiation therapy, endocrine dysfunction, rectal surgery, rectal medications, allergies, vasomotor disturbance that interferes with normal muscle control, and food poisoning.

Complications

Proctitis can lead to ulcerations, crypt abscesses, bleeding, fissures, and fistulas. Submucosal inflammation with fibrosis may occur, leading to stricture.

Assessment findings

The patient typically complains of these key symptoms: constipation, a feeling of rectal fullness, and cramps in the left abdomen. The history may also reveal tenesmus producing a few bloody or mucoid stools.

Diagnostic tests

Sigmoidoscopy in acute proctitis shows edematous, bright red or pink rectal mucosa that is shiny, thick, friable, and possibly ulcerated. In chronic proctitis, sigmoidoscopy shows thickened mucosa, loss of vascular pattern, and stricture of the rectal lumen.

Biopsy is performed to rule out cancer.

Bacteriologic and viral analyses are used to detect the cause.

Treatment

The goal of therapy is to remove the underlying cause of proctitis, such as fecal impaction or laxative abuse. Anti-infective medications are given for infection. Corticosteroids (in enema or suppository form) may reduce inflammation as may sulfasalazine, mesalamine, or similar agents. Tranquilizers may relieve emotional stress.

Nursing diagnoses

- u Anxiety
- u Knowledge deficit
- u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will verbalize an understanding of the disease process and treatment regimen.
- u The patient will avoid complications.
- u The patient will verbalize feelings of anxiety and exhibit adequate coping mechanisms.

Nursing interventions

- u Offer emotional support and reassurance during rectal examinations and treatment, as appropriate
- u Administer anti-infective medications, sulfasalazine, and tranquilizers as ordered. Provide soothing enemas, steroid foam, or steroid suppositories as ordered to relieve pain. Monitor the patient's response.

Patient teaching

- u Explain proctitis and its treatment to help the patient understand the disorder and prevent its recurrence.
- u Instruct the patient to watch for and report anal bleeding and other persistent signs and symptoms.
- u Review prescribed medications.
- u Teach the patient how to administer steroid enemas, foam, or suppositories as needed.
- u If constipation adds to symptoms, teach about fluid intake, a high-fiber diet, and stool softeners.

RECTAL PROLAPSE

Rectal prolapse is the circumferential protrusion of one or more layers of the mucous membrane through the anus. It occurs in two forms. Partial (mucosal) prolapse involves rectal mucosa up to the internal sphincter; complete prolapse involves both the rectal mucosa and the rectal wall.

Rectal prolapse is more common in women than in men and is most common after age 40. It also occurs in children—typically between ages 1 and 3—especially those with cystic fibrosis.

Causes

Increased intra-abdominal pressure—for example, from straining during defecation—usually triggers rectal prolapse. Other causes include relaxed anal sphincters and weak pelvic muscles that can result from neurologic disorders, injury, tumors, aging, and chronic wasting diseases, such as tuberculosis and cystic fibrosis.

Complications

Rectal prolapse may lead to rectal ulceration, bleeding, and incontinence.

Assessment findings

The patient may report tissue protrusion from the rectum, which occurs during defecation or some type of exertion such as walking. She may also report one or more of the following problems: a persistent sensation of rectal fullness, mucus discharge, bloody diarrhea, fecal incontinence and, occasionally, lower abdominal pain.

Inspection is used to distinguish between complete and partial prolapse. Complete prolapse involves a protruding rectal mass that exposes the full thickness of the bowel wall and, possibly, a protruding sphincter muscle with mucosa falling into bulky, concentric folds. Partial prolapse involves a partly protruding mucosa and a smaller mass of radial mucosal folds. If necessary, ask the patient to squat before you inspect the prolapse. Sometimes, the prolapse is obvious only when the patient squats.

Diagnostic tests

Physical examination is used to confirm the diagnosis.

Treatment

The type of therapy depends on the symptoms and the underlying cause. Eliminating the cause (straining or coughing) may be the only treatment needed. In a child, prolapsed tissue usually diminishes as the child grows. In an older patient, a sclerosing agent may be injected to cause a fibrotic reaction that fixes the rectum in place. Severe or chronic prolapse requires surgical repair by strengthening or tightening the sphincters with wire or by resecting prolapsed tissue anteriorly or rectally.

Nursing diagnoses

u Anxiety u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's vital signs will remain stable.
- u The patient will remain free from signs and symptoms of infection.
- u The patient and family members will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Provide psychological support to the patient. She's likely to be upset and anxious about her condition.
- u Before surgery, give appropriate care. After surgery, monitor vital signs and intake and output. Administer pain medications as needed, and watch for desired effects and possible adverse reactions. Also watch for immediate complications (hemorrhage) and later ones (pelvic abscess, fever, pus drainage, pain, rectal stenosis, constipation, or pain during defecation).

Patient teaching

- u Explain the causes of rectal prolapse. Review treatment options and answer the patient's questions.
- u Help the patient prevent constipation. Explain the role of diet and stool softeners. If she has severe prolapse and incontinence, tell her to wear a perianal pad.
- u Teach perineum strengthening exercises: Have the patient lie down with her back flat on the mattress; then ask her to pull in her abdomen and squeeze while taking a deep breath. Or have her repeatedly squeeze and relax her buttocks while sitting on a chair.
